Figure 1 plots the hydraulic conductivity with respect to void ratio, density and vertical effective stress. With increase in effective stress the soil compacts leading to decreased void ratio and increased bulk density and finally a decrease in hydraulic conductivity. Most of the samples reached hydraulic conductivity lower than 10^{-9} m/s when the effective stress exceeded above 150 kPa. Note that the effective stress of oedometer tests is the vertical effective stress and that of the flexible wall permeameter and triaxial test are mean effective stresses.

It can also be seen from the plots that the permeability measurements are widely distributed unlike soils reconstituted in the laboratory under well controlled environments. Table 2 lists the initial

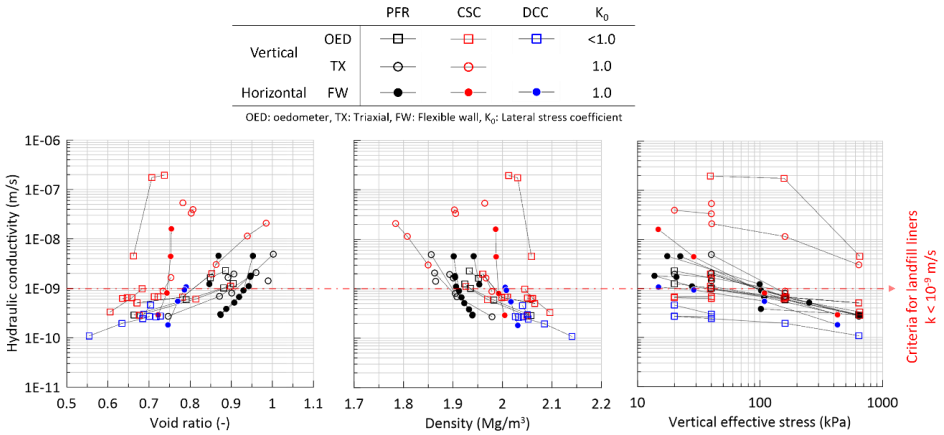

Figure 1. Hydraulic conductivity with respect to void ratio, density and vertical effective stress.

properties of each material compacted in-situ (In Table 2, k_v is the vertical hydraulic conductivity, e is the void ratio and ρ is the density). Large variability was detected for initial vertical hydraulic conductivity, void ratio and bulk density. PFR and CSC results showed large scatter, whereas the DCC results were more constant. Such a distinction seems to be from the origin of the specimens compacted and sampled in the field, noting that DCC were from a single core and PFR and CSC samples were from multiple cores extracted from various locations.

Table 2. Range of initial properties of intact materials.

Material	k_v (m/s)	e (-)	ρ (Mg/m³)
PFR	4.9×10^{-9} – 1.2×10^{-10}	1.00 – 0.67	1.86 – 1.96
CSC	1.9×10^{-7} – 6.4×10^{-10}	0.98 – 0.65	1.78 – 2.05
DCC	2.7×10^{-10} – 4.6×10^{-10}	0.73 – 0.70	2.03 – 2.04

Comparing the vertical and horizontal permeabilities, the horizontal permeability was not necessarily larger than the vertical which is often reported for reconstituted consolidated soils (Adams et al., 2013; Clennell et al., 1999; Zhang et al., 2019).

The evolution of horizontal permeability was more significant than the vertical permeability with the equivalent amount of void ratio decrement (Figure 1 left) and increase in bulk density (Figure 1 centre). This may be due to the anisotropic structure of the compacted soils. Similar to the vertical hydraulic conductivity, the value dropped below 10^{-9} m/s satisfying the Norwegian criteria for landfill liners for non-hazardous and hazardous waste after loading to high stresses.

4 FINAL REMARKS AND DISCUSSION

This paper observed the hydraulic conductivity characteristics of three materials, using three different apparatuses in the laboratory. The following points summarize and discuss the observations made:

- The field compacted PFR and CSC initial properties such as void ratio and bulk density had a wide variability. For the DCC, the initial properties varied less compared to others.
- Most of the recycled samples (PFR and CSC) did not satisfy the criteria for landfill liners ($k \leq 1.0\times10^{-9}$ m/s) at the low consolidation stresses (approx. below 100 kPa). Increasing the effective stress led to a large drop in hydraulic conductivity; with effective stresses exceeding 150 kPa the hydraulic conductivity decreased satisfying the criteria. The criteria may be met with sufficient deposition of landfills; however, this does not guarantee the suitability of landfill barriers and may require further improvement to ensure impermeability.
- The evolution of hydraulic conductivity with respect to void ratio change was more significant on the horizontal direction than on the vertical direction. Such behaviour may be attributed to the anisotropic soil structure of the compacted soils. This observation suggests that the horizontal flow should be considered for sidewalls of landfill liners.
- The permeating fluid was deionized water that does not necessarily represent the field conditions as permeating leachates tend to have high salt content. Changes in salt content/species of the permeant has the possibility of changing the permeability in orders of magnitude (Das & Bharat, 2021). Therefore, the effect of salt concentration of permeants on the hydraulic conductivity of these materials should be investigated prior to implementing to the field.

Identifying porosity distribution and swell anisotropy of laboratory sedimented high plasticity clay through NMR imaging

Identification de la distribution de la porosité et de l'anisotropie du gonflement de l'argile à haute plasticité sédimentée en laboratoire grâce à l'imagerie RMN

E.M. Kinslev*, I. Rocchi, L.T.P. Meireles

ABSTRACT: When studying fundamental features of soil behaviour it is common to resediment or remould "artificial" soil samples under well-defined conditions to limit uncertainties caused by variability in soil structure. Therefore, the laboratory sedimented sample is a useful reference state for a given soil. However, the sedimentation process inevitably causes anisotropy which is previously linked to sedimentation structure. This is related to the anisotropic stress state of oedometric confinement used in laboratory sedimentation. As such anisotropy is unavoidable it is necessary to identify it. More troublesome is the potential unwanted heterogeneity caused by the separation of constituents during the sedimentation process. To investigate these two features, large (Ø20cm x 6cm) laboratory sedimented high plasticity clay discs were prepared. On both vertically and horizontally oriented subsamples at different locations in these discs, the porosity distribution was mapped through low field Nuclear Magnetic Resonance (NMR) imaging. This allowed verification of the level of homogeneity achieved by the laboratory sedimentation procedure. Further, the anisotropy of the discs was studied by measuring the free swell of the subsamples at the two orientations. The obtained results provide insights into the effectiveness of laboratory sedimentation for creating homogeneous reference soil samples and further exemplify the usefulness of NMR imaging in identifying initial porosity distribution and porosity evolution during swelling.

RÉSUMÉ: Lors de l'étude des caractéristiques fondamentales du comportement du sol, il est courant de resédimenter ou de remouler des échantillons de sol « artificiels » dans des conditions bien définies afin de limiter les incertitudes causées par la variabilité de la structure du sol. Par conséquent, l'échantillon sédimenté en laboratoire constitue un état de référence utile pour un sol donné. Cependant, le processus de sédimentation provoque inévitablement une anisotropie qui est auparavant liée à la structure de la sédimentation. Ceci est lié à l'état de contrainte anisotrope du confinement oedométrique utilisé en sédimentation en laboratoire. Une telle anisotropie étant inévitable, il est nécessaire de l'identifier. Plus gênante est l'hétérogénéité potentiellement indésirable provoquée par la séparation des constituants au cours du processus de sédimentation. Pour étudier ces deux caractéristiques, de grands disques d'argile sédimentés en laboratoire (Ø20 cm x 6 cm) à haute plasticité ont été préparés. Sur des sous-échantillons orientés verticalement et horizontalement à différents endroits de ces disques, la distribution de la porosité a été cartographiée par imagerie par résonance magnétique nucléaire (RMN) à faible champ. Cela a permis de vérifier le niveau d'homogénéité atteint par la procédure de sédimentation en laboratoire. De plus, l'anisotropie des disques a été étudiée en mesurant le gonflement libre des sous-échantillons aux deux orientations. Les résultats obtenus donnent un aperçu de l'efficacité de la sédimentation en laboratoire pour créer des échantillons de sol de référence homogènes et illustrent en outre l'utilité de l'imagerie RMN pour identifier la distribution initiale de la porosité et l'évolution de la porosité au cours du gonflement.

Keywords: Resedimentation; sample homogeneity; swelling anisotropy; nuclear magnetic resonance (NMR).

1 INTRODUCTION

Soil behaviour depends both on the material properties (i.e. mineralogical and particle size distribution, and particle size and morphology) as well as its state (porosity and its distribution, particle arrangement, bonding/cementation, etc.). Burland (1990) devised a reference state, namely a remoulded conditions, which represents the intrinsic material behaviour by providing a term of comparison and thereby allowing to distinguish between behavioural features linked to material properties and those linked to soil "structure", defined by Cotecchia and Chandler (2000), as the

combination of fabric (i.e. particle orientation) and bonding. Although the remoulded sample starts from an isotropic state (no preferential particle orientation), the anisotropic stress state experienced during oedometric compression, which is used for laboratory preparation of fine-grained samples, induces a preferred particle orientation. Furthermore, when using resedimentation rather than remoulding as a preparation method, Stallebrass et al. (2007) observed particle sorting caused by the sedimentation process (similar to the effects utilized when determining particle size distributions, see e.g. ASTM D7928). This led to a parallel shift of the compression line relative to the intrinsic one, based on the reconstitution method proposed by Burland (1990).

It is apparent, that laboratory produced soil samples will inevitably contain some degree of anisotropy and potentially some unwanted heterogeneity. A large laboratory resedimented disc (D=20cm x H=6cm) of Røsnæs Clay was created and several small (D=2cm x H=2cm) specimens were taken at different locations to investigate these aspects. The degree of heterogeneity was determined through measurements of the pore size distribution and porosity at these varying positions through Nuclear Magnetic Resonance (NMR). The degree of anisotropy was estimated by exposing both vertical and horizontal plugs to demineralised water and monitoring the free swell process also through NMR measurements.

The combination of these observations provides an assessment of laboratory resedimentation procedures for creating relevant reference soil samples.

2 METHODS AND MATERIALS

The material used as the basis of the study is the already mentioned disc of resedimented Røsnæs Clay. The details of the resedimentation procedure are described by Kinslev et al. (2022) and are briefly summarised as: The soil is mixed into suspension with artificial pore water (composition) ensuring a water content of 500%, after which it is sedimented in a purpose build consolidometer and compressed to 1000 kPa. The final product (the disc) is removed and stored in several layers of waxed cling film while not being sampled.

The specimens are sampled in plastic confining rings to enable NMR measurements since metal rings would interfere with the magnetic field. These confining rings have a perforated base, on which is placed a filter paper, resulting in uptake of water from both ends but one-sided swelling once exposed to demineralised water. In total seven specimens were sampled from the disc, positioned as illustrated in Figure 1.

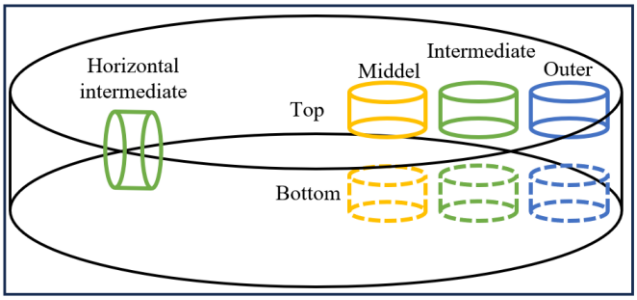

Figure 1. Position of specimens in the resedimented disc.

The Røsnæs Clay used in this study originates from core samples taken during the ground investigation campaign performed for the Fehmarn Belt tunnel project and has properties as listed in Table 1.

Table 1. Selected properties of Røsnæs Clay. Data from Awadalkarim 2014, Di Remigio 2021 and Kinslev 2022.

Grain density	[-]	2.75-2.85
Liquid limit	[%]	93-181
Plastic limit	[%]	26-39
Clay mineral content	[%]	64-68
Kaolinite	[%]	11-18
Illite	[%]	13-15
Smectite	[%]	33-43
Specific surface area	[m^2/g]	56-68

The Røsnæs Clay formation was deposited in the North Sea during the Palaeogene period. In Table 1 only the clay mineralogy is detailed but it should be added, that the remaining mineralogy is dominated by very fine particles (primarily quartz) as nothing is retained by a 63 micron sieve.

The NMR measurements are based on T_2 relaxation; hence the exponentially decaying relaxation of the nuclear angular momentum of hydrogen nuclei to an external magnetic field after tilting by 90 degrees via a timed magnetic pulse. This relaxation is governed by three mechanisms: Bulk relaxation, diffusion and surface relaxation. At the fast diffusion limit (almost all soils), relaxation is dominated by the surface relaxation and T_2 relaxation times correlate linearly to pore size.

Bulk NMR measurements were taken for each specimen to determine the relative pore size distribution as well as total porosity. Subsequently the specimens were exposed to a 0.18M NaCl solution and allowed to free swell for 800 min, while NMR bulk measurements were taken at relevant time intervals (more closely spaced initially, when the free swell process is fastest).

3 RESULTS AND DISCUSSION

The homogeneity of the produced disc is evaluated comparing porosity distributions. The total porosity in Figure 2 is obtained as the area under the curve (also reported in legend), while the T_2 relaxation time distribution is a proxy for pore size distribution. Figure 2 shows the values for each of the vertical specimens (see Figure 1).

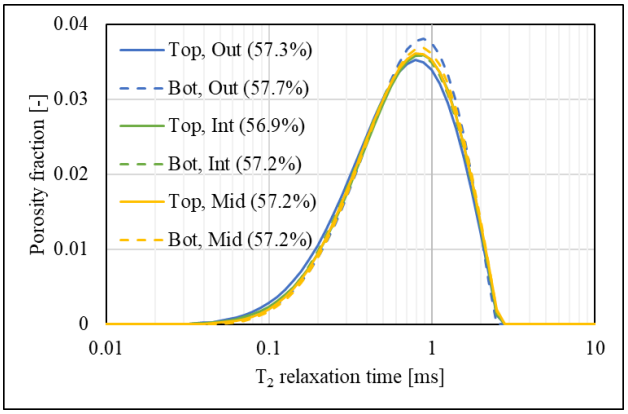

Figure 2. Distribution of porosity fractions with T_2 relaxation times for the six vertical specimens with their total porosity noted in the legend.

From Figure 2 it may be seen that the porosity varies between 56.9 and 57.7% across the disc, which is deemed to be minimal. Further, since there is no consistent trend in the total porosity distribution between the positions in the disc (from middle to outer or top to bottom) the variations in porosity are more likely related to the accuracy of the NMR measurements as well as potential small disturbances during the sampling process. In addition to the consistent total porosity between the specimens, Figure 2 also shows that the pore size distribution is almost identical between them. They all display a similar build up from 0,05 ms to a single peak at 8-9 ms and a maximum relaxation time of approx. 2.5 ms. Altogether this indicates that particle segregation was minimal and that the applied sedimentation procedure resulted in a homogenious sample. This sucess is of course related to the particular soil in this study as another attempt of laboratory sedimentation by Stallebrass et al. (2007) was visibly heterogenous. However, it is worth noting that Røsnæs Clay is a natural material with a heterogenious mineralogy albeit with limited partice size varriation.

In the assessment of sample anisotropy generated by the oedometric compression the development of total porosity with time during free swell is plotted in Figure 3.

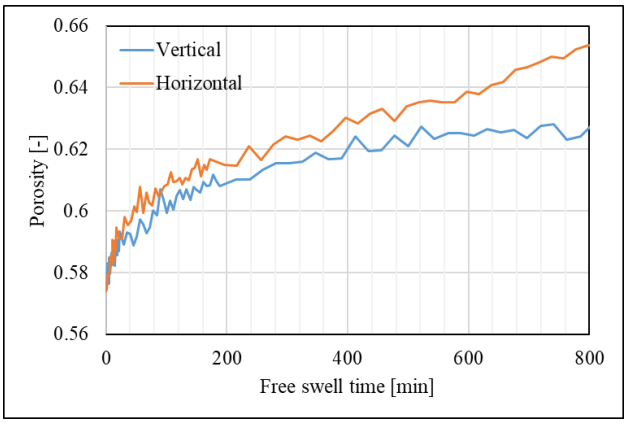

Figure 3. Time development of porosity in the vertical and horizontal specimens subjected to free swell.

From Figure 3 it may be seen that the horizontal specimen swells faster and more compared to the vertical one. At the 800 min mark the vertical specimen has a porosity of 62.8% relative to the 65.4% for the horizontal one, resulting in roughly 50% more swelling (relative to the starting point at 57.4%) of the later. Despite the horizontal specimen swelling slightly faster than the vertical one, the porosity development between the two is very comparable up to the 600 min mark, where the vertical plug plateaus while the horizontal one keeps swelling at a close-to-constant rate. This indicates, that the free swell should have been allowed to continue for a longer period of time to ensure stability of the results. However the overall trend is still clearly evident from the tests.

The clear swelling anisotropy of the sample shows that the anisotropic stress state during compression caused particle rearrangement, which is retained after release of this stress state (during dismantling where the stress state becomes isotropic). The NMR free swell tests can be used to quantify the degree of anisotropy, however for a more direct assessment of the particle arrangement, these results must be compared to e.g. molecular dynamic modelling or scanning electron microscopy performed on planes positioned at different height along the specimens.

While Figure 3 shows the development of porosity during free swell, no information is gained about how the pore space changes to accommodate this increase of porosity. To illustrate this, the pore size distribution before and after free swell are compared in Figure 4. Here it may be seen, that the pore size distribution retains its general shape during the free swell regardless of the specimen orientation. The curves expand in the direction of the largest pores, such that the initial build up of the porosity distribution is completely unchanged, while the front moves to larges relaxation times.

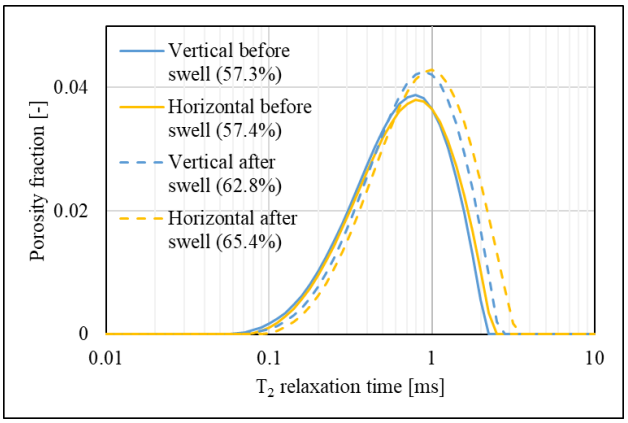

Figure 4. Bulk porosity before and after free swelling with their total porosity noted in the legend.

Because the size of the smallest pores are almost unchanged, the particle interactions occur at the same positions (hence the electro-static repulsion is unchanged) and the stress release causes "only" an elastic rebound of the entire soil skeleton. Since this process is the same in both the horizontal and vertical directions, the anisotropy must be related to boundary conditions of the plugs hence which plane (vertical or horizontal) allowed to deform.

4 CONCLUSIONS

The presented investigations confirm the usefulness of laboratory resedimentation for creating representative reference samples with minimal heterogeneity, provided particle size is below 63 microns. After laboratory sedimentation and compression of a high plasticity clay (Røsnæs Clay) a homogeneous pore size distribution, as measured through NMR T_2 relaxation, was observed throughout the sample. Only minimal variations occurred, which fall within the accuracy of the measurement method. In addition to the particular presented case, the study illustrates the usefulness of NMR measurements in evaluating sample homogeneity. Although applied destructively in this study (by sub-sampling), the method also has potential for being applied non-destructively through imaging or slice selective bulk measurements. Beyond the evaluation of the homogeneity, the investigations showed that significant sample anisotropy emerges from the sedimentation and compression process as a 4% increase of free swell is observed in the horizontal relative to vertical direction. This quantification represents a key step in understanding the development of stress induced anisotropy.

ABSTRACT: Reducing carbon dioxide (CO_2) emissions is an important aspect of global climate change. In Japan, CO_2 emissions from cement production account for approximately 5% of total CO_2 emissions. A technology system for the substantial reduction of CO_2 emissions was developed. In this system, high-slag cement with a slag content of over 60% was newly developed. Carbonate-demolished recycled concrete fine powders (RCFs) have also been developed. RCFs contain cement hydrates, that react with CO_2 and transforms into calcium carbonate. They can be used as carbon capture and utilization (CCU) materials. New cement and carbonate RCFs have been used for soil stabilization. The new cement has a reduction performance of 70% and 40% compared whit Ordinary Portland Cement (OPC) and conventional Blast furnace cement type B (BB cement). The RCFs were carbonated under dry conditions to form a CCU material that could fix 10% CO_2 by mass. This study presents the properties of RCFs and carbonate RCFs. Subsequently, in laboratory tests, the fluidity before hardening and the compressive strength of soil stabilization were investigated. The fluidity decreased when carbonate RCFs were used, requiring the use of a chemical admixture. The compressive strength of mixtures containing carbonated RCFs was found to be 1.1 to 1.5 times higher than those without it. Based on these findings, we conclude that these new materials can be applied as environmentally friendly ground improvement solutions.

RÉSUMÉ: La réduction des émissions de CO_2 est une question importante en ce qui concerne le changement climatique mondial. Au Japon, les émissions de CO_2 liées à la production de ciment représentent environ 5% des émissions totales de CO_2 japonaises. Un système technologique permettant une réduction substantielle des émissions de CO_2 a été développé. Dans ce système, un ciment à haute teneur en laitier avec une teneur en laitier supérieure à 60% a été nouvellement développé. De plus, une poudre fine de béton recyclé décarbonatée (RCFs) a été développée. Les RCFs contiennent de l'hydratation de ciment, qui réagit avec le CO_2 et se transforme en carbonate de calcium. Ils peuvent être utilisés comme matériau de capture et d'utilisation du carbone (CCU). Le nouveau ciment et les RCFs à base de carbonate ont également été utilisés pour la stabilisation des sols. Le nouveau ciment présente une performance de réduction de 70% et 40% respectivement par rapport au ciment Portland ordinaire et au ciment de type haut fourneau conventionnel (ciment BB). Les RCFs ont été carbonatés dans des conditions sèches pour former un matériau de CCU capable de fixer 10% de CO_2 en masse. Cet article présente les propriétés des RCFs et des RCFs à base de carbonate. Ensuite, lors d'essais en laboratoire, la fluidité avant durcissement et la résistance à la compression de la stabilisation des sols ont été étudiées. Il a été observé que la fluidité diminuait lors de l'utilisation de RCFs à base de carbonate, nécessitant l'utilisation d'un adjuvant chimique. La résistance à la compression des mélanges contenant des RCFs carbonatés s'est avérée être de 1,1 à 1,5 fois supérieure à celle des mélanges sans RCFs. Sur la base de ces résultats, nous concluons que ces nouveaux matériaux peuvent être utilisés comme solutions d'amélioration des sols respectueuses de l'environnement.

Keywords: Recycled concrete fines; carbon capture and utilization; soil stabilization.

1 INTRODUCTION

Recently, reduction in CO_2 emissions has been required as a countermeasure against global warming, and in the field of geotechnics, decarbonization is additionally required because a significant amount of cement is consumed during soil stabilization, which emits a considerable amount of CO_2. Some studies have been conducted to reduce environmental impact of soil stabilization, such as adding ground- granulated blast-furnace slag, which is a by-product of steel production that serves as a binder (Kawamura and Kasai, 1999), and performing soil stabilization using

ladle furnace slag and the application of cement with a high blast furnace slag content cement had been carried out for soil stabilization (Kono et al. 2016). improvement. However, it is not possible to achieve carbon neutrality by achieving a 100% slag substitution rate, because there are limitations to the extent of substitution.

One countermeasure to achieve carbon neutrality in soil–cement stabilization is the use of recycled concrete fines (RCFs). A significant amount of RCFs is generated during the production of recycled fine and coarse aggregates from demolished concrete, and these RCFs contain cement hydrates, such as calcium hydroxide and dicalcium silicate (Jiang et al., 2022). Therefore, the use of RCFs as a carbon capture and utilization (CCU) materials are being considered because RCFs can absorb CO_2 when the powder is soaked in water containing a high concentration of CO_2 (Ho et al., 2021).

In this study, a soil stabilizer composed of cement and carbonated and CO_2-fixed RCFs was introduced to further reduce the environmental impact of soil stabilization. The RCFs were carbonated, and the amount of CO_2 fixed in the RCFs was investigated using thermogravimetric differential thermal analysis (TG/DTA). To clarify the changes in the amounts and types of hydrates in the RCFs before and after carbonation, X-ray diffraction (XRD) analyses of the uncarbonated and dry-carbonated RCFs were conducted. To confirm the fluidity of the cement slurry and the change in the strength properties owing to the addition of uncarbonated and carbonated RCFs, P-funnel and unconfined compressive tests were conducted.

2 RECYCLED CONCRETE FINES

2.1 RCFs material

The RCFs used in this study were demolished from an office building in Tokyo. The average compressive strengths of the cores were 27.4 N/mm^2. The concrete was blasted under dry conditions, which resulted in the formation of recycled fine and coarse aggregates and RCFs.

2.2 Carbonation methods

In this study, the dry RCFs method (Nishiie et al., 2023) was used. Figure 1 shows the dry carbonation system used in this study. In the dry carbonation method, naturally dried RCFs were exposed for 9 days in a chamber with a CO_2 concentration of 10%, temperature of 20 °C, and relative humidity of 60%, and they were stirred and weighed every 3 days. When the mass change of the RCFs stabilized, the carbonation of the RCFs was regarded as complete.

Figure 1. Dry carbonation system.

2.3 Physicochemical properties of RCFs

Figure 2 shows the particle size distributions of the carbonated RCFs obtained via laser diffraction analysis. The median diameters of the carbonated RCFs were 33.4 μm. Table 2 lists the densities of the RCFs before and after carbonation obtained using the gas replacement method. The density of the carbonated RCFs is approximately equal to that of the uncarbonated RCFs.

Figure 3 shows the XRD patterns of uncarbonated and dry-carbonated RCFs. Regarding the uncarbonated RCFs, the peaks of cement hydrates, such as calcium hydroxide and ettringite, appeared; however, these peaks disappeared after carbonation. This indicated that the cement hydrates reacted with CO_2 to form calcium carbonate, whereas after carbonation, cement hydrates did not appear in the RCFs.

2.4 Mass of CO_2 fixed in RCFs

The mass of CO_2 fixed in the RCFs was investigated via thermogravimetric/differential thermal analysis (TG/DTA). The relationship between the change in sample weight loss and temperature was determined via TG/DTA. In this study, weight loss occurred at temperature from 550 °C to 950 °C owing the decomposition of calcium carbonated (CaCO3), and the percent weight loss in this temperature range was regarded as the mass percentage of fixed CO_2 (Chang & Chen, 2006). The weight loss percentages in these temperature ranges were 8.2% and 11.1%, respectively. RCFs had already fixed 8% CO_2 by mass before the carbonation process, and after carbonation, the mass of CO_2 fixed in RCFs increased by 3%; hence using carbonated RCFs, approximately 10% of CO_2 by mass could be fixed, including CO_2 fixed prior to carbonation. The uncarbonated RCFs had already absorbed CO_2 because they reacted with atmospheric CO_2 in the months following production.

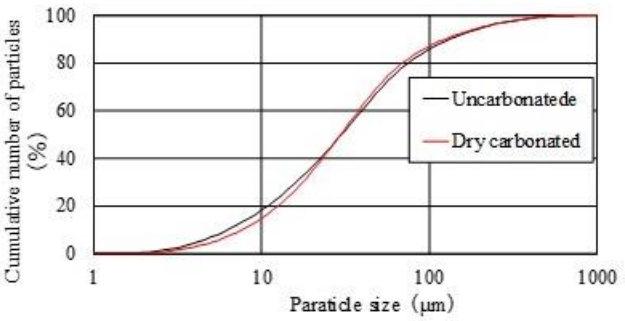

Figure 2. Particle size distribution of RCFs.

Table 1. Density of RCFs.

Type of RCFs	Density (Mg/m^3)
Uncarbonated	2.46
Dry carbonated	2.45

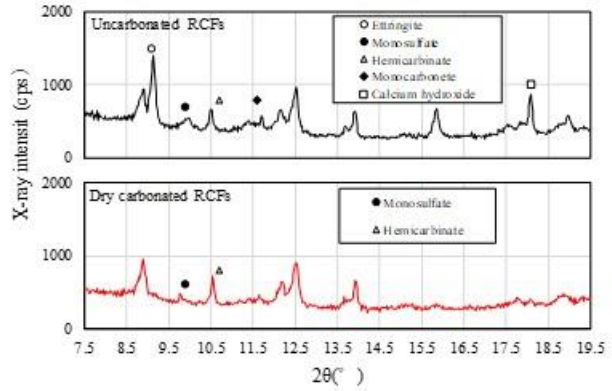

Figure 3. XRD pattens of RCFs.

3 SOIL STABILIZATION USING RCFS

3.1 Test specimens

To investigate the applicability of carbonated RCFs for soil stabilization, test specimens with simulated soil–cement columns were prepared. The type of cement used in this study was blast-furnace slag cement type B (based on the Japanese Industrial Standard), the mass of cement per unit volume (1 m^3) of soil was set to 300 kg, and the water–cement ratio was set to 1.0 The sandy soil used in the experiment was composed of silica sand and Gairome clay at a mass ratio of 9:1 and a water content of 18%. All the specimens were cylindrical with a radius of 50 mm and a height of 100 mm.

Table 1 lists the mix proportions and masses of each specimen. The effects of the type and amount of carbonated RCFs added to the soil–cement column on its physicochemical properties were investigated. In addition, to investigate the effect of the reduced water–powder ratio owing to powder addition on the strength of the soil–cement column, specimens with sandstone powder, which featured low reactivity and a particle size distribution similar to that of the RCFs, were prepared. Uncarbonated and carbonated RCFs and sandstone powder were added at 30%, 60%, and 90% of the cement mass.

Table 1. Mix proportion.

No	Mass of cement (kg/m^3)	Mass of water (kg/m^3)	Type of add material	Mass of add material (kg/m^3)
1	300	300	-	-
2	300	300	Uncarbo. RCFs	90
3	300	300	Uncarbo. RCFs	180
4	300	300	Uncarbo. RCFs	270
5	300	300	Carbo. RCFs	90
6	300	300	Carbo. RCFs	180
7	300	300	Carbo. RCFs	270
8	300	300	Stone powder	90
9	300	300	Stone powder	180
10	300	300	Stone powder	270

3.2 Fluidity of cement slurry

In this study, the CDM method was used to construct soil stabilization using RCFs. The fluidity of the cement slurry was evaluated using the P-funnel flow time. Using a Hobart mixer, cement, added material, and water were mixed for 5 min to produce a cement slurry. Figure 4 shows the P-funnel flow time of the cement slurry. It was found that adding RCFs increased the P-funnel flow time compared to the addition of sandstones. In particular, for dry carbonated RCFs, the impact on the increase in the P-funnel flow time was significant. Furthermore, when 90% of the RCFs had been added, the test could not be conducted.

In the CDM method, the pumping of the cement slurry is possible if the P-funnel flow time is less than 15 s (Ban et al., 1995). Therefore, if the water-cement ratio of the cement slurry is 100%, it would be necessary to use chemical admixtures to improve the fluidity and add RCFs in a proportion greater than 30%.

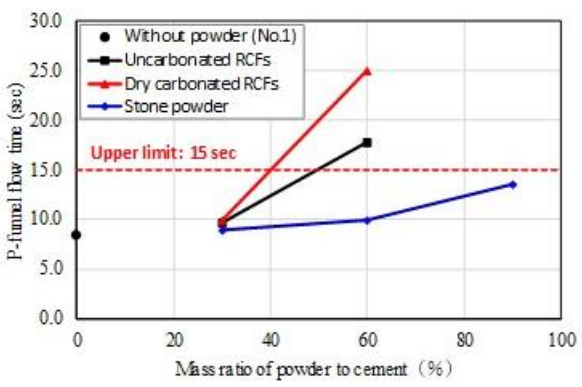

Figure 4. Test results of P- funnel flow time.

3.3 Unconfined compressive strength

Figure 5 shows the compressive strength after curing period of four weeks. The compressive strengths of the specimens containing sandstone powder were 1.05 to 1.13 times higher than those without powder. In the specimens containing uncarbonated RCFs, the compressive strengths were 1.24 to 1.39 times higher than those without powder. The compressive strengths of the specimens containing dry carbonated RCFs were 1.15 to 1.52 times higher.

Based on these results, a greater increase in compressive strength was observed in the specimens containing uncarbonated and carbonated RCFs than in those containing sandstone powder, confirming the effectiveness of adding RCFs in increasing the strength of the soil stabilization, and an increase in the RCFs ratio increased the strength of the soil stabilization.

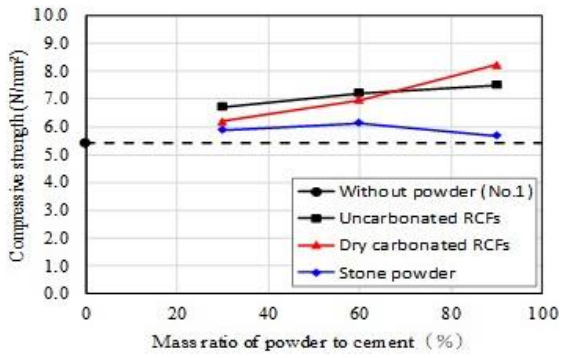

Figure 5. Compression strength of soil stabilization.

4 CONCLUSION

In this study, the physicochemical properties of the RCFs generated during the crushing of waste concrete with CO_2 fixed and the applicability of soil stabilization with carbonated RCFs were investigated. The density of the RCFs slightly increased after wet carbonation, whereas it did not change after dry carbonation, and the particle size distribution did not change regardless of the carbonation condition. The RCFs absorbed CO_2 and were fixed at a 10% CO_2 mass. By adding carbonated RCFs, the compressive strength of the soil stabilization was 1.2 to 1.5 times higher than that of the soil stabilization without using RCFs. The impact of the RCFs' carbon dioxide fixation capacity of RCFs and the strength of soil stabilization are influenced by properties such as the strength of the dismantled concrete; therefore, it will be necessary to investigate this variability. Furthermore, it is necessary to investigate the alkaline properties and hexavalent chromium leaching characteristics of carbonated RCFs as well as soil stabilization using carbonated RCFs.

Formulation of a practical multi-surface plasticity model for sands

Formulation d'un modèle pratique de plasticité multi-surfaces pour les sables

ABSTRACT: This paper presents a new effective stress constitutive model for sands subjected to either monotonic or cyclic loading; the model is referred to as 'PIMSS' (Parallel Iwan Multi-Surface Sand). PIMSS has been developed for geotechnical design applications with an emphasis on the simulation of offshore wind turbine (OWT) monopile foundations in sand. The model employs a parallel Iwan approach, comprising multiple elastoplastic micro-models; it is capable of predicting Masing-type nonlinear hysteretic response without the need for translating surfaces and kinematic hardening rules. From an industry perspective, an attractive feature of the PIMSS model is that it can readily be calibrated via standard geotechnical laboratory testing procedures. An advantage of this modelling concept is that each micro-model is numerically implemented as a single-surface plasticity model; this eases the model implementation process. The theoretical framework and calibration processes for the model are explained. Single-element simulations and comparisons with available test data are described.

RÉSUMÉ: Cet article présente un nouveau modèle constitutif de contrainte effective pour les sables soumis à un chargement monotone ou cyclique; le modèle est appelé « PIMSS » (Parallel Iwan Multi-Surface Sand). PIMSS a été développé pour les applications de conception géotechnique en mettant l'accent sur la simulation des fondations monopieux d'éoliennes offshore (OWT) dans le sable. Le modèle utilise une approche Iwan parallèle, comprenant plusieurs micro-modèles élastoplastiques; il est capable de prédire la réponse hystérétique non linéaire de type Masing sans avoir besoin de surfaces de translation et de règles de durcissement cinématique. Du point de vue de l'industrie, une caractéristique intéressante du modèle PIMSS est qu'il peut être facilement calibré via des procédures d'essais géotechniques standard en laboratoire. Un avantage de ce concept de modélisation est que chaque micro-modèle est implémenté numériquement comme un modèle de plasticité à surface unique; cela facilite le processus de mise en œuvre du modèle. Le cadre théorique et les processus d'étalonnage du modèle sont expliqués. Des simulations à élément unique et des comparaisons avec les données de test disponibles sont décrites.

Keywords: Constitutive model; monotonic and cyclic loading; sands; multi-surface plasticity; parallel Iwan approach.

1 INTRODUCTION

Consideration of cyclic loading is crucial for designing offshore wind turbine (OWT) foundations, necessitating the use of appropriate constitutive models for accurate numerical simulations of their response. Over the past decades, there has been a proliferation of advanced constitutive models that have been proposed and effectively employed in the simulation of the monotonic loading of sandy soils. However, these models exhibit limitations in their ability to replicate faithfully the behaviour of sands under cyclic loading conditions (Konstantinidis et al., 2023). Moreover, these models often require extensive calibration procedures and frequently prove insufficient for accurately representing all loading conditions using a single set of parameters.

This paper intends to present further details of a recently-developed effective stress model, 'PIMSS' (Konstantinidis et al., 2023), for monotonic and cyclic loading. This model has been developed for the simulation of OWT monopile foundations in sand, aiming to predict the behaviour during representative storm loading. The predictability of the PIMSS model is assessed with single-element simulations and comparisons with experimental data from laboratory tests performed on Karlsruhe fine sand (Wichtmann & Triantafyllidis, 2016a, 2016b).

2 DESCRIPTION OF THE PIMSS MODEL

The PIMSS model is classified within the multi-surface model category and is based on the parallel approach. The multi-surface plasticity concept originated with Iwan (1967), who proposed two one-dimensional models, termed as 'parallel-series' and 'series-parallel' respectively, for brevity replaced by

'parallel' and 'series' in this paper. Subsequently, various three-dimensional continuum models have been developed using both the parallel (Dawson, 2013; Whyte et al., 2020) and series (Cerfontaine, 2014; Prevost, 1985) concepts as a basis.

A motivation for the development of PIMSS was the promising predictive performance of the Prevost model (Cerfontaine, 2014), which inspired an exploration into the potential performance of a parallel version of the model without kinematic hardening. When the parallel approach is employed to formulate a constitutive model, several individual micro-models are arranged in parallel and consequently experience the same strain history (Whyte et al., 2020). The resulting macro-stress tensor ($\boldsymbol{\sigma}$) is computed by aggregating the individual micro-stress tensors ($\boldsymbol{\sigma}_{micro}$) through a weighted sum, as follows:

$$\boldsymbol{\sigma} = \sum_{i=1}^{n} w_i \cdot \boldsymbol{\sigma}_{micro}; \qquad \sum_{i=1}^{n} w_i = 1 \quad (1)$$

where n is the total number of micro-models and w_i is the weight corresponding to each micro-model.

The numerical implementation of PIMSS involves the parallel arrangement of several stationary micro-models incorporating the same yield surface, plastic potential, and elasticity as the Prevost model implementation by Cerfontaine (2014). The yield surface equation of the *i*th micro-model is

$$f^i = \boldsymbol{s}^i : \boldsymbol{s}^i - \frac{2}{3}\left(p^i \cdot M^i\right)^2 = 0 \quad (2)$$

where $\boldsymbol{s}^i$and p^i are the deviatoric stress tensor and the mean effective stress respectively, and M^i is a material parameter controlling the aperture of the cone of each micro-model. The incremental plastic strain direction $\boldsymbol{P}^i$ of each micro-model is broken down into a deviatoric component, which is associative, and a volumetric component, which is non associative, as:

$$\boldsymbol{P}^i = (\boldsymbol{P}^i)' + (P^i)'' \cdot \boldsymbol{\delta} \quad (3)$$

$$\left(\boldsymbol{P}^i\right)' = \frac{2 \cdot \boldsymbol{s}^i}{\left\| \frac{\partial f^i}{\partial \boldsymbol{\sigma}^i} \right\|} \quad (4)$$

$$(P^i)'' = \frac{\psi^i}{3} \cdot \frac{(\eta^i)^2 - (\bar{\eta}^i)^2}{(\eta^i)^2 + (\bar{\eta}^i)^2} \text{ and } \eta^i = \frac{(3/2 \cdot \boldsymbol{s}^i : \boldsymbol{s}^i)^{1/2}}{p^i} \quad (5)$$

where $(\boldsymbol{P}^i)'$ is the deviatoric component of the plastic strain rate direction and $(P^i)'' \cdot \boldsymbol{\delta}$ is its volumetric component, ψ^i is a material parameter scaling the volumetric component of the plastic strain rate and $\bar{\eta}^i$ is a material parameter indicating the stress ratio at phase transformation. In terms of the elastic part of each micro-model, the dependency of stiffness on the mean effective stress is:

$$G^i(p^i) = {G_0}^i \cdot \left(\frac{p^i}{p_{ref}}\right)^{0.5} \quad (6)$$

where G^i is the shear stiffness, p_{ref} is a reference pressure, ${G_0}^i$ is the small-strain shear modulus at the reference pressure. A constant Poisson's ratio of ν=0.05 is adopted.

3 CALIBRATION OF THE PIMSS MODEL

As PIMSS is not a critical state model a specific set of parameters is needed for different sand densities. This paper examined the performance of PIMSS for both loose and medium dense Karlsruhe fine sand with corresponding relative densities D_{r0} in the range 15% to 29% and 57% to 68% respectively. The parameters adopted for these relative density ranges are listed in Table 1 and Table 2.

PIMSS was calibrated by fitting the backbone stress-strain curve of a drained triaxial compression test corresponding to each density range. This included the distribution of the stiffness and strength parameters among its components, each assigned equal weighting, following the procedure:

- The maximum shear stiffness, G_{max}, is estimated from the backbone curve.
- The amount of shear stiffness decrease for each micro-model, from its maximum value, G_{max}, is equal to $G_{step} = G_{max}/\text{NMM}$ (where NMM is the total number of micro-models).
- The shear stiffness of each micro-model is calculated as:

$$G^1 = G_{max}$$
$$G^N = G^{N-1} - G_{step} \quad (7)$$

- The deviatoric strain values, ${\varepsilon_q}^i$, corresponding to the yield of each micro-model are selected.
- The deviatoric yield stresses, q_i, are found as:

$$q^i = 3G^i \times {\varepsilon_q}^i \quad (8)$$

The deviatoric yield stresses, q^i, can be used to find M^i, by solving equation (2) for each micro-model considering that $\Delta q^i / \Delta p^i = 3$. In relation to the plastic potential parameters $\bar{\eta}^i$ and ψ^i, the micro-models are grouped into two categories. Micro-models 1-7 are configured such that they lead to a purely contractive behaviour, while micro-models 8-15 initially exhibit a smaller contractive response but then a more

pronounced dilation. The combination of these two sets of micro-models results in an appropriate overall response. As indicated in Table 1 and Table 2, $\bar{\eta}^i$ and ψ^i required adjustments for the cyclic simulations, and therefore, the values within parentheses were used, which differ from the values used in the monotonic simulations.

4 SINGLE-ELEMENT SIMULATIONS

Figure 1 illustrates simulations of monotonic drained triaxial compression tests conducted on loose ($15\% \leq D_{r0} \leq 25\%$) and medium dense sand samples ($57\% \leq D_{r0} \leq 68\%$) under different initial stress conditions (cell pressures of 50, 100, 200 and 400 kPa). Concerning the looser densities, PIMSS can reproduce all stress-strain curves quite accurately. However, PIMSS overestimates the shear strength of the medium dense sand samples at large strain levels as its current formulation does not account for softening. Regarding the volumetric response, PIMSS performs well overall, however it slightly overestimates contraction for the loose sands and underestimates dilation for the denser ones.

Figure 2 depicts simulations of monotonic undrained triaxial compression tests conducted on loose ($D_{r0} = 29\%$) and medium dense sand samples ($60\% \leq D_{r0} \leq 64\%$) under various initial stress conditions (cell pressures of 100, 200, 300 and 400 kPa). PIMSS captures the stress-strain response of the undrained tests well, overpredicting slightly the dilative tendency of the looser sample. Good agreement between the simulations and the laboratory data can also be deduced regarding the stress paths. However, for the density of $D_{r0} = 29\%$ the initial contractive tendency of the sample was underestimated.

Figure 3 shows simulations of undrained cyclic triaxial tests on loose ($D_{r0} = 29\%$) and medium dense ($64\% \leq D_{r0} \leq 66\%$) sand samples after isotropic consolidation. Large strain amplitudes are applied to the samples. From the stress-strain responses, it is seen that PIMSS can predict adequately the stiffness degradation that occurs in the sand sample. However, PIMSS cannot predict liquefaction of the samples as shear locking occurs.

5 CONCLUSIONS

A practical multi-surface effective stress model, PIMSS, employing a parallel arrangement of stationary micro-models, has been presented. This study compared single-element simulations with test data, yielding promising results under both monotonic and cyclic conditions under different densities. As the core PIMSS model framework is flexible, it can be adapted to address specific geotechnical problems through extensions and customized calibration, aligned with the design application at hand. Future modifications of the model will further improve its predictive capability.

Adaptation of a constitutive model for sand to account for non-plastic fines

Adaptation d'un modèle constitutif du sable pour tenir compte des fines non plastiques

ABSTRACT: With the continued development of offshore wind farms in the North Sea it is apparent that seabed sand layers often incorporate a significant fines content within the sand grain skeleton. The presence of fines can alter the mechanical behaviour of the soil from the 'clean sand' case. When modelling sand with fines it is common industry practice to employ constitutive models for clean sand, either by re-calibrating the models to account for the presence of fines or by disregarding the influence of fines. This paper describes modifications to an existing constitutive model for sand, 'Ta-Ger', so that it is able to predict the behaviour of sand with a range of fines contents, f_c. The influence of the fines is addressed via equivalent granular state theory (EGST). The resulting model is shown to capture the effects of initial void ratio and stress level as well as being able to account for a varying fines content. Comparisons with some available test data are described.

RÉSUMÉ: Avec le développement continu des parcs éoliens offshore en mer du Nord, il apparaît clairement que les couches de sable des fonds marins incorporent souvent une teneur importante en fines dans le squelette des grains de sable. La présence de fines peut altérer le comportement mécanique du sol du cas « sable propre ». Lors de la modélisation du sable contenant des fines, il est courant dans l'industrie d'utiliser des modèles constitutifs pour le sable propre, soit en recalibrant les modèles pour tenir compte de la présence de fines, soit en ignorant l'influence des fines. Cet article décrit les modifications apportées à un modèle constitutif existant pour le sable, « Ta-Ger », afin qu'il soit capable de prédire le comportement du sable avec une gamme de teneurs en fines, f_c. L'influence des fines est abordée via la théorie de l'état granulaire équivalent (EGST). Il est démontré que le modèle résultant capture les effets de l'indice de vide initial et du niveau de contrainte, tout en étant capable de prendre en compte une teneur variable en fines. Des comparaisons avec certaines données de test disponibles sont décrites.

Keywords: Constitutive model; sand; fines; critical state; equivalent granular state theory.

1 INTRODUCTION

Over the past decades, constitutive modelling for clean sand has advanced significantly. One notable achievement has been the incorporation of critical state theory (Roscoe et al., 1958) together with the state parameter framework (Been & Jefferies, 1985) within the core formulation of constitutive models for sand. Models based on this approach (e.g. Li & Dafalias, 2000) attempt to unify the prediction of dense and loose sand behaviour, accounting for the effects of void ratio and stress level with a single set of material parameters.

However, natural sand deposits often contain significant quantities of fines within the sand grain skeleton. Hence, a need for predicting the behaviour of sand with different fines contents, f_c, has arisen. In terms of constitutive modelling, this suggests that a model should be able to simulate the behaviour of a sand with different percentages of fines, without the need to adjust the model constants for each specific case. This has been achieved via equivalent granular state theory (EGST) (Rahman, 2021) for sands with non-plastic or low-plasticity fines. Specifically, the void ratio e and state parameter ψ in a 'clean sand' state-dependent model are replaced by an equivalent granular void ratio e^* and equivalent granular state parameter ψ^* (Lashkari, 2014; Rahman et al., 2014; Rahman & Dafalias, 2022). This paper evaluates whether EGST can be used to develop a sand-with-fines model based on the state-dependent sand model 'Ta-Ger', specifically its 'formulation B' (Tasiopoulou & Gerolymos, 2016), denoted here as 'Ta-Ger B'. The predictive capability of the proposed model is assessed via single element simulations and comparisons with data from laboratory tests on mixtures of Sydney sand and Majura silt (Rahman et al., 2011).

2 MODEL DEVELOPMENT

2.1 Equivalent granular void ratio e^* and state parameter ψ^*

This study concerns sand-silt mixtures that fall under the 'fines-in-coarse' category (Thevanayagam & Martin, 2002). To account for the participation of fines in load-bearing microstructure and the density state of 'fines-in-coarse' mixtures, the equivalent granular void ratio e^* was defined by Thevanayagam & Martin (2002) as:

$$e^* = \frac{e+(1-b)f_c}{1+(1-b)f_c} \quad (1)$$

where b is the fraction of fines that actively takes part in force transmission in the soil skeleton. For the calculation of b, this study adopts a semi-empirical equation proposed by Rahman & Lo (2008):

$$b = \left[1 - exp\left(-0.3\frac{1}{1-\chi^{-0.25}}\frac{f_c}{f_{thre}}\right)\right]\left(\frac{1}{\chi}\frac{f_c}{f_{thre}}\right)^{1/\chi} \quad (2)$$

where χ is the particle size ratio, defined as D_{10}/d_{50} (D_{10} is the effective size of the host sand and d_{50} is the median size of the fines). f_{thre} is the threshold fines content, which delimits a 'fines-in-sand' from a 'sand-in-fines' mixture (Thevanayagam & Martin, 2002), and can be determined either from empirical relationships (Rahman & Lo, 2008) or experimentally.

As described by the state parameter framework (Been & Jefferies, 1985), the mechanical behaviour of clean sands depends on the combined effects of the void ratio and the mean effective normal stress. Been and Jefferies proposed a state parameter $\psi = e - e_c$, where e_c is the void ratio on the critical state line (CSL) corresponding to the current mean effective stress p. Accordingly, with EGST, an equivalent granular state parameter ψ^* can be defined in terms of the equivalent granular void ratio as $\psi^* = e^* - e_c^*$ (note that $e_c^* = e_c$, as the equivalent granular CSL coincides with the CSL for $f_c = 0$).

2.2 Constitutive formulation

The Ta-Ger model is based on a framework that combines perfect elastoplasticity with smooth hysteresis by introducing a Bouc-Wen motivated hardening law. The main deviation of this approach from classical plasticity is the introduction of a plastic modulus which scales the plastic part of the incremental stiffness matrix instead of being defined as an additive term in the denominator (Tasiopoulou & Gerolymos, 2016):

$$\boldsymbol{E}_h^{ep} = \boldsymbol{E}^e\left[\boldsymbol{I} - \frac{\boldsymbol{\Phi}_g\boldsymbol{\Phi}_f{}^T\boldsymbol{E}^e\boldsymbol{H}}{\boldsymbol{\Phi}_f{}^T\boldsymbol{E}^e\boldsymbol{\Phi}_g}\right] \quad (3)$$

where $\mathbf{E}^e$ is the elastic stiffness matrix, $\boldsymbol{\Phi}_f$ and $\boldsymbol{\Phi}_g$ are the gradients of the yield surface and plastic potential surface, and $\mathbf{H}$ is the matrix playing the role of the plastic modulus. $\mathbf{H}$ is defined as $\mathbf{H} = \zeta^n\mathbf{I}$, where ζ is responsible for the hardening/softening through a mapping rule and n is a hardening parameter.

In line with the approach suggested by Rahman et al. (2014), all the constitutive equations of Ta-Ger B are retained as originally proposed (Tasiopoulou & Gerolymos, 2016) with no further reformulation, except for the substitution of e^* and ψ^* for e and ψ. Other variables affected by this substitution will also be denoted with a superscripted star. For brevity, only the modified equations will be shown. The elastic matrix $\mathbf{E}^e$ of Ta-Ger B is composed of terms that are functions of non-linear shear (G) and bulk (K) moduli (Li & Dafalias, 2000), giving:

$$G^* = G_0 p_a \frac{(2.97-e^*)^2}{1+e^*}\left(\frac{p}{p_a}\right)^m \quad (4)$$

where G_0 and m are dimensionless material parameters, and p_a is atmospheric pressure. The bulk modulus K^* is obtained from $K^* = 2G^*(1+v)/3(1-2v)$ assuming a constant Poisson's ratio, v. Rahman et al. (2012) showed that the influence of fines on the shear modulus G can be adequately captured by substituting e^* for e as shown in equation (4). Critical state compatibility is achieved via the phase transformation stress ratio, M_{pt}, and the bounding surface stress ratio, M_s, which are modified via the substitution of ψ^* for ψ:

$$M_{pt}^* = M_{cs}e^{n_d\psi^*},\ M_s^* = M_{cs}e^{-n_b\psi^*} \quad (5)$$

where M_{cs} is the critical state stress ratio, and n_d, n_b are positive material constants. The dilatancy, d, and hardening parameter, ζ, are also affected as they depend on M_{pt} and M_s correspondingly:

$$d^* = R_d\left(\sqrt{\frac{2}{3}}M_{pt}^* - \frac{\boldsymbol{s}}{p}:\boldsymbol{n}\right) \quad (6)$$

$$\zeta^* = \frac{|\boldsymbol{r}-\boldsymbol{r}_p|}{\sqrt{\frac{2}{3}}M_s^* - n_p} \quad (7)$$

where R_d is a parameter capturing densification effects, $\boldsymbol{s}$ is the deviatoric stress tensor, $\boldsymbol{n}$ is a normalised stress ratio tensor, $\boldsymbol{r}$ is the current deviatoric stress ratio tensor, $\boldsymbol{r}_p$ is a deviatoric stress

tensor that plays the role of the 'back-stress' ratio in conventional bounding surface models, and n_p is an inner tensor product obtained as $n_p = \boldsymbol{n}:\boldsymbol{r}_p$.

3 TRIAXIAL TEST SIMULATIONS

The predictive capability of the proposed model was evaluated against experimental data on Sydney sand mixed with Majura silt (Bobei, 2004). The parameters used for the simulations are shown in Table 1. Parameters related to elasticity, critical state, bounding surface, dilatancy, and fines content are taken from previous work (Lashkari, 2014). The hardening exponent parameter, n, has been calibrated by fitting the stress-strain curves of drained monotonic triaxial tests (Bobei, 2004) on the sand-silt material studied by Rahman et al. (2011). These tests were conducted with different initial void ratios (e_0 of 0.780, 0.749, 0.732 and 0.722) and mean effective stresses (p_0 of 100, 300, 400 and 600 kPa), but covered only a single fines content (f_c of 10%). The results from the experiments and the simulations are shown in Figure 1. The proposed model can reproduce all stress-strain curves quite accurately, despite slightly overpredicting the deviator stress at lower strains. Regarding the volumetric response, the model also performs well overall.

Figure 2 shows a second set of model predictions, for undrained monotonic triaxial tests (Rahman et al., 2011). Specifically, subfigures (a) and (b) concern samples with different fines contents (f_c of 0, 15 and 20%), initial void ratios (e_0 of 0.743, 0.535 and 0.573) and initial mean effective stresses (p_0 of 350 and 600 kPa). Subfigures (c) and (d) relate to samples with a single fines content (f_c of 15%) but different initial void ratios (e_0 of 0.645, 0.569 and 0.535) and mean effective stresses (p_0 of 600, 1100 and 1300 kPa). Generally, model prediction works best for flow (contractive) behaviour, but the quality of the prediction reduces as the behaviour changes to limited flow (dilative response) and non-flow (strongly dilative response). Discrepancies between predictions and observations for samples with denser behaviour are primarily attributed to the fact that the parameters utilised were determined from tests showcasing looser behaviour. Nevertheless, the simulations generally align reasonably well with the experimental data. The significance of the model's ability to capture the responses of the sand-silt material reliably can be appreciated by studying the response of the sample with $f_c = 20\%$ and $e_0 = 0.573$ (subfigures (a), (b)). Focusing solely on the negative initial value of the state parameter ($\psi_0 = -0.236$) would misleadingly imply a tendency for the sample to dilate. However, in adherence to EGST, the modified model considers the equivalent state parameter ψ^* instead of the state parameter ψ. With the equivalent state parameter taking a positive initial value ($\psi_0^* = 0.064$), the model correctly predicts liquefaction triggering rather than strain hardening.

4 CONCLUSIONS

A constitutive model for sand containing varying proportions of non-plastic fines has been proposed. The present work involved the modification of a state-dependent model for clean sands, Ta-Ger B, by replacing the void ratio e and state parameter ψ with the equivalent granular void ratio e^* and equivalent granular state parameter ψ^*. It has been shown that, with a single set of parameters, the model can predict the drained and undrained monotonic behaviour of sand with fines over a range of initial mean effective stresses, void ratios, and fines contents. Additional modifications and enhancements of the core formulation of the model could further improve its predictive capability. However, this could compromise the model's straightforwardness, its small number of input parameters, and the simplicity of the calibration procedure.

ABSTRACT: In the process of a hydraulic recultivation of former brown coal mines, it is necessary to address the issues related to the subsequent stability of the retaining slopes. It is evident that the determination of the design value of the shear strength of the soil will be crucial and decisive, particularly in relation to the contact between the clay and the coal seam in their natural position after being flooded with water. The determined values of the shear strength of the affected soils were used in stability calculations for the retaining slopes. In the first step a large-scale shear apparatus was designed and constructed. The test results provided the peak strength before the sample collapsed and the residual strength value determined by the movement of the soil along the shear plane. The large-scale shear field test provided a more precise view of soil behaviour, especially under lateral stress, on a larger scale. The determination of the actual values of the soil shear parameters can then be used for modelling the stability of the original/retaining slopes from the end of mining to lake filling.

RÉSUMÉ: Dans le processus de recultivation hydraulique des anciennes mines de charbon brun, il est nécessaire de s'attaquer aux problèmes liés à la stabilité ultérieure des pentes de retenue. Il est évident que la détermination de la valeur de conception de la résistance au cisaillement du sol sera cruciale et déterminante, en particulier par rapport au contact entre l'argile et la veine de charbon dans leur position naturelle après avoir été inondées d'eau. Les valeurs déterminées de la résistance au cisaillement des sols affectés sont ensuite utilisées dans les calculs de stabilité pour les pentes de retenue. Dans une première étape, un appareil de cisaillement à grande échelle a été conçu et construit. Les résultats des tests ont fourni la résistance de pointe avant que l'échantillon ne soit détruit et la valeur de résistance résiduelle déterminée par le déplacement du sol le long du plan de cisaillement. Le test de cisaillement sur le terrain à grande échelle a fourni une vision plus précise du comportement du sol, en particulier sous contrainte latérale, à une plus grande échelle.

Keywords: Large-scale shear device; clay; geomechanical parameters.

1 INTRODUCTION

As part of the anticipated flooding (hydraulic reclamation) of surface brown coal quarries, the question of the subsequent stability of their retaining slopes arises. It is necessary to address the final form and reclamation of residual pits in broader relationships and correlations, especially in terms of the process of creating dump bodies and the shape of the resulting retaining slopes of the quarry. Subsequent hydraulic reclamation must be carried out without major technical problems and within hydraulically, ecologically, and economically tolerable limits.

Practically no study has so far dealt with the stability of the slopes of anticipated lakes (with a depth of up to 200 m). The knowledge of the design values of the contact shear strengths of individual soils, which subsequently enter the model calculations, can be considered completely significant. This mainly concerns the contact surfaces of original materials (claystone and coal layer), this contact is crucial for the project of residual pits and prediction of their changes. Before the design work, which among other things, includes proper deformation and stability calculations, it is necessary to establish real values of input geotechnical parameters (especially values of shear strength).

For this purpose, it was necessary to perform engineering geological survey. The research included

the following activities: research; development of a large-scale shear device for use in situ; the application of a large-scale shear device in situ at the coal x subsoil (bedrock) contact; determination of geomechanical parameters for subsequent stability calculations. The research area is situated on the north part of the bohemia (Figure 1).

Figure 1. Research area.

2 SCOPE AND METHODOLOGY OF WORK PERFORMED

The performance of the large-scale shear test was preceded by excavation of large-profile notches and exposure of problematic sections. The tests provided a more accurate view of soil behaviour, especially under lateral stress, on a larger scale. The monitored areas contained more heterogeneity than what can be captured in a laboratory test performed on undisturbed samples of soils/rocks, including the inclusion of possible discontinuities across the tested area and the possibility of testing in situ. Therefore, the natural deposition and natural degree of saturation of the observed contact was guaranteed.

2.1 History of the device

Shear strength of soils is a basic property for slope stability evaluation. The box shear test is the oldest method for determining shear strength. Traditionally, a soil sample is placed in a rigid metal box, subjected to a vertical force, and sheared along a horizontal plane between the two halves of the shear box.

Large-scale shear frames were originally designed to test drained materials containing large particles, such as gravelly soils, industrial slag, rubble, or mining spoil. Regarding the history of direct field shear tests in former Czechoslovakia, large shear tests were already conducted in the 1960s, for example on rock blocks measuring 500 x 500 mm^2 x 150 mm during surveys for the construction of the Czech Television building at Pankrác plain.

Various engineers performed field measurements to determine the shear strength parameters of the rock mass, e.g., Hudek in 1980, Líbal in 1983, Hanák and Horák in 1988, and Mencl in 1992. Typical frame dimensions were 500 x 500 mm^2 x 300 mm or less frequently 700 x 700 mm^2 x 305 mm. Shift-controlled loading allowed evaluation of both maximum and residual shear strength. Hydraulic jack introducing normal stress into the sample could be supported by the surrounding rock in the rock mass.

Líbal, based on his previous experience in 1991, performed a set of in situ shear tests at the Nástup Tušimice Mine with Seyček to evaluate the contact of the coal seam and its substrate consisting of clay and claystone. The 500 x 500 mm2 x 145 mm sample was loaded using a hydraulic jack supported by an anchored load bridge. The study of the shear strength of deeply located coal and rock interfaces for stability analysis requires a large-scale device capable of transmitting the large stresses that occur in the deep contact layers of extensive slopes. One of the largest shear devices in the world was developed at the University of Newcastle in 2013 for testing square samples of up to 720 mm edge under high vertical stress of up to 4 MPa. In this case, this shear device was designed for laboratory testing, so it was possible to use a massive loading frame to ensure normal pressures that occur in large rock dams and high spoil heaps. In addition to these unique devices, some traditional manufacturers also offer large-scale devices for soil and rock testing again for use in laboratories, such as Wille with their shear boxes up to 1,000 x 1,000 mm^2 and normal stress up to 1 Mpa (in Molina at all, 2020).

2.2 Technical requirements for the device

The purpose of the large-scale shear device is to determine the cohesion coefficient c and the shear friction angle ϕ of the geological environment in situ from Mohr-Coulomb diagrams. A necessary premise for the development of a device enabling field shear strength tests was the ability of the device to apply a normal force of 120 kN and a tangential force of 35 kN to a test sample of dimensions 500 x 500 x 150 mm. The loading must be displacement-controlled in the tangential direction, with a shearing speed of 0.05 mm/min in the first phase (reaching peak strength) and 0.5 mm/min in the second phase. In the four corners of the spreader plate, four displacement sensors will be placed in the normal direction and three displacement sensors in the tangential direction.

2.3 Proposed solution

The first variant was designed with a spreader frame. Here, a groove about 2 m deep and about 4 m wide was considered. The spreader frame would be anchored into the coal seam using spiral anchors. The load

capacity of spiral anchors depends on the depth of the anchor and also on the distance of the anchor from the free edge. This law affects the stiffness of the spreader frame and its weight, which is decisive for manipulation and the necessary presence of a crane, thus increasing the cost and time of performing the shear test. A static stress calculation of the beam loaded with a normal force of 112.5 kN was carried out by the finite element method. From the results, it was clear that near the middle of the beam and at both ends, stress was already occurring close to the slip (deformation about 6 mm). The weight of the beam without the spreading consoles was 120 kg. With the spreading consoles, the weight would increase to about 200 kg. This option was rejected due to manipulation and the results of the strength calculation.

The attempt to reduce the weight of the loading frame and its manageability led to the idea of using a truss. In principle, it is a similar variant as the variant with a beam, but the difference is that the weight decreased but there was still no improvement in the stiffness of the device. Therefore, another variant was approached.

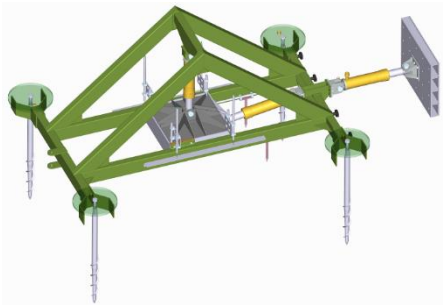

Figure 2. Final shear test device.

The final variant of the large-scale shear device meets the requirements of easy manipulation, appropriate weight, and sufficient stiffness. The advantage of this variant is the fixation (anchoring) of the frame to the clay subsoil, an open area where there is no danger of the operator being buried by the coal layer sliding into the deep groove. Another advantage is the small size of the frame. The Figure 2 shows a frame placed over the test sample together with a support box, spreader plate, and hydraulic cylinders for vertical and horizontal directions.

An industrial computer, Getac, equipped with the WinMost program (INSET) and an 80-channel measuring card from National Instruments, was used to measure displacements and loads.

Inductive LVDT sensors DH_100 with a spring-loaded tip and a measuring range of 0 to 100 mm were used for displacement measurement with resolution 10^{-3} mm and extended combined uncertainty U(k=2) = 5 * 10^{-2} mm. Vertical measurement was carried out between the fixed frame and the movable spreading plate resting on the soil sample (coal layer). For measuring the displacement of the test sample in the horizontal direction, a boxed sensor holder equipped with a tip, hammered into the clay subsoil, was used. An alternative (which was used in most cases) was anchoring into the bedrock using drilled earth spiral anchors, with a concrete filling. For this purpose, test breakout tests of anchors were conducted to declare the required pull - an equivalent necessary counterforce, which is to be used for the large-scale shear device. Control tests demonstrated sufficient load-bearing capacity.

2.4 Preparation of the test field

The creation of the test field by machine mechanization had several phases. First, the entire area around the test field was revealed down to the coal by a bucket ripper, then the coal layer was lowered to a height of 1 m. After the longitudinal and transverse grooves were marked out, they were machine-made using a tractor excavator to create transverse and longitudinal grooves in the coal, and finally the terrain was adjusted for the movement of workers and equipment - creating drivable and handling areas for the purpose of manually separating future samples from the rock mass. An indispensable condition was to preserve the natural deposition of the rock environment (there could be no predisposition to damage the shaped body). A combination of a disc saw with water cooling, a jackhammer, and especially a chainsaw with water cooling served as a manual tool. The sample was manually formatted to the necessary size of 500 x 500 x 150 mm. This was followed by the positioning of the loading device (large-scale shear device).

2.5 Result of the large-scale shear test

Large-scale in-situ shear tests (Figure 3) were performed in groups with varying normal stress, specifically 50, 200 and 350 kPa. Analogous to the laboratory evaluation of box shear tests, it was then possible to obtain the values of the friction angle ϕ and the cohesion c. In total, three groups of tests were carried out and evaluated, which can be considered a statistically evaluable sample of material (coal layer - underlay contact), from which the average values of geomechanical parameters were derived.

Figure 3. Large-scale shear test.

The results of the realised large-scale tests are provided in Table 1.

Table 1. Results of the conducted large-scale tests.

Group	ϕ [°]	c [kPa]
I	34.6	29.0
II	38.0	40.0
III	25.8	88.0

3 CONCLUSION

The conducting of a large-scale shear test was preceded by the excavation of large-profile notches and the exposure of problematic sections, i.e., the contact of the brown coal seam with the underlying claystones. The excavation work for the large-scale tests (experiments) allowed a spatial view of the observed contact of the affected soils, their documentation, and collection of undisturbed samples of the observed soils. The large-scale shear field test provided a more accurate view of soil behaviour, especially under lateral stress on a larger scale. The observed place contained more heterogeneities than the laboratory test, including the inclusion of possible discontinuities across the test area within in situ testing. Thus, the natural positioning and the natural degree of saturation of the observed contact were guaranteed. The concept of the shear test device for a large-scale in situ shear test was based on the traditional laboratory box shear device.

During the large-scale shear test, all the data needed to determine the values of shear parameters determine the values of shear parameters, the size of deformation, normal stress, shear stress, and pore pressure, were recorded. The result of the test was determining the peak strength before breaking the sample and determining the value of the residual strength given by the movement of the soil over the created shear face. Also, a statistically evaluable set of large-scale shear tests was carried out in a total of 9. This provided a sufficient set of shear parameter values at the observed coal layer - claystone contact in its natural positioning. The values of shear parameters obtained from the performed large-scale shear tests will subsequently be compared with the data obtained from the literature review and the laboratory results. A literature review will be conducted using a set of samples collected over the last 3 years during mining exploration, feasibly exploration, and drilling exploration in interest. At the same time, drilling work was carried out as part of the field tests, including the collection of undisturbed samples at the contact of the brown coal layer with the overburden and the substrate for subsequent laboratory tests. After evaluating these three sets of data, the characteristic values of shear strengths will be determined. The determination of real values of shear parameters of soils will be used for the modelling of the stability of original/final slopes from the end of mining to the filling of the lake. The calculations will simulate the prediction of the behaviour of individual stages and the overall slope of the spoil body during the gradual filling of the lake. Eventually, the real values of shear strengths (obtained particularly from the field) will influence the design of technical measures to ensure the stability of the studied area as part of the planned study of filling lakes (hydraulic reclamation).

Thermal activation of sewers and embedding in a heating-cooling network

Activation thermique des canalisations d'eaux usées et intégration dans un réseau de chaleur et de froid

T. Kugler*, Ch. Moormann
University of Stuttgart, Institute of Geotechnical Engineering, Stuttgart, Germany
**till.kugler@igs.uni-stuttgart.de*

ABSTRACT: The thermal activation of foundation elements through the installation of absorbers in components being in contact with the underground has become state-of-the-art. A new approach involves the thermal activation of sewers as a part of the urban hydraulic infrastructure. These so called ´hybrid sewers´ enable energy extraction or storage from both the inner sewer climate and the subsoil in which the sewer is embedded. The wastewater flow continuously supplies thermal energy, so that a higher thermal energy can be obtained than from usual activated foundation elements. Consequently, the system is base load-capable and is therefore suitable as the basic system of a regenerative heating network. The thermal performance of hybrid sewers, previously unexplored, has now been validated using numerical simulations and measurements.

RÉSUMÉ: L'activation thermique des éléments de fondation consiste à installer, dans les éléments en contact avec le sol, des absorbeurs qui sont traversés par un liquide caloporteur et qui absorbent l'énergie thermique. L'activation thermique des égouts hybrides est particulièrement judicieuse, car l'énergie thermique provient à la fois du sol et de la terre. Les eaux usées qui s'écoulent fournissent de l'énergie thermique en continu, ce qui permet de récupérer une quantité d'énergie thermique nettement plus importante et plus constante que dans le cas d'un simple contact avec le sol. Le système peut donc supporter une charge de base et convient donc comme système de base d'un réseau de chaleur régénératif. Le comportement thermique du canal hybride était jusqu'à présent inconnu et a maintenant été validé par des simulations numériques et des mesures.

Keywords: Hybrid sewer; district heating; wastewater heat absorber; hydrothermal coupled numerical simulation.

1 INTRODUCTION

Renewable energy sources, unlike fossil energy sources are widely accessible based on local applications. However, they may have a limited capacity to provide a consistent base load capacity in certain cases. Therefore, it is logical to integrate different renewable energy sources within a heating network.

The thermally activated “hybrid sewer”, investigated in the research project “IWAES” offers the benefit of being able to extract and supply thermal energy from the surrounding subsoil, the inner sewer climate and the wastewater. In this context, the term “hybrid” denotes the sewer’s capability of the to simultaneously transport wastewater and gain thermal energy. Moreover, the hybrid sewer can enable bidirectional compensation among various consumers due to additional transport functions. In order to heat and cool, the individual users do not necessarily produce solely their own thermal energy; instead, they can use the waste heat and cooling energy of other users within the network.Thus, the users within the network become both producers and consumers of thermal energy. The efficient integration of energy sources and storage facilities into the heating network should also considered.

2 ENERGY GEOSTRUCTURES

An “energy geostructure” refers to the incorporation of absorber pipes, typically made of copper or plastic, into construction elements which serve a structural primary purpose. These pipes facilitate heat transfer through fluid flow (see Figure 1) (Laloui & Rotta Loria, 2020). The heat transfer fluid absorbs thermal energy while flowing through the component and then transfers the energy to a heat pump or heat exchanger. The heat pump increases the temperature to the desired level with the aid of electrical energy.

Theoretically, all foundation elements can be thermally activated, so there are thermally activated diaphragm walls (u. a. Sterpi et al., 2017), tunnelling

structures (u.a. Moormann et al 2019), piled fondations and also mixed in placed methods (Brandl, 2006). To prevent the water in the concrete from freezing, the flow temperature should not fall below the freezing point for all statically effective foundation structures. Water should mainly be used as the heat transfer fluid instead of a water-glycol mixture.

Typically, shallow geothermal systems can only operate efficiently for a certain period of time before requiring deactivation to regenerate. Foundation elements that border both the subsoil and a flowing medium are permanently self-regulating and can therefore efficiently generate thermal energy almost indefinitely. Such elements include tunnelling structures, sheet pile walls and sewers.

The thermal activation of underground infrastructure diminishes the necessity for additional resources typically required for constructing alternative geothermal systems like geothermal probes or collectors. Additionally, the ground that has already been heated by anthropogenic use (such as sewers) undergoes subsequent cooling.

3 HYBRID SEWER

3.1 General

The thermal activation of sewers represents a logical progression of the thermal activation of structurally necessary components.

Figure 1. Thermally activated sewer `hybrid sewer´.

The term “hybrid sewer” refers to a sewer segment that effectively carries out the primary task of transporting wastewater. By incorporating externally helically arranged absorbers, thermal activation enables the extraction of thermal energy from the surrounding soil, sewer air and wastewater (Figure 1). The three-dimensional design of the hybrid sewer depicts a section of an activated sewer with a length of 6 m made of plastic. Alternatively, other prefabricated lengths of the sewer sections are conceivable. Additional transport lines installed above enables the thermal energy to be transported through the district at varying temperature levels (Figure 2). In an optimal scenario, the transported thermal energy does not require a heat pump to raise the temperature level, thus eliminating the need for additional electrical energy.

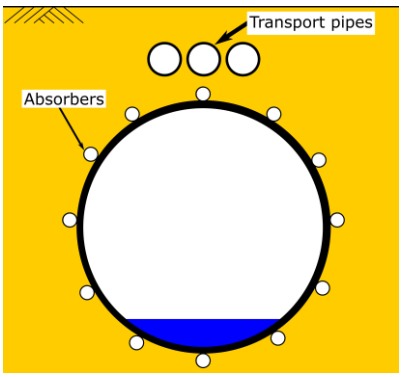

Figure 2. Schematic section of a hybrid sewer.

3.2 Thermal performance

The advantage of the thermally activated sewer over foundation elements surrounded exclusively by soil, e.g. piles, lies in the permanent thermal regeneration facilitated by the downstream wastewater. Unlike conventional energy geostructures that are not installed in flowing groundwater, the continuous thermal regeneration due to the wastewater flow leads to a certain base load capacity. The thermal energy from the wastewater can be harnessed not only in the sewer but also within the building and in the sewage treatment plants. While existing methodologies and effective implementations for this have already been established, as indicated in reference Nagpal et al, (2021), comprehensive dimensioning aids have not yet been developed.

There are mathematical models to determine the effects of heat extraction on wastewater temperature (Dürrenmatt & Wanner, 2014). However, there are currently no models available to infer the heat extraction capacity from the wastewater temperature and volume flow.

It is also known that the wastewater flow (l/s), as well as the filling level (cm) and the wastewater temperature have an influence on the performance of thermally activated wastewater absorbers (weighting increases with sequence) (Adam & Markiewicz, 2009).

To assess the thermal performance, new approaches and calculations are required. The approach of calculating the sum of all heat flows acting on the absorber is challenging, as the heat flux that directly impacts on the absorber is crucial for its performance. This heat flux is influenced by various heat flows, such as solar, geothermal heat flow that act within and in the vicinity of the hybrid sewers. There

are interdependencies between the different heat flows. Additionally, heat flows must be categorised according to their specific mode of heat transfer (conductive, convective). Since a closed analytical solution is not available, numerical simulations are carried out. For these simulations, all thermal-hydraulic parameters must be known. With regard to the climate inside sewers, hardly any reliable measured data have been published. Existing publications on the topic take a stochastic approach to the topic, as seen in reference (Abdel-Aal et al. 2021). Therefore, field measurements were carried out in selected sewers to gather necessary data.

3.3 Sewer air investigations

Investigations on thermally activated tunnel structures have revealed a significant influence of the tunnel air on the possible heat extraction (Schneider, 2011; Schneider, 2013; Buhmann 2019). Similarly, to assess the thermal performance of hybrid sewers, it is crucial to have accurate information about the temperature and flow of the sewer air. To achieve this, sewers with different diameters and gradients were equipped with measurement sensors and investigated (Figure 3).

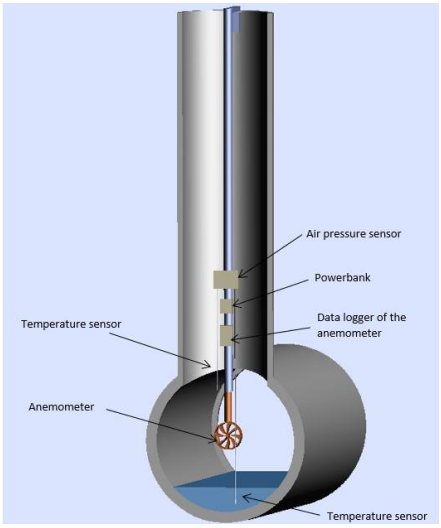

Figure 3. Sewer equipped with measurement technology.

Figure 4 illustrates the presence of an airflow within the sewer, which can occur independently of the direction of wastewater flow. Concequently, it can be inferred that the heat transfer between the sewer air and the inner sewer surface primarily occurs through convection. This fact is additionally supported by literature (Bischofberger, 1984). The dimensionless convective heat transfer coefficient is significantly higher than the heat transfer coefficient solely from conduction. Since wastewater in the sewer flows continuously, there is no direct thermal coupling between energy extraction and water temperature. The heat transfer, which is the product of the temperature gradient and the heat transfer coefficient, is therefore significantly higher than for foundation elements with pure soil contact.

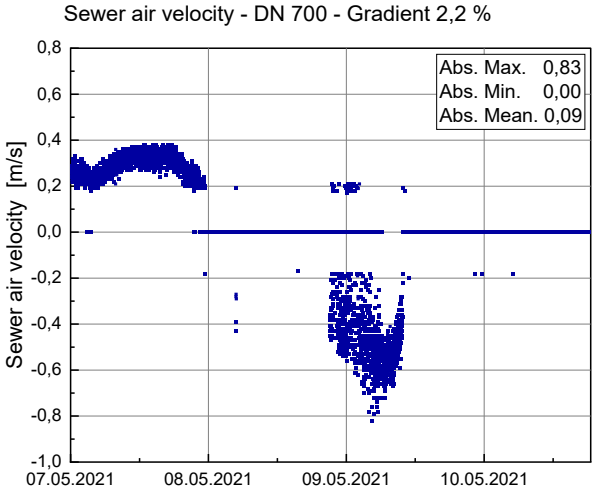

Figure 4. Measurement of the sewer air velocity.

3.4 Numerical investigations

The thermal performance of the hybrid sewers was evaluated through conducting numerical simulations, both two- and three-dimensional, which involved coupled thermal-hydraulic calculations. The simulations were carried out using the COMSOL® simulation software and the model used is depicted in Figure 5. To mitigate boundary effects arising from unsuitable geometry and network effects, extensive sensitivity analyses were carried out beforehand. In this study, the factors influencing the individual heat flows were quantified in order to identify those requiring further investigation. The analysis revealed that the velocity and temperature of the wastewater and the sewer air in particular are crucial for the performance of the absorber. Additionally, the atmospheric heat input, especially convective heat flow due to wind, has an influence that must be considered. The dimensionless convective heat transfer coefficient, which acts as a result of air currents on terrain surfaces, was calculated according to Beisel (1999) by means of the average wind speed (v), as shown in Equation (1). The average wind speeds and surface temperatures were obtained from the test reference years of the German Weather Service for the year 2045.

$$\alpha = \begin{cases} 1{,}8 + 4{,}1 \cdot v & v \leq 5\frac{m}{s} \\ 7{,}3 \cdot v^{0{,}73} & v > 5\frac{m}{s} \end{cases} \quad (1)$$

All pertinent parameters required to generate the thermal load profile were derived from the urban

planning design. The thermal load profile illustrates when the analysed user requires what amount of thermal energy. The thermal effects of the wastewater temperature were evaluated using the hourly temperature measurements at the main wastewater treatment plant in Stuttgart.

The diameters, lengths and expected flow velocity of the wastewater could be taken from the conceptualised wastewater network.

The flow within the absorbers exhibits a slightly turbulent flow (Re = 3000), represting the energetic optimum between the pump flow used and the heat energy extracted (VDI 4640, 2019). The findings from the aforementioned investigations were utilised for the sewer air data. Initially, a non-cohesive, homogeneous soil without groundwater flow was assumed for simulation of the soil continuum. The applied thermal load curve was developed within the project for a typical building block.

In the initial step, a supply temperature of +2°C of the heat carrier fluid is provided to the numerical model. The simulation then calculates the outflow temperature of the absorber. According to Equation (2), the required performance $\dot{Q}$, the volumetric flow $\dot{V}$ and the return temperature ϑ_{Outlet} can be used to calculate the supply temperature ϑ_{Inlet}. The heat capacity and density are given by c_p, ρ.

$$\dot{Q} = \dot{V} \cdot c_p \cdot \rho \cdot (\vartheta_{Inlet} - \vartheta_{outlet}) \qquad (2)$$

The thermal energy requirement for each hour is determined from the thermal load profile. By adjusting the formula based on the temperature differential, it becomes feasible to calculate the temperature difference at which the heat transfer medium needs to be cooled in order to 4ulfil the thermal energy demand. Subsequently, the new inlet temperature is calculated by subtracting the temperature difference from the determined outlet temperature.

The result of the numerical investigation represents the average thermal performance of the hybrid sewer. The average thermal performance of the hybrid sewer was determined using the following equation and divided by the number of annual full load hours (heating load hours: 1240 h, cooling load hours: 360 h) are shown in Table 1. Applied to a district with a high population density, the hybrid sewer can cover approximately 15% of the total thermal demand (heating and cooling) of the district. The degree of energy coverage here is in line with the literature (DWA M 114, 2020).

Table 1. Numerical results for the thermal performance of the investigated sewers.

Diameter [mm]	Heating [W/m²]	Cooling [W/m²]
300	140	830
400	130	700
800	115	640

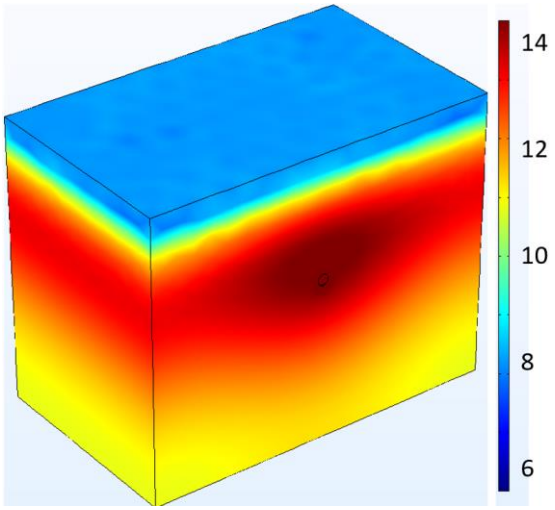

Figure 5. Three-dimensional thermo-hydraulically coupled model of the hybrid sewer [°C].

For comparison, the performance of thermally activated diaphragm walls and floor slabs is between 10 W/m² and 35 W/m².

4 VALIDATION

To facilitate further parameter studies, it is imperative to validate the simulation model using monitored real hybrid sewers. Therefore, an experimental test setup under laboratory conditions and a pilot plant were developed within the framework of the IWAES project. The parameter studies carried out by the simulation model validated by back-analysis of the results of the experimental tests and of the pilot plant will serve as the basis of a thermal resistance-capacity model. This model, in turn, will provide the foundation for a simplified design concept for the engineering practice.

4.1 Experimental tests under laboratory conditions

The experimental setup exists of a 4.0 m long hybrid sewer which is embedded in a test box (width: 2.8 m, length: 4.8 m, height: 1.5 m) filled with moist sand (see Figure 6). The hybrid sewer, has an internal diameter of 200 mm and is continuously flowed through by water. The "waste water" is consistently heated by a flow heater, while the absorber fluid is

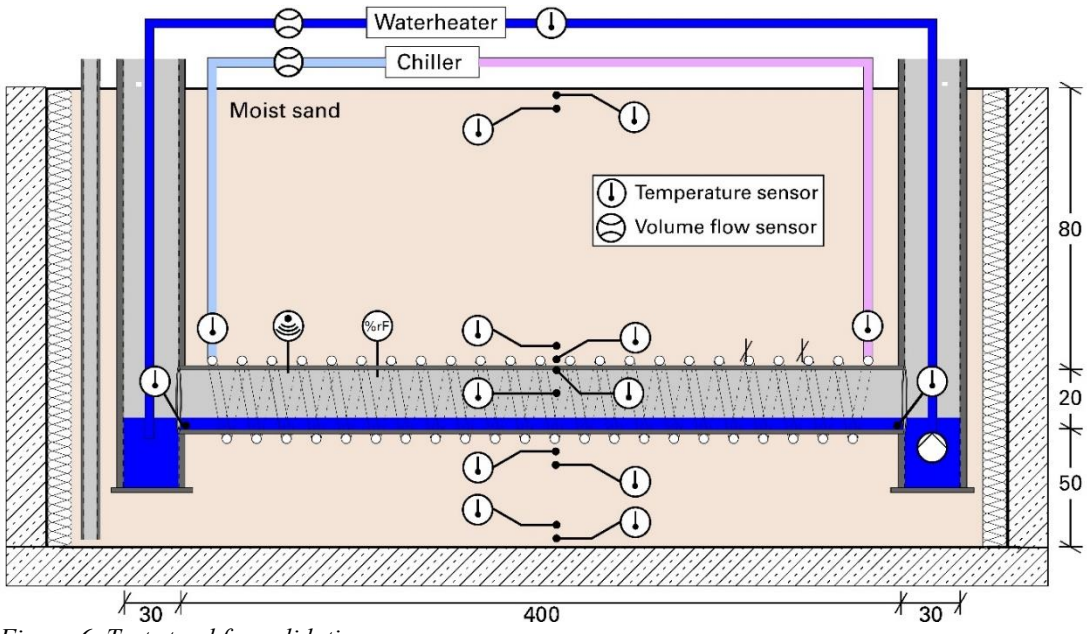

Figure 6. Test stand for validation.

cooled by a flow cooler, mimicking the evaporator of a heat pump. The absorber fluid will cool down as it flows through the absorber pipe, as in a real hybrid sewer.

The numerical model precisely replicates the physical system described. Validation of the numerical model will be based on the congruence between the numerically determined and measured return flow temperature.

The temperatures as well as the volume flow can be varied. In addition, a sewer air flow can be simulated by applying a blower.

4.2 Pilot plant

In Bavaria, a hybrid sewer is repurposed as a penstock for a small hydropower plant. The pressure tunnel links a spring pond with a water turbine, and the channel cross-section is fully filled. All pertinent variables are measured and logged and used for back-analysis.

Figure 7 illustrates the temperature of the flow and return for a six-metre-long section of the sewer. Despite continuous operation, the difference between the flow and return is around 2 K, with a flow rate of 25 litres/min. Using Equation 2, this results in a performance of 220 W/m² concerning to the length of the sewer. Compared to thermally activated piles, which typically have extraction capacities of 18-32 W/m², the extraction capacity of the hybrid sewer is significantly higher. The conductivity of thermally activated floor slabs and diaphragm walls is also significantly lower (Brandl, 2006). The reason for this is the convective heat transfer between the flowing water and the sewer´s walls.

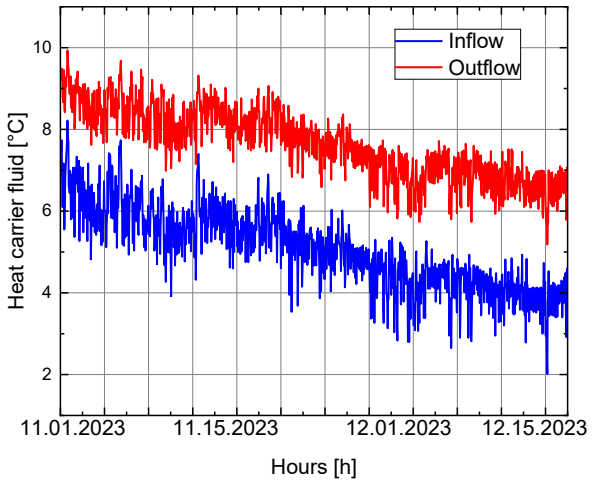

Figure 7. Measurement of the flow and return temperature of the heat carrier fluid for a 6 m long segment, volume flow 25 l/min.

The measurement data gained are currently being used to validate the numerical model developed.

5 THERMAL NETWORK

Since the concept of the hybrid sewer cannot fulfill the entire thermal demand of an urban district with a high population density, additionaly renewable energy sources are required to achieve self-sufficient heat management. These additional energy sources, as along with the exchange of surplus energy, must be facilitated by an interconnected network.

The developed concept aims to achieve equilibrium between thermal demands and surpluses at the district level, obviating the need for additional energy

generation. To accomplish this, the transport network must be capable of bidirectional operation, meaning it must be able to both absorb and release heat. Heat networks with these characteristics are termed as “5th generation heat networks” (Wirtz, 2022). Within the developed transport network, a three-pipe system is implemented for this purpose, comprising of one supply pipe each for "heat" and "cold" along with a common return pipe. The hybrid sewer serves as the fundamental component of the integrated thermal network. The concept of the heat network is further elaborated in Kugler et al, (2022).

6 CONCLUSION

The hybrid sewer can extract thermal energy from both the ground and the waste water. The waste water leads to continuous thermal regeneration of the surrounding soil due to its continuous outflow.

The thermal conductivity of the hybrid channel was determined through numerical analyses. To validate the numerical model, a real hybrid sewer and a real-scale test-setup were equipped with measurement devices. The numerical model, validated by back analysis of the measurement results, is subsequently utilized to develop a design aid that enables rapid pre-dimensioning.

The results obtained thus far demonstrate that the heat extraction capacity is significantly higher compared to conventional thermally activated foundations.

ACKNOWLEDGEMENT

The IWAES research project is funded by the German Federal Ministry of Education and Research (BMBF) as a part of the research program RES:Z under grant number 033W106A. Their support is gratefully acknowledged.

Accelerated stabilization of municipal solid waste in bioreactor landfills

Stabilisation accélérée des déchets solides municipaux dans les décharges de bioréacteurs

ABSTRACT: In recent years, bioreactor landfills, which involve leachate recirculation/injection operations to enhance the moisture levels within the municipal solid waste (MSW) landfills and facilitate rapid waste decomposition and early waste stabilization have emerged as a promising MSW management option. However, unlike conventional landfills, there is a lack of well-established procedures/methods for an effective design and operation of such landfills primarily due to a limited understanding of the physical, chemical and biological processes and their coupled interactions that influence the MSW behaviour in landfills. Several researchers have developed numerical models to simulate MSW behaviour in landfills but only a few models have comprehensively considered the simultaneous interactions of hydraulic, mechanical, biochemical, and thermal processes within the waste in their numerical models. In this study, a brief overview of the past studies at University of Illinois Chicago (UIC) including laboratory, field, and numerical investigations regarding MSW behaviour in bioreactor landfills is presented. Further, a numerical modelling framework newly developed at UIC that incorporates the coupled thermo-hydro-bio-mechanical processes in MSW landfills is briefly discussed. Finally, the predictive capabilities of the developed coupled numerical model in demonstrating the accelerated stabilization of MSW and associated long-term performance of bioreactor landfills are highlighted.

RÉSUMÉ: Ces dernières années, les décharges de bioréacteurs, qui impliquent des opérations de recirculation/injection des lixiviats pour augmenter les niveaux d'humidité dans les décharges de déchets solides municipaux (MSW) et faciliter la décomposition rapide des déchets et la stabilisation précoce des déchets, sont apparues comme une option prometteuse de gestion des DSM. Cependant, contrairement aux décharges conventionnelles, il existe un manque de procédures/méthodes bien établies pour une conception et une exploitation efficaces de telles décharges, principalement en raison d'une compréhension limitée des processus physiques, chimiques et biologiques et de leurs interactions couplées qui influencent le comportement des DSM dans les décharges conventionnelles. décharges. Plusieurs chercheurs ont développé des modèles numériques pour simuler le comportement des DSM dans les décharges, mais seuls quelques modèles ont pris en compte de manière exhaustive les interactions simultanées des processus hydrauliques, mécaniques, biochimiques et thermiques au sein des déchets dans leurs modèles numériques. Dans cette étude, un bref aperçu des études antérieures menées à l'Université de l'Illinois à Chicago (UIC), y compris des enquêtes en laboratoire, sur le terrain et numériques concernant le comportement des DSM dans les décharges de bioréacteurs, est présenté. En outre, un nouveau cadre de modélisation numérique intégrant des processus couplés thermo-hydro-bio-mécaniques développés à l'UIC est présenté. Enfin, les capacités prédictives du modèle numérique couplé développé pour décrire la stabilisation accélérée des DSM dans les décharges ont été mises en évidence.

Keywords: Municipal solid waste; bioreactor landfills; leachate recirculation; coupled processes.

1 INTRODUCTION

Bioreactor landfills are emerging as a promising alternative to conventional MSW landfills due to enhanced waste decomposition rates facilitating early waste stabilization and numerous other short-term and long-term benefits (e.g., enhanced methane gas production rates, reduced leachate treatment and disposal costs, reduced post-closure monitoring costs). However, unlike the conventional landfills, the procedures/methods for the design, construction, and effective operation of bioreactor landfills are not well-established in that there needs be careful consideration towards the flow and distribution of the injected leachate within the landfill, the liquid and gas

pressures developed and their influence of the structural stability of the landfill slopes, the heat generation and temperature distribution within the landfill, and the differential settlement of waste and its influence on the integrity of the landfill components, among others (Reddy, 2006). The holistic behaviour of the abovementioned aspects of bioreactor landfills on their long-term performance is not well-understood primarily due to an incomplete understanding of the fundamental coupled processes that dictate the MSW behaviour. In this regard, several researchers have performed large-scale laboratory experiments, pilot-scale experiments, full-scale field investigations, and numerical modelling studies to develop a greater understanding of the different landfill processes and their interactions on the MSW behaviour in bioreactor landfill conditions. A comprehensive review of the previous investigations by other researchers on various aspects of landfill processes is summarized in Reddy et al. (2017) and Kumar and Reddy (2019).

In this paper, an overview of the previous work involving field-scale investigations, lab-scale experiments, and development of numerical model performed at UIC, which formed the basis of a more comprehensive coupled thermo-hydro-bio-mechanical model (CTHBM) presented in this paper, is reviewed and summarized. Additionally, the application of the developed model to demonstrate the accelerated stabilization of MSW in bioreactor landfills as compared to conventional landfills and the representative results from those analyses are discussed. Finally, the ongoing research in the development of the CTHBM model are highlighted.

2 PREVIOUS INVESTIGATIONS AT UIC

2.1 Field-scale investigations

Extensive field investigations were performed at Orchard Hills (OH) landfill located in Davis Junction, Illinois, USA where leachate recirculation was carried out in one of the landfill cells. The various field investigations performed included but not limited to:

- Monitoring of leachate recirculation and in situ moisture conditions using a comprehensive electrical resistivity tomography to non-invasively assess the zone of influence by the leachate recirculation systems (LRS) implemented (Grellier et al. 2007b).
- Optimization of leachate recirculation and moisture distribution at the OH landfill by interior imaging of the landfill using electromagnetic conductivity and ground penetrating radar (Carpenter et al. 2008).
- Seismic imaging using P-waves and S-waves through the landfilled waste to identify spatial and temporal changes and to evaluate the effects of leachate recirculation and degradation on the dynamic properties of MSW (Carpenter et al. 2013).
- Extensive sampling of both fresh waste from working face of the landfill and landfilled waste at different waste depths (Grellier et al. 2007a). The field waste samples collected from the OH landfill were sorted to identify the waste fractions and for waste characterization and further investigated in the laboratory as discussed in the section below.

2.2 Laboratory-scale investigations

Fresh waste samples, the landfilled waste samples, and the leachate samples collected from the OH landfill were transported to laboratory for additional comprehensive geotechnical testing to determine the engineering properties of MSW. These laboratory investigations (Grellier et al. 2007a, Reddy et al., 2009a-d) included but not limited to:

- Determining engineering properties such as particle size distribution, moisture content, organic content, specific gravity, hydraulic conductivity, compressibility, shear strength parameters, and biochemical properties such as the biochemical methane potential (BMP) of the waste.
- Long-term anaerobic bioreactor column tests on representative bulk samples of fresh waste and landfilled waste subjected to leachate recirculation. Waste samples were exhumed from the anaerobic bioreactors at different stages of degradation, based on gas composition and gas volumes, and tested for engineering properties.
- Analysis of moisture content, organic content, and BMP of the landfilled waste at different distances form the LRS to assess the effectiveness of LRS in moisture distribution at the OH landfill.
- Laboratory testing was performed on synthetic MSW (SMSW) simulating typical fresh waste composition of MSW generated in the United States to systematically evaluate the reproducibility of the test results for identical SMSW composition. Statistical analyses of the test results were performed to validate the laboratory test results.

2.3 Numerical modelling

With a better understanding on the engineering properties of waste developed from the abovementioned comprehensive field and laboratory investigation, numerical modeling efforts were carried out to further understand the complex coupled behaviour of MSW on the performance of bioreactor landfills. The intent of the modelling efforts was to develop guidance and/or recommendations that can be used by landfill owners and operators to designing safe and effectively operating bioreactor landfills in practice. These modelling efforts are summarized in Kumar (2021) and include but not limited to:

- Modelling of the mechanical behaviour of MSW for the prediction of long-term settlement of waste in MSW landfills, using a new constitutive model developed based on the concept of critical state soil mechanics (Babu et al. 2010).
- Hydraulic modelling of bioreactor landfills to evaluate the effectiveness of different LRS in enhancing the moisture distribution in bioreactor landfills (Reddy et al. 2020).
- Coupled hydro-mechanical (CHM) modelling to evaluate the stability of landfill slopes under different MSW slope and leachate injection configurations (Reddy et al., 2015). Coupled hydro-bio-mechanical (CHBM) modelling of bioreactor landfills by incorporating the effects of biodegradation on the engineering properties of MSW (Reddy et al. 2018).
- Incorporating the effects of temperature on the biodegradation rates of MSW to evaluate long-term performance of MSW landfills (Kumar et al. 2021).

3 COUPLED THERMO-HYDRO-BIO-MECHANICAL (CTHBM) MODEL

Although the previous numerical modelling efforts at UIC progressively advanced the comprehensiveness of the numerical model to simulate MSW behaviour landfills, there were several important limitations in the developed CHBM model, and the numerical models developed by other researchers (Reddy et al. 2017) including but not limited to the following:

- Ignoring the effects of coupled fluid-mechanical interactions and the interdependencies of biochemical and thermal processes
- Ignoring the effects of creep behaviour and if considered using a highly empirical approach to simulate the phenomenon
- Incorporating the effects of biodegradation on waste settlement using an empirical approach instead of a fundamental constitutive approach.
- Ignoring the large-strain kinematics.
- Inability of the models to assess broader performance aspects of MSW landfill systems (e.g., slope stability, liner/cover stability and integrity).

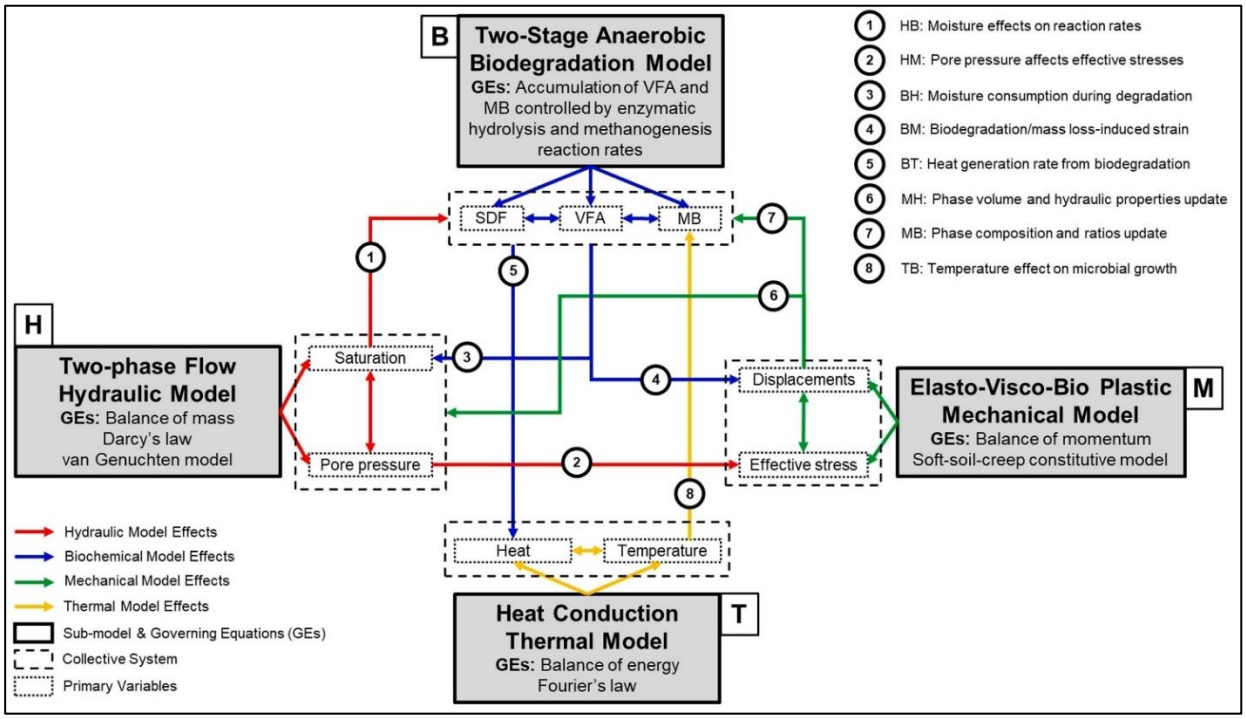

Figure 1. Conceptual CTHBM model.

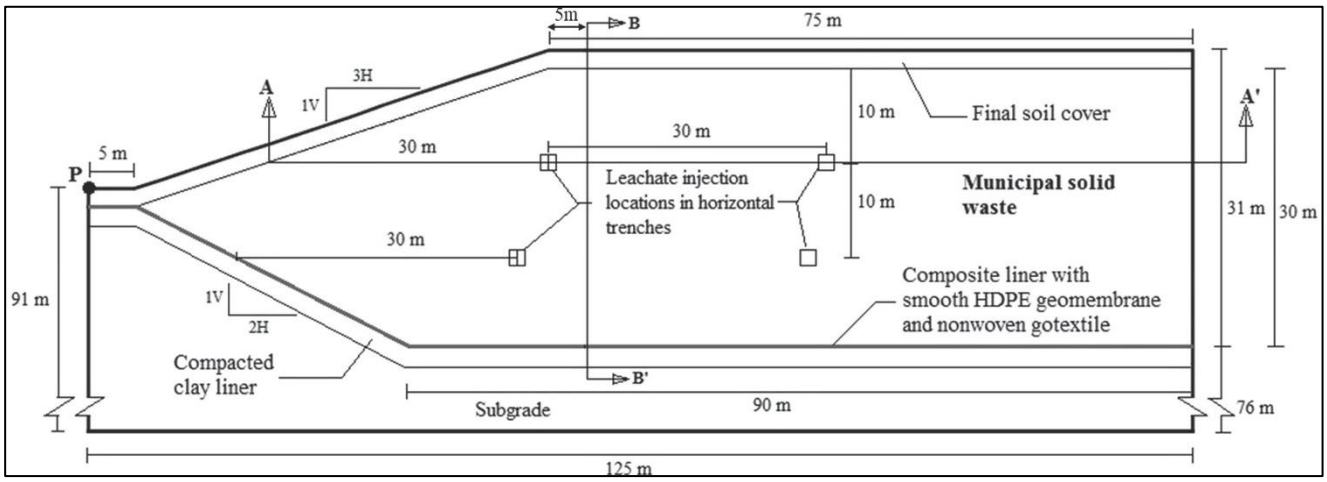

Figure 2. Schematic of landfill cell configuration.

Incorporating the abovementioned limitations, a new CTHBM model is developed to realistically simulate the coupled thermo-hydro-bio-mechanical processes in MSW landfills and thereby evaluate the holistic short-term and long-term performance of MSW landfills under conventional and bioreactor conditions. The CTHBM model is implemented in Fast Lagrangian Analysis of Continuum (FLAC), a finite difference code. A schematic of the CTHBM conceptual model mentioning the governing equations used for each of the landfill processes and the interdependencies incorporated within the CTHBM model is presented in Figure 1 below. For brevity, detailed description of the CTHBM model components and its implementation algorithm in FLAC is not presented in Kumar and Reddy (2021).

4 ACCELERATED STABILIZATION OF MSW IN BIOREACTOR LANDFILLS

To demonstrate the applicability of the CTHBM model for assessing long-term performance of MSW landfills under conventional and bioreactor conditions, a deterministic analysis was performed by running two simulations of a full-scale realistic landfill cell configuration as shown in Figure 2.

The two numerical simulations performed (i.e., one for conventional landfill conditions and another for bioreactor landfill conditions) included same landfill construction sequence, same material models and properties for soil and MSW, same boundary, initial, and interior conditions, with the only difference between the two simulations being the simulation of leachate (for simplicity assumed to be water) injection through horizontal trenches (HTs) at an injection pressure of 50 kilo pascal (kPa) in the bioreactor simulation. The simulation process, material and numerical parameters/properties, boundary, initial, and interior conditions for the two simulations are described in detail in Kumar and Reddy (2021).

Figure 3 below presents the comparison of certain long-term hydraulic, mechanical, biochemical, and thermal characteristics between the conventional and bioreactor simulations.

Figure 3(a) depicts that the model can enable landfill designers to evaluate different leachate injection configurations including different leachate recirculation/injection systems to evaluate the anticipated pore pressures near side slopes and thereby develop design guidance for safe injection pressures and spacing for effective distribution of moisture. Figures 3(b) and 3(c) demonstrate that the model can be used to realistically simulate and predict the spatial and temporal variation in the anticipated surface settlement and methane (CH_4) gas generation, which in-turn demonstrates the accelerated stabilization of MSW in landfills, thus assisting landfill operators to effectively plan bioreactor landfill operations, waste capacity, and maintaining the integrity of the landfill components (final cover). Figure 3(d) demonstrates that enhanced degradation rates through leachate injection can accelerate anaerobic heat generation leading to relatively higher temperatures than conventional landfills with similar waste conditions. Detailed description of the comparison of short-term and long-term performance characteristics along with a discussion on their influence on the stability/integrity of landfill liner and cover components derived from the two conventional and bioreactor landfill simulations are discussed in Kumar and Reddy (2021). However, the results presented in this study clearly indicates that leachate recirculation into landfills indeed enhances the waste stabilization rates in bioreactor landfills.

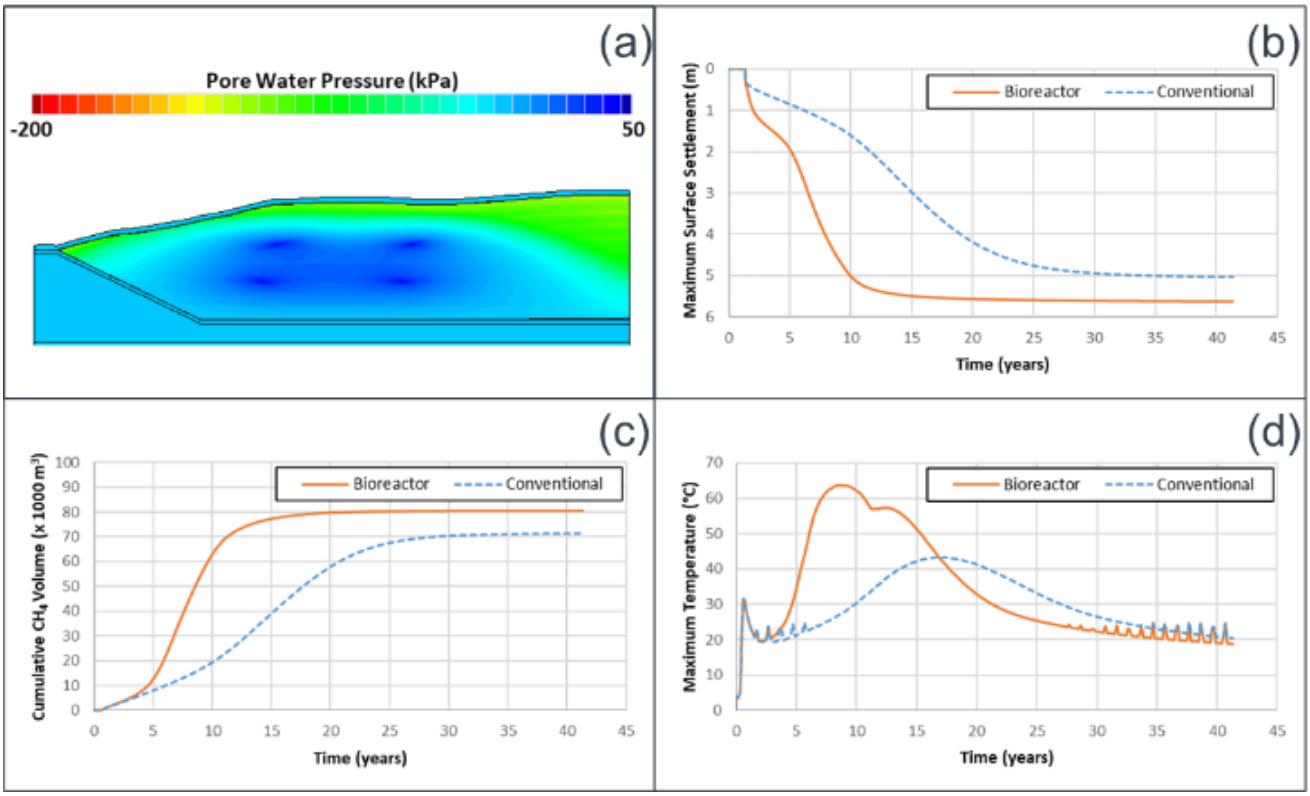

Figure 3. (a) Pore water pressure distribution in bioreactor landfill at the end of 40 years, and (b) maximum surface settlement, (c) cumulative CH_4 gas generation, and (d) maximum waste temperatures, with time.

5 CONCLUSIONS AND ONGOING RESEARCH

The newly developed CTHBM model has been successfully validated and demonstrates it's ability to accurately and realistically simulate the observed trends in the hydraulic (leachate distribution), mechanical (waste settlement), biochemical (gas generation), and thermal (temeprature distribution) characteristics observed in laboratory experiments and full-scale landfill cell under conventional and bioreactor conditions. Additionally, the CTHBM model can be used to perform parametric analyses on different landfill configurations to develop design recommendations for effective deisgn and operation of bioreactor landfills. Finally, the CTHBM model can be used to perform probabilistic analysis by considering spatial variability in the MSW properties acorss landfills and assist with creating realistic bounds for the predicted long-term characteristics of bioreactor landfills.

Continued research is ongoing at UIC to futher develop the CTHBM model by incorporating other importat processes such as convective heat transport, leachate characteristics, alternative heat generation mechanisms, liner interface shear behavior, among others.

Basic characteristics of environment-friendly soil-cement material with added biochar

Caractéristiques de base d'un matériau sol-ciment écologique avec biochar ajouté

Y. Kurimoto*, Y. Asaka
Institute of Technology/Shimizu Corporation/Tokyo, Japan
**yuhei.kurimoto@shimz.co.jp*

ABSTRACT: This paper describes research in which carbon-rich biochar is added to a soil-cement slurry in the laboratory with the purpose of offsetting the carbon emissions of the stabilizer used in cement-treated soil. The effect of the biochar on strength development and resistance to material separation is investigated. Blast furnace cement type B is used as the stabilizer, which is added to solidify the soil. Specimens with five different ratios of stabilizer relative to the volume of the soil-water mixture are tested (40, 80, 120, 150 and 300 kg/m^3) and different proportions of biochar are added to offset and more than offset the CO_2 emissions of the stabilizer. The assumed CO_2 sequestration resulting from biochar addition is 2.51 kg-CO_2/kg, based on methodologies used for the addition of biochar to mineral soil in cropland/grassland. The unconfined compression strength of the soil-cement with biochar after curing for 28 days tends to be higher than that of the material without biochar, except for the 40 kg/m^3 cases. The maximum ratio of increase in unconfined compression strength is 1.04, 1.43, 1.37, 1.36 and 1.16 for the 40 to 300 kg/m^3 cases. The material segregation resistance of the soil-cement is also improved when the amount of biochar added exceeds 30 kg/m^3, regardless of the amount of stabilizer added.

RÉSUMÉ: Cet article décrit des recherches dans lesquelles du biochar riche en carbone est ajouté à une boue sol-ciment en laboratoire dans le but de compenser les émissions carbone du stabilisateur utilisé dans le sol traité au ciment. L'effet du biochar sur le développement de la résistance mécanique et sur la résistance à la séparation des matériaux est étudié. Du ciment de haut fourneau de type B est utilisé comme stabilisateur, qui est ajouté pour solidifier le sol. Des échantillons avec cinq ratios différents de stabilisateur par rapport au volume du mélange sol-eau sont testés (40, 80, 120, 150 et 300 kg/m^3) et différentes proportions de biochar sont ajoutées afin de compenser et faire plus que compenser les émissions de CO_2 du stabilisateur. La séquestration de CO_2 supposée résultant de l'ajout de biochar est de 2,51 kg-CO_2/kg, sur la base des méthodologies utilisées pour l'ajout de biochar à un sol minéral dans des terres cultivées/prairies. La résistance à la compression monoaxiale du sol-ciment avec biochar après 28 jours de durcissement tend à être supérieure à celle d'un matériau sans biochar, à l'exception des cas à 40 kg/m^3. Le ratio d'augmentation maximum de la résistance à la compression monoaxiale est de 1,04, 1,43, 1,37, 1,36 et 1,16 pour les cas allant de 40 à 300 kg/m^3. La résistance à la ségrégation des matériaux du sol-ciment est également améliorée lorsque la quantité de biochar ajoutée dépasse 30 kg/m^3, indépendamment de la quantité de stabilisateur ajoutée.

Keywords: Carbon sequestration; biochar; cement-treated soil; unconfined compression strength; bleeding.

1 INTRODUCTION

The building and construction industry accounts for around 37% of global energy usage and process-related CO_2 emissions (UNEP, 2022). Emissions from the manufacture of concrete, aluminium and steel used in the construction of buildings are estimated to represent around 2.3 Gt-CO_2 globally. Other materials used in the construction of buildings, such as bricks and glass, are estimated to account for a further 1.2 Gt-CO_2 of emissions globally. NILIM (2008) reported that CO_2 emissions associated with construction (embodied carbon) and demolition account for approximately 30% of the life cycle CO_2 emissions of a building. Meanwhile, research and development related to carbon capture and storage (CCS) and carbon capture, utilization and storage (CCUS) is being pursued in the field of geotechnical engineering. Furthermore, both artificial and natural low-carbon building materials, such as recycled concrete fines and bio-improved soils, are being investigated. The use of wood in construction projects is also being actively promoted (e.g., Kuittinen, 2013) to increase carbon accumulation and mitigate climate change. Moreover, carbon-rich materials, such as wood and biochar, have attracted attention in recent years not only in the agriculture field but also among geotechnical engineers. Biochar is a solid material

generated by heating biomass to a temperature in excess of 350°C under conditions of controlled and limited oxidant concentration to prevent combustion. Senadheera (2023) summarized comprehensively the physicochemical properties of biochar when added to cementitious materials, considering both the environmental and economic impact.

In this paper, the effect of adding biochar to soil-cement used as a material for backfilling, earth retaining and ground improvement is studied through laboratory tests.

2 TEST OVERVIEW

2.1 Materials

A soil-water mixture consisting of silica sand in air-dried condition, a 1:1 mix of Kibushi clay and Kaolin clay by mass, and water with a mass ratio of 4:1:2.15 was used as the original mud. Blast furnace cement type B (symbol: BB) complying with the Japan Industrial Standard (JIS R 5211, 2019) was used as the stabilizer; its characteristics are density 3.04 g/cm^3, specific surface area 3950 cm^2/g, ignition loss 1.39%, SO_3 2.14%, and addition ratio of blast furnace slag 40%. The cement used was of the type generally distributed in Japan with ingredients stipulated by JIS, bearing in mind that cement ingredients differ among countries.

Biochar was used as an admixture to improve the segregation resistance of the soil-cement material. It was manufactured by Nara Tanka Industries Co., Ltd. and had been sieved to a grain size of 5 mm or less. The original feedstock for this biochar is sawdust produced while cutting coniferous and broad-leaved trees. The sawdust is compression-molded into briquettes, then carbonized, pulverized, and sieved for use as biochar. Biochar can be highly porous depending on the original feedstock and pyrolysis conditions, and the specific surface area differs by three orders compared to the stabilizer. The water absorption of the biochar is 21-25%. Other basic physical properties of the biochar are available in Kurimoto (2023).

2.2 Mix proportions

Five amounts of stabilizer (40, 80, 120, 150 and 300 kg/m^3) were used relative to the volume of the soil-water mixture. The target water content of both the soil-water mixture and the soil-cement was 43%. The target unconfined compression strength of the soil-cement was set to 100-3000 kPa.

Based on the CO_2 emissions inventory data of the stabilizer (MLIT, 2017), the amount of biochar used was adjusted to offset the CO_2 emissions of the stabilize or more than offset them. Note that the amount of CO_2 sequestration by the biochar was assumed to be the ratio of organic carbon content for this type of biochar (0.77) × fraction of biochar carbon remaining after 100 years (0.89) × relative molecular mass ratio of carbon dioxide to carbon (44/12) = 2.51 kg-CO_2/kg, based on methodologies used in regard to biochar addition to mineral soil in cropland/grassland (J-Credit Scheme, 2023). Biochar was added as a material percentage at the beginning of mixing. In this experiment, CO_2 emissions related to the manufacture and transport of the biochar were not considered.

2.3 Mixing and testing

The soil-cement material was prepared by kneading for three minutes in a small mixer. Details of the process are given in Kurimoto (2023). Immediately after kneading, the temperature, density, flow, and bleeding characteristics of the soil-cement in a slurry state were measured. Test specimens were prepared with a size of 50 mm in diameter and 100 mm in height and these were demolded at the age of 28 days. The specimens were then tested for shear wave velocity and unconfined compression. Sher wave velocity was measured by bender element test. Shear wave velocity and unconfined compression strength results are the averages of three test specimens.

3 EXPERIMENTAL RESULTS

Table 1 shows the physical properties and unconfined compression strength of the soil-cement specimens. Test IDs consist of "type of stabilizer - amount of stabilizer added - ratio of CO_2 fixation in biochar to CO_2 emissions of stabilizer." For example, "BB-80-1" represents the case in which the stabilizer is blast furnace cement type B, the amount of stabilizer added is 80 kg/m^3, and biochar is added to exactly offset the CO_2 emissions of the stabilizer. Figures 1 to 4 show the results for all test specimens. The vertical axes in Figure 1 and Figure 2 are normalized by the value for the soil-cement without biochar in each case.

Table 1 and Figure 1 show that, although there is no effect of adding biochar on the density of the soil-cement after kneading, the flow and bleeding tend to decrease as the amount of biochar increases, except for BB-40-0 to BB-40-3. In other words, the material segregation resistance of the soil-cement is improved when the amount of biochar added exceeds 30 kg/m^3, regardless of the amount of stabilizer added.

Table 1 and Figure 2 demonstrate that the unconfined compression strength of the soil-cement without biochar in five cases is 169-2695 kPa, which satisfies the target strength. By contrast, the unconfined compression strength of the soil-cement with biochar is

Table 1. Physical properties and unconfined compression strength of the soil-cement material.

Test ID	Biochar (kg/m^3)	CO_2 emissions of stabilizer (kg/m^3)	CO_2 fixation in biochar (kg/m^3)	Density (g/cm^3)	Flow (mm)	Bleeding (%)	Unconfined compression strength (kPa)

BB-300-3.5	209	150	525	1.75	171	0.00	3015
BB-300-4	239	150	600	1.77	156	0.00	3126

slightly higher, except for BB-40. The maximum ratio of unconfined compression strength increase in each case is 1.04 for BB-40, 1.43 for BB-80, 1.37 for BB-120, 1.36 for BB-150 and 1.16 for BB-300. This slight increase in strength is because the highly porous biochar absorbs water over time, thereby reducing the water-cement ratio of the soil-cement (Kurimoto, 2023). On the other hand, the water-cement ratio of the soil-cement in BB-40 is larger than in the other cases; consequently, the water absorption of biochar has little effect on strength of the soil-cement. Figure 3 shows that when the unconfined compression strength of the soil-cement is in range of 141-3127 kPa, the corresponding deformation modulus is in the range 26-712 MPa. The ratio of the deformation modulus E_{50} and the unconfined compression strength q_u is in the range 180-260. The unconfined compression strength exhibits a unique relationship with shear wave velocity

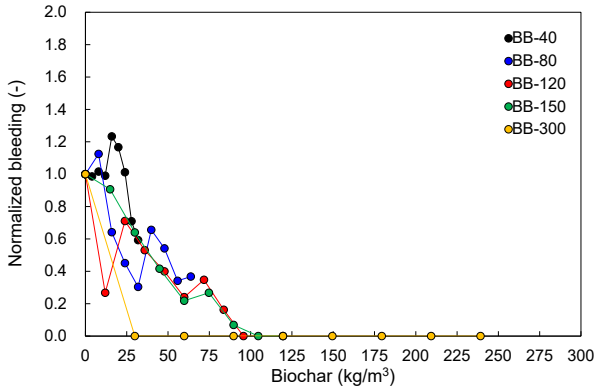

Figure 1. Normalized bleeding results.

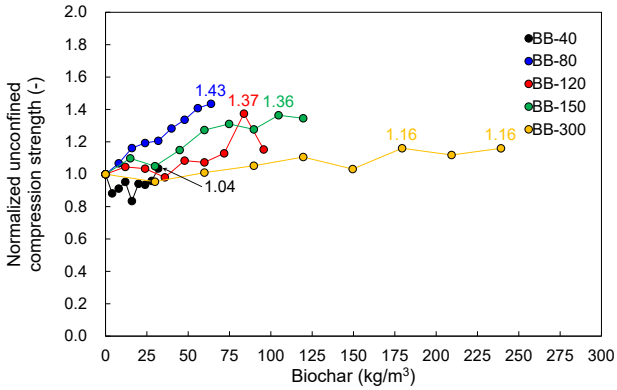

Figure 2. Normalized unconfined compression strength results.

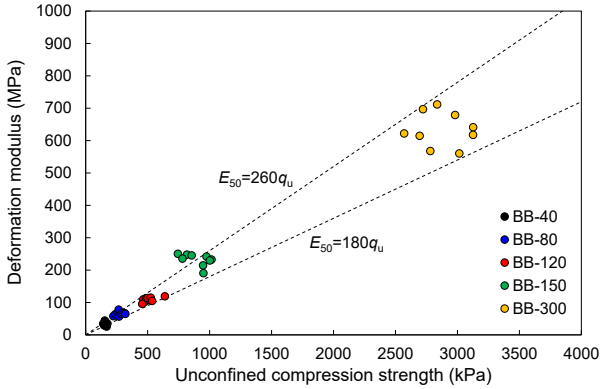

Figure 3. Relationship between deformation modulus and unconfined compression strength.

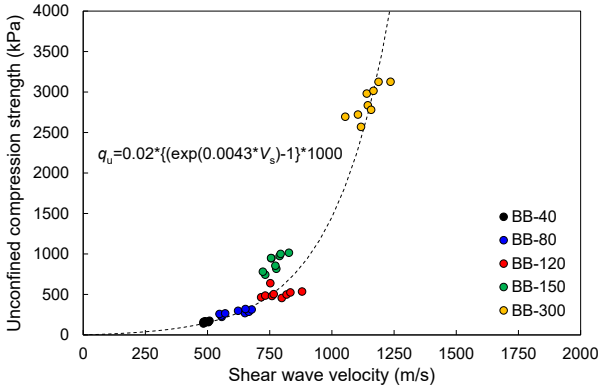

Figure 4. Relationship between unconfined compression strength and shear wave velocity.

regardless of the presence or absence of biochar and can be expressed as an exponential of the shear wave velocity, as shown in Figure 4. This relation is very similar to a description by Asaka (2011).

4 CONCLUSIONS

Biochar was used as an admixture to sequester the CO_2 in the soil-cement, and its effect on the physical and mechanical properties of the soil-cement was evaluated by laboratory tests.

As a result of adding biochar to reduce the emissions resulting from the soil-cement stabilizer, the unconfined compression strength of the material increased with the amount of stabilizer (80, 120, 150 and 300 kg/m^3) while material segregation resistance improved when the amount of biochar added exceeded 30 kg/m^3. Additionally, it was found that the relationship between the unconfined compression strength, deformation modulus and shear wave velocity was not affected by the addition of biochar.

ABSTRACT: This paper presents some initial results of an experimental campaign aimed at extending the existing database of pile lateral field tests. Monopiles with low slenderness ratios (L/D, ratio of pile embedment to pile diameter) less than 4.5 are deemed to be representative of current and future monopile foundation designs for the offshore wind industry. The monopile field testing consisted of both monotonic and cyclic tests with slenderness ranging from 2.2 to 4.4. A total of 6 piles with an outer diameter of 457 mm were driven and tested in dense sand at the Blessington test site, located south to Dublin in Ireland. Three different approaches were used to predict the monotonic pile responses. Traditional approaches (API and PISA rule) were found to significantly underestimate both piles stiffness and ultimate capacity. A novel set of CPT based correlations of HS-small parameters for three-dimensional finite-element analyses recently developed by Trinity College Dublin was found to provide very accurate predictions of both stiffness and ultimate reaction.

RÉSUMÉ: Cet article présente les premiers résultats d'une campagne expérimentale visant à étendre la base de données existante d'essais in-situ de pieux chargés latéralement. Des rapports d'élancement (L/D, rapport entre la profondeur et le diamètre du pieu) plus faibles sont plus représentatifs des dimensions des fondations monopieux supportant actuellement les éoliennes en mer. Des pieux avec des rapports d'élancement allant de 2.2 à 4.4 ont été testés sous charges monotoniques et cycliques. Au total, 6 pieux d'un diamètre extérieur de 457 mm ont été battues et testés dans du sable dense sur le site d'essai de Blessington, situé au sud de Dublin en Irlande. Trois approches différentes ont été utilisées pour prédire la réponse des pieux sous chargement monotone. Les approches traditionnelles (API et PISA rule) ont sous-estimé de manière significative la rigidité et la capacité ultime des pieux. Trinity College Dublin a récemment développé un jeu de corrélations basées sur le CPT pour les paramètres du model de sol constitutif HS-small, populaire pour les analyses éléments finis 3D. Cette approche s'est avérée fournir des prédictions très précises de la rigidité et de la réaction ultime des pieux.

Keywords: Offshore wind; geotechnical engineering; monopiles; field tests.

1 INTRODUCTION

This paper outlines the preliminary findings from an experimental initiative aimed at expanding the current repository of lateral field tests for low L/D monopiles. Monopiles are large diameter open ended steel pipe piles which are typically impact driven into the seabed and are the most commonly used foundation for offshore wind turbines. As the offshore wind industry matures, larger wind turbines are being designed which require monopiles with diameters in excess of 10 m. These XL monopiles typically have slenderness ratios (L/D, where L is the embedded length and D the diameter) less than 4.5. In this paper, the results from one of the monotonic field test piles with L/D=3.3 is compared to three different approaches for predicting the lateral responses of the piles. The paper shows that current rule-based beam-spring approaches such as API (2011) and PISA-rule based method (Burd et al. 2020) both significantly underestimate the stiffness and ultimate capacity of these small scale piles. In contrast, a 3D Finite Element approach developed at Trinity College Dublin, using CPT-based correlations, provides highly accurate predictions for the entire load-displacement response.

2 METHODOLOGIES

This section presents 3 different approaches to predict the response of piles subjected to monotonic lateral loading in sands.

2.1 API

The traditional industry practice used to follow the oil and gas industry design standard (API, 2014). The 'p-y approach' involves modelling the pile by means of one-dimensional elastic beam elements. At each depth, a 'p-y curve' defines the non-linear relationship between the soil resistance, p, mobilised as a result of the pile lateral displacement, y. The soil layers are assumed to behave independently, therefore the curves are uncoupled. API RP 2GEO (API, 2014) provides basis for the formulation of the non-linear p-y curves in sands, soft clays and stiff clays. In sands, it takes the form of a hyperbolic tangent as shown by equation (1):

$$p = Ap_u \tanh\left(\frac{kz}{Ap_u} y\right) \quad (1)$$

where:

- $A = \left(3 - 0.8\frac{z}{D}\right) \geq 0.9$ for monotonic loading.
- p_u is the ultimate lateral resistance at depth z.
- k is the rate of increase with depth of initial modulus of subgrade reaction at depth z.
- y is the lateral pile deflection at depth z.
- z is the depth below ground level.

The interested reader is invited to refer to API (2014) section 8.5.6 for additional information, including basis for calculation of p_u and k.

2.2 PISA rule

The PISA design model (Burd et al., 2020) represents the state-of-the-art design methodology for monopiles and is now used globally in the industry. Like API, the PISA approach rely on one-dimensional finite-element analyses. However, PISA considers three other soil reaction components in addition to the distributed lateral load: the distributed moment, the base shear and the base moment (see Figure 1). The soil reaction curves can be constructed from a set of equations referred to as 'depth variation functions' (DVFs). The DVFs provide basis to generate nornalised soil reaction curves. The soil inputs required to un-normalised the curves in sand are the soil realtive density, small strain shear modulus, and unit weight. Following the PISA rule-based approach, the DVFs from the Generalised Dunkirk Sand Model (GDSM) developed by Burd et al. (2020) is considered in this study.

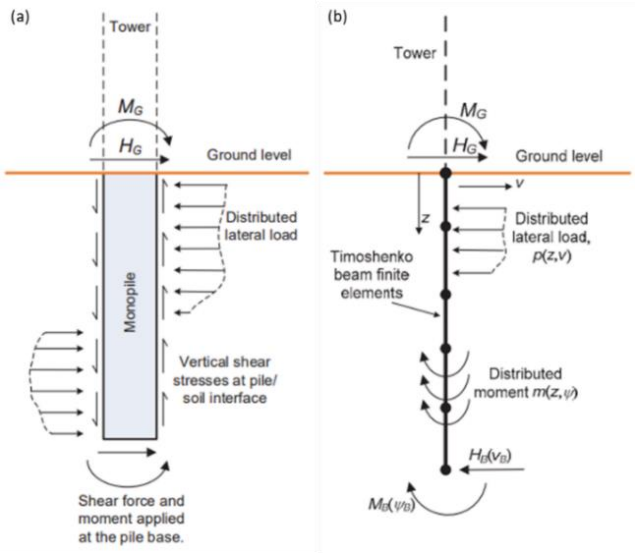

Figure 1. PISA design model: (a) soil reaction components acting on the pile; (b) implementation in 1D FE (after Burd et al., 2019).

2.3 3D FEA

With the development of computational power, it is now standard practice to use three-dimensional finite element analyses for monopile design.

In this study, the piles were modelled at full scale and half-space in Plaxis 3D. The pile structure is modelled using linear-elastic isotropic plate elements with standard steel properties (Young's modulus of 210 GPa and Poisson's ratio of 0.3). The pile is weightless since the focus is on lateral loading. Interfaces at the outside and inside of the pile capture the soil-structure interactions.

The sand is modelled with the Hardening soil model with small strain stiffness (HS-small) assuming drained conditions. All the inputs required for the constitutive models were calibrated from site specific CPTs following the approach recently developed in Trinity College Dublin and presented in Igoe and Jalilvand (2020). The approach has already been validated against a large database of lateral pile field tests, including the PISA test in Dunkirk.

3 EXPERIMENTAL CAMPAIGN

The test site is located in Blessington, in an active quarry approximately 25 km south-west of Dublin, Ireland. Prior to pile installation, cone penetration testing (CPT) was undertaken at each desired pile location. Relevant CPT profiles are plotted on Figure 2 demonstrating minimum vertical or lateral soil variability. The site comprises of homogenous dense sand deposits.

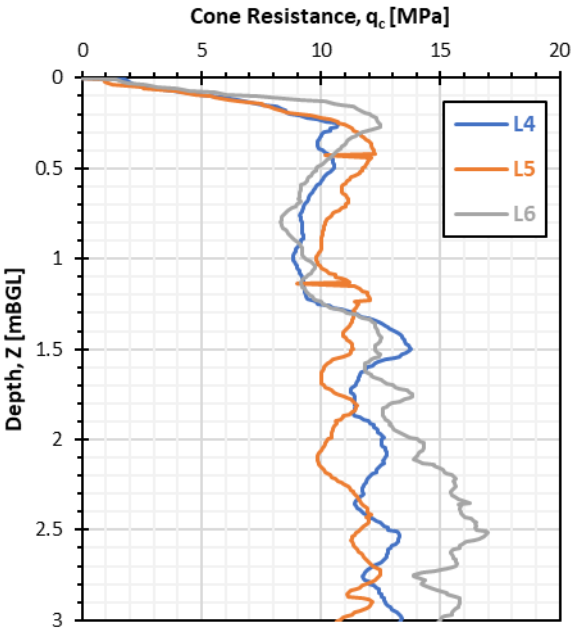

Figure 2. CPT profiles in terms of cone tip resistance (after Lapastoure and Igoe, 2024).

A total of 6 piles with an outer diameter (D) of 457 mm were driven at CPT locations. Pile embedded lengths (L) are ranging from 1 m to 2 m (L/D ranging from 2.2 to 4.4). The piles were installed in a 3x2 grid with the longer piles installed at the centre as shown on Figure 3. The longer piles were used as reaction piles to test the shorter piles. A stick-up length of 1.5 m was left out to ensure the lateral load could be applied with sufficient eccentricity to be representative of offshore conditions. The loads were applied at an eccentricity of 1.37 m (about 3*D).

During each test, both piles were instrumented with inclinometers and linear variable differential transducer at ground level. The lateral load was applied with a hydraulic jack and measured with a tension load cell. The experimental campaign consisted of 5 field tests:

- Test 1: Monotonic test between L6 (L/D=2.2) and L5 (L/D=4.4).
- Test 2: Monotonic test between L4 (L/D=3.3) and L5 (L/D=4.4).
- Test 3: Cyclic test (4000 cycles in total) followed by monotonic push over between L3 (L/D=3.3) and L2 (L/D=4.4).
- Test 4: Cyclic test (3670 cycles in total) followed by monotonic push over between L1 (L/D=2.2) and L2 (L/D=4.4).
- Test 5: Cyclic test (3160 cycles in total) between L2 (L/D=4.4) and L5 (L/D=4.4).

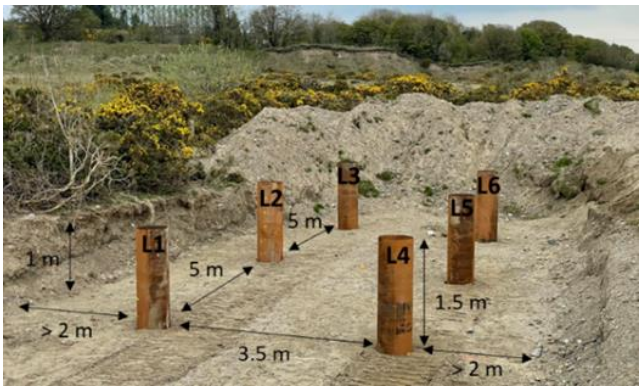

Figure 3. Piles arrangement (after Lapastoure and Igoe, 2024).

Only the results of the monotonic tests are considered for this study (Test 1 and Test 2). The interested reader is invited to refer to Lapastoure and Igoe (2024) for more information.

4 PRELIMINARY RESULTS

Figure 4 presents a comparison of experimental and predicted load-displacement response at ground level for pile L4 (L/D=3.3). For consistency, all three approaches (API, PISA rule and 3D FEA) are based on the soil parameters correlated from the CPT based approach presented in section 2.3 (all parameters provided in Igoe & Lapastoure, 2024). The predictions based on the API and PISA rule approaches are found much softer than the actual pile response. The 3D FEA approach is found to provide a very good prediction.

Figure 4 presents a comparison of experimental and predicted load-displacement response at ground level for pile L4 (L/D=3.3). For consistency, all three approaches (API, PISA rule and 3D FEA) are based on the soil parameters correlated from the CPT based approach presented in section 2.3 (all parameters provided in Igoe & Lapastoure, 2024). The predictions based on the API and PISA rule approaches are found much softer than the actual pile response. The 3D FEA approach is found to provide a very good prediction.

Table 1 compares the blind predicitons to the experimental response for piles L4 (L/D=3.3), L5 (L/D=4.4) and L6 (L/D=2.2) in terms of initial stiffness and ultimate reaction. The initial stiffness is defined as the secant stiffness for a pile displacement of D/1000 at ground level, where D is the pile diameter. The ultimate reaction is defined for a pile displacement of D/10 at ground level for the numerical models, and as the maximum lateral load reached for the experimental tests. Ultimate reaction could not be reached during the test for L5 due to limitations with the loading system.

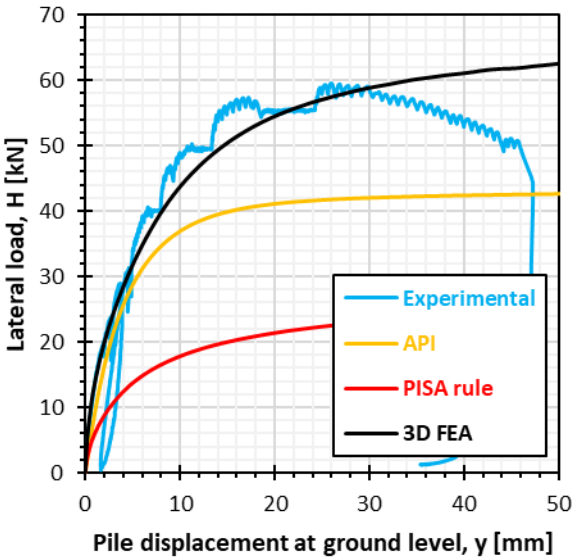

Figure 4. Comparison of experimental and predicted load-displacement response at ground level for pile L4 (L/D=3.3).

PISA rule is found to largely underestimate the stiffnesses and the ultimate reactions by more than 50%. This is because the depth variation functions from the General Dunkirk Sand Model (GDSM) are being used outside of their calibration space. Indeed, Burd et al. (2020) calibrated the GDSM against three-dimensional finite element analyses with pile diameters ranging from 5 m to 10 m. In this experimental study, piles have a diameter of 457 mm.

Although the API 'p-y' approach was developed for long and flexible piles, it is found to perform slightly better than PISA rule for these short and rigid piles. However, it still significantly underestimates stiffnesses (37% to 53%) and ultimate reactions (about 30%).

3D FEA is found to provide very good matches with the experimental data, the average error being less than 5% accross the different pile penetrations. These results further validate the CPT based correlations of HS-small parameters developed by Igoe and Jalilvand (2020).

Table 1. Comparison of blind predictions to experimental piles response in terms of initial stiffness and ultimate capacity.

Approach	Initial stiffness relative error [%]			Ultimate capacity relative error [%]		
	L4	L5	L6	L4	L5	L6
Field test	Ref	Ref	Ref	Ref	-	Ref
API	-44.4	-36.9	-53.3	-28.6	-	-30.6
PISA rule	-50.9	-48.8	-57.9	-59.2	-	-57.3
3D FEA	8.8	4.5	5.6	3.9	-	-2

5 CONCLUSION

This paper presents the initial results of a recent campaign of pile lateral field tests. 6 piles with diameter of 457 mm and penetration ranging from 1 m to 2 m were driven into dense sands at the Blessington test site in Ireland and subjected to monotonic and cyclic loading.

The piles response to monotonic loading were predicted ahead of testing using three approaches: API 'p-y curve' approach, PISA rule-based approach and three-dimensional finite-element analysis with a novel set of CPT based correlations for all the input parameters to the soil constitutive model. The API and the PISA rule approaches were found to largely underestimate both initial stiffness and ultimate reaction for all piles. The 3D FEA prediction with CPT based input parameters were found to match very well with the experimental monotonic response for all piles.

These results further validate the CPT based correlations developed by Igoe and Jalilvand (2020) and suggest that the approach can be used for monopile foundations design supporting offshore wind turbines which are characterised by low slenderness ratios (L/D). The full list of correlations and parameters used in the 3D FE modelling is provided in Igoe and Lapastoure (2024).

ABSTRACT: Biopolymers have been emerged as an innovative and environmentally friendly construction material due to their significant strengthening effect, causing minimal environmental pollution when compared to traditional binders. This research examines the viability of using a biopolymer to enhance resistance against erosion. The impact of biopolymer treatment was assessed through laboratory tests, including hole erosion and hydraulic flume tests. The earthen levee models treated with a 1% biopolymer-to-soil mass ratio demonstrated remarkable resistance to piping erosion. In conclusion, this study suggests that implementing biopolymer treatment would be effective in practical applications.

RÉSUMÉ: Les biopolymères sont apparus comme un matériau de construction innovant et respectueux de l'environnement en raison de leur effet fortifiant significatif, provoquant une pollution environnementale minimale par rapport aux liants traditionnels. Cette recherche examine la viabilité de l'utilisation d'un biopolymère pour améliorer la résistance à l'érosion. L'impact du traitement aux biopolymères a été évalué par des tests en laboratoire, notamment des tests d'érosion des trous et des canaux hydrauliques. Les modèles de digues en terre traitées avec un rapport massique de biopolymère/sol de 1% ont démontré une résistance remarquable à l'érosion des canalisations. En conclusion, cette étude suggère que la mise en œuvre d'un traitement par biopolymère serait efficace dans des applications pratiques.

Keywords: Sustainable geotechnical engineering; biopolymer; biological ground improvement; Xanthan gum; Biopolymer-based soil treatment (BPST).

1 INTRODUCTION

This study investigates the efficacy of biopolymer-soil treatment (BPST) in reducing erosion. Recently introduced in geotechnical engineering as a biological ground improvement method, microbial biopolymer-based soil treatment (BPST) aligns with the global demand for sustainable engineering technologies. Leveraging its interparticle bonding characteristic and high yield point (shear strength), BPST is anticipated to elevate the critical shear stress in hydraulic erosion situations.

While earthen levees play a crucial role in safeguarding inhabited and cultivated lands, their susceptibility to failure primarily stems from external erosion (overtopping, 34%) and internal erosion (piping, 28%). Consequently, numerous researchers have endeavoured to comprehend piping behaviour and explore mitigation technologies (Foster & Fell, 2001; Masannat & Hydrogeology, 1980; Ojha, Singh, & Adrian, 2003). The potential effectiveness of biopolymer-soil treatment (BPST) lies in the assumption that coagulating particles enhance erosion resistance.

Two experimental programs were performed. In detail, the effectiveness of BPST was assessed in terms of critical shear stress by Hole Erosion Test (HET) and the laboratory-scale model test was carried out in order to verify applicability on the earthen levee structures.

2 MATERIALS AND METHOD

2.1 Soils

The employed soil is Sydney sand, categorized as SP (Poorly graded soil) according to the Unified Soil Classification System (USCS). The mean diameter (d_{50}), maximum void ratio (e_{max}), and minimum void ratio (e_{min}) are 0.36, 0.92, and 0.6, respectively. The coefficient of curvature (C_c) and uniformity (C_u) are 0.96 and 1.18. The specific gravity (G_s) is 2.6. Kaolinite, derived from weathered feldspar and mica, has a structural composition comprising a silica layer and an alumina layer via hydrogen bonding. Research-grade kaolinite (Walker Ceramics, CAS number: 1332-58-7) was used in this study.

2.2 Xanthan gum biopolymer

This study incorporates a polysaccharide-based biopolymer, xanthan gum, chosen for its workability and notable bonding characteristics. Xanthan gum is derived from the bacterium *Xanthomoas campestris* and features a primary repeating structure consisting of two glucose units, two mannose units, and one glucuronic acid unit. In this study, research-grade xanthan gum (Merck, CAS number: 11138-66-2) was used.

2.3 Sample preparation in common

To create a xanthan gum hydrogel, powdery xanthan gum and deionized water were admixed at a specified mass ratio ($m_{biopolymer}/m_{water}$). Subsequently, a xanthan gum-soil mixture was formulated by blending oven-dried soils with the xanthan gum hydrogel, maintaining a designated moisture ratio ($m_{moisture}/m_{soil}$). Concurrently, the mass ratio of xanthan gum content to soil ($m_{biopolymer}/m_{soil}$) was controlled.

Figure 1. Hole erosion test (HET) apparatus.

2.4 Laboratory hole erosion test

2.4.1 Sample preparation

Soil mixtures, comprising Sydney sand and kaolinite clay, were prepared according to Table 1. Following the incorporation of xanthan gum hydrogel into the soil mixture, the resultant samples were poured into a cylindrical acrylic mould (10 cm in a diameter and 10 cm in a height) featuring a vertical rod with a 6 mm diameter. The vertical rod was strategically positioned to simulate a pre-drilled hole throughout the duration of the experiment. Subsequently, the prepared samples were saturated under a 5 kPa confinement for a period of 24 hours.

2.4.2 Test method

Laboratory hole erosion test (HET) apparatus was manufactured based on the specifications from previous studies (Lüthi, Fannin, & Millar, 2012; Wan & Fell, 2004). While Wan and Fell (2004) suggested a horizontal HET apparatus, our design deviated by adopting a vertical arrangement to minimize the impact of sedimentation following the pre-drilled hole. Illustrated in Figure 1, the apparatus consisted of upstream, specimen, and downstream components. Following the assembly of the upstream and downstream parts to the sample mould, the upstream section was connected to the pressure volume controller (GDS STDDPC) to induce a hydraulic head differential across the soil sample.

2.5 Hydraulic flume test

A hydraulic flume test was performed to simulate the semi-field scale examination. The hydraulic flume test apparatus had dimensions of 10 m in length, 0.6 m in width, and 0.9 m in height. Test samples were positioned within the hydraulic flume test device as depicted in Figure 2.

Table 1. Information of HET (Hole Erosion Test) samples.

Annotation	% of clay	% of sand	% of xanthan gum	Water content (%)	Dry density (kg/m^3)
C100	100	0	-	55	1150
C20S80	20	80	-	18	2214
C20S80XG1	20	80	1	20	2185
S100XG1	0	100	1	20	1988

Table 2. Information of Hydraulic flume test samples.

Annotation	% of clay	% of xanthan gum (ratio of cross-sectional area)	Treatment morphology

S90C10-XG25	10	25	Surface

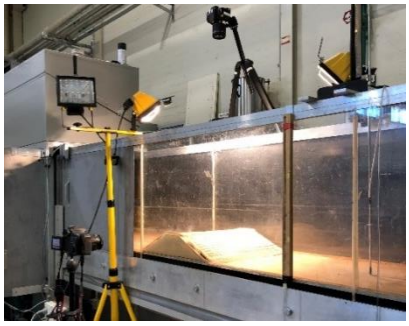

Figure 2. Hydraulic flume test device.

3 RESULTS AND DISCUSSION

3.1 Experimental results from HET

C100 demonstrated a critical shear stress of 99 Pa and an erosion rate index of 3.2. In contrast, C20S80 exhibited a critical shear stress of 7.8 Pa and an erosion rate index of 3.3. However, the critical shear stress increased to 18.8 Pa while the erosion rate index remained at 2.54 when xanthan gum was added (C20S80XG1). It affirms that the application of xanthan gum to soils induces inter-particle bonding, leading to an enhancement in critical shear stress. In short, the xanthan gum treatment, by delaying erosion initiation, contributes to an overall improvement in structural stability. Meantime, S100XG1 achieved a critical shear stress of 14.9 Pa, whereas pure sand typically exhibits negligible critical shear stress.

Table 3. Critical shear stress from laboratory HET.

Test specimen	Critical shear stress (Pa)
C100	99
C20S80	7.8
C20S80XG1	18.8
S100XG1	14.9

3.2 Hydraulic flume test results

In the case of S100, monitoring the progression of piping erosion proved challenging as seepage rapidly developed throughout the soil specimen. Concurrent with seepage, the pre-drilled hole collapsed rather than propagating as intended, leading to the collapse within a minute. Conversely, S90C10 displayed evident piping erosion corresponding to the pre-drilled hole, resulting in overall structure instability.

S90C10-XG10 and S90C10-XG25 exhibited a backward erosion behaviour which refers erosion proceeding to upstream direction. Furthermore, turbulent flow developed following the rapid xanthan gum-treated layer in the case of S90C10-XG25.

The improvement in erosion resistance can be attributed to inter-particle bonding (Khatami & O'Kelly, 2012; Renault, Sancey, Badot, & Crini, 2009), and disturbance in soil particle movement caused by biopolymer dissolution, coupled with the dampening behaviour of the viscous pore-fluid (Fujino, Sun, Pacheco, & Chaiseri, 1992).

4 CONCLUSIONS

The objective of this study is to evaluate the impact of biopolymer-based soil treatment (BPST) on erosion mitigation using the hole erosion test (HET), and hydraulic flume test. The application of xanthan gum to treated soil enhances critical shear stress, and the corresponding earthen levee model exhibits turbulence development following the rigid xanthan gum-treated layer during surface treatment.

The experimental findings suggest that the introduction of biopolymers contributes to the stability of earthen levee models by alleviating surface erosion.

Through fostering interparticle bonding among sand particles, biopolymers impart resistance against external shear forces induced by water flow.

It is extensively documented that conventional earthen levee structures often fail as a result of piping or overtopping during events such as hurricanes, Katrina, and other natural disasters (Briaud, 2008). The application of xanthan gum treatment emerges as a potentially effective mitigation method, noteworty for its ability to address these concerns without posing environmental risks.

Modelling hysteretic damping of soils for monopiles

Modélisation de l'amortissement hystérétique des sols pour les monopieux

A.R. Leon Bal*, M. Jafari, L.A. Berenguer Todo Bom, M. Goodarzi
COWI A/S, Hamburg, Germany

*arbl@cowi.com

ABSTRACT: This paper proposes a new method to evaluate the hysteretic soil damping in offshore wind turbines (OWT) with monopiles. Soil damping is a key factor affecting the design of OWT and its fatigue life span. Dynamic 3D finite element analyses incorporating the Hardening Soil-small model are performed. The OWT damping is obtained from the decay of tower displacements. Depending on the expected monopile deflections and soil stiffness, it is found that the widely adopted Cook and Vandiver (1982) method from the oil and gas industry, can underestimate the soil hysteretic damping.

RÉSUMÉ: Cet article propose une nouvelle méthode pour évaluer l'amortissement hystérétique du sol dans les éoliennes offshore (OWT) avec des monopieux. L'amortissement du sol est un facteur clé qui affecte la conception de l'éolienne et sa durée de vie en fatigue. Des analyses dynamiques par éléments finis en 3D intégrant le modèle Hardening Soil-small ont été réalisées. L'amortissement de l'OWT est obtenu à partir de la décroissance des déplacements de la tour. En fonction des déflexions attendues du monopieu et de la rigidité du sol, on constate que la méthode Cook et Vandiver (1982), largement adoptée dans l'industrie pétrolière et gazière, peut sous-estimer l'amortissement hystérétique du sol.

Keywords: Soil damping; offshore wind turbines; finite element analyses; hardening soil model; decay test.

1 INTRODUCTION

The impact of damping in the performance of offshore wind turbines with monopile foundations cannot be understated, as it helps in the reduction of peak displacements of the structure, steel quantities and costs (Versteijlen et al., 2011) and the extension of its life span (Malekjafarin et al., 2022). Therefore, accurate representation of the soil-structure interaction is crucial for the achievement of optimized designs.

Although different damping sources affecting the dynamic response of OWT have been identified, namely, aerodynamic, hydrodynamic, structural and foundation damping, foundation damping remains as one of the major contributors (Malekjafarin et al., 2022). Foundation damping includes radiation, seepage, and hysteretic components, where the soil hysteretic damping is more relevant for OWT and will be the focus of this paper.

2 METHOLOGY

A series of dynamic 3D finite element analyses (FEA) were conducted with Plaxis 3D. The tower geometry in terms of the outer diameter (OD) and wall thickness is also shown in Figure 1 (left). The model setup as well as the FE mesh are shown in Figure 1 (right). Viscous absorbing boundary conditions are used to model the energy dissipation into the far field (radiation damping). The tower was modelled as linear elastic using plate elements. The Rotor-Nacelle Assembly (RNA) was modelled using a rigid circular plate with a fictive density at the tower top to give a mass of 809 tons. Half symmetry in the fore-aft direction was also employed to reduce the model size and hence, the simulations time. The soil behaviour was captured with the Hardening Soil model with small strain stiffness (HS-small). The soil properties are presented in Table 1. Due to the expected low levels of pile deformations under fatigue limit state conditions, the stress dependency of the stiffness parameters of the HS-small model are ignored.

Table 1. Soil parameters of the numerical model.

Unit	Depth [m]	γ_{sat} [kN/m3]	γ_{70} [-]	G_0 [MPa]	E_{50} [MPa]	*Eur [MPa]
A	0-2	19	1.37E-04	25.1	8.6	25.6
B	2-16	19.6	3.90E-04	76.7	22.8	68.4
C	16-49	19.4	3.23E-04	234	41.6	125

*G_{ur} was computed based on E_{ur} and assuming a Poisson's ratio of $\nu = 0.25$.

As discussed in Brinkgreve et al. (2007), the γ_{70} parameter in HS-small is calibrated so that the Plaxis damping ratio curve agrees well with the resonant column test results. The HS-small model employs a shear strain-dependent reduction curve for the shear modulus, which allows for the development of hysteresis loops but yields zero hysteretic damping at very small strains. However, resonant column tests in general show a certain amount of damping even at very small strain levels. Such damping cannot be captured using HS-small model. As a result, Rayleigh damping is often added to the finite element models. Resonant column tests of the soil units in Table 1 indicate that a Rayleigh damping ratio amounting to 1.5% should be added to get a better match of the Plaxis soil damping curves to that of the lab tests. The Raleigh damping coefficients are set to α = 0.01257 and β = 0.01592. These set of parameters result in a Raleigh damping of 1.5% at the natural frequency of the structure (0.17 Hz). Nevertheless, the authors found that the contribution of the Rayleigh damping is negligible due to the extremely low natural frequency of the structure (below 0.2 Hz) and resulting low tower velocity during the structural vibrations.

To observe the free lateral vibrations of the tower in the first mode, the tower head is displaced from the initial position (x = 0 m) to one side (e.g., x = 0.25 m) in a static phase. Then, the tower head is released in a dynamic phase and allowed to vibrate freely. The total duration of dynamic phase is 100 seconds with a step size 0.4 seconds. Several dynamic analyses with different initial lateral displacements (x = 0, 0.5, 1 and 1.5 m) are considered.

3 RESULTS AND DISCUSSION

Time histories of the computed displacement at the mudline for maximum displacements in x-direction of u_{max} = 1.14, 2.34, 5.17 and 8.70 mm are depicted in Figure 2 (left), considering various initial cycle amplitudes at tower top (A_0 = 0, 0.5, 1 and 1.5 m).

A Fast Fourier Transform (FFT) was also performed to extract the frequency content of the displacement time history at the tower head. As seen in Figure 2 (right), the FFT reveals that the natural frequency of the modelled structure is 0.17 Hz.

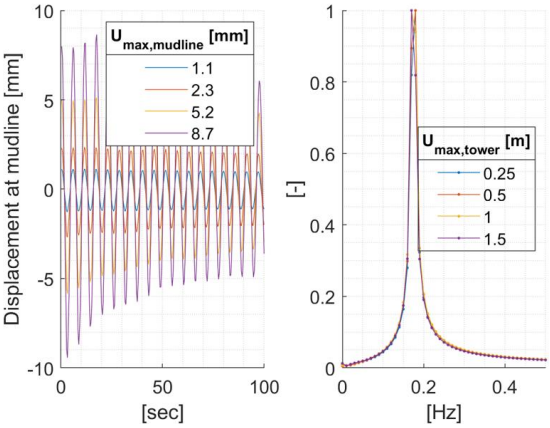

Figure 2. Computed time history of the displacement at the (left) mudline and (right) Fast Fourier Transform of the tower top displacement.

From each displacement time history, cycle peaks are extracted to evaluate the decay of the displacement amplitude. In order to obtain a representative damping ratio coefficient ζ (%) of the system, an exponential decay function $u(t) = A_0 e^{-\zeta 2\pi f_n t}$ is fitted to the extracted cycle peaks of the tower top in which t (s) is the time, A_0 (m) is the displacement amplitude at t = 0 (s) and f_n (Hz) is the natural frequency of the system. The fitted curves can be seen in Figure 3 (left). The back-calculated damping ratios are plotted against the initial mudline displacement in Figure 3 (right).

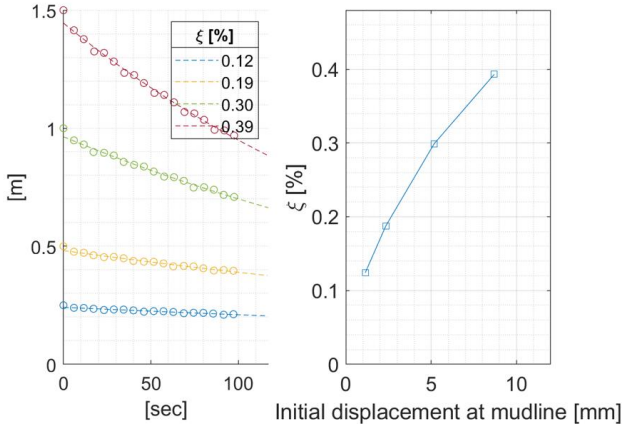

Figure 3. Fitting the exponential decay function to the tower head displacement to find the soil hysteretic damping: (left) Source data from Plaxis and (right) fitted ζ values for the selected cycle amplitudes (0.25, 0.50, 1, and 1.5 m) in correlation to the initial mudline displacement.

The FE-based damping ratio values are compared against those computed using the Cook and Vandiver method (Cook and Vandiver, 1982) for the first vibration mode of the structure. In this method, the pile is discretized into n nodes to which soil reaction springs are connected. The damping ratio ζ is calculated as

$$\zeta = \frac{1}{\omega_n^2 M}\sum_{i=1}^{n} K_s(z_i)\Psi_i(z_i)\zeta_{smd}(z_i) \quad (1)$$

in which $\omega_n = 2\pi f_n$ is the circular natural frequency, M is the modal mass of the structure, $K_s(z_i)$ is the soil spring stiffness for node i at depth z_i, $\Psi_i(z_i)$ is the mode shape of the node for the first deformation mode and $\zeta_{smd}(z_i)$ is the specific soil damping.

The first mode shape and modal mass are obtained by conducting an eigen frequency analysis of the structure, for which the soil interaction springs are extracted from the FE model at every meter along the embedded pile length. The $\zeta_{smd}(z_i)$ is interpolated from the calibrated damping ratio versus shear strain curve, considering the shear strain γ calculated after (Skempton, 1951)

$$\gamma = \frac{1+\upsilon}{2.5\,OD}\cdot y(z_i) \quad (2)$$

in which υ is the soil Poisson's ratio, and $y(z_i)$ is the lateral monopile deflection at z_i computed from a static push-over analysis of a 1-D beam model of the monopile. The soil stiffness K_s is calculated assuming two scenarios:

- K_s is taken as the initial stiffness of the soil reaction springs.
- K_s is taken as a linearized secant stiffness of the soil springs. The linearization level is determined by a static push-over analysis of the 1-D beam model of the monopile, where the mudline is laterally pushed to a certain amount u_{max}. For the analyses u_{max} = 1.14, 2.34, 5.17 and 8.70 mm.

Figure 4 displays the calculated damping ratio as a function of the normalized initial mudline displacement (u_{max}/OD = 0.01, 0.02, 0.05 and 0.09%) considering the two scenarios for the calculation of the soil spring stiffness. In general, the FE-based and the Cook and Vandiver method compares well up to u_{max}/OD = 0.02%, beyond which the Cook and Vandiver method underestimates the soil damping. Therefore, using the secant soil spring stiffness in the Cook & Vandiver method results in very conservative damping ratios. However, taking K_s as the initial stiffness of the springs, a plateau is reached with increasing u_{max}/OD. A plateau indicates that the maximum damping ratio for all the soil damping curves for each node along the monopile has been reached.

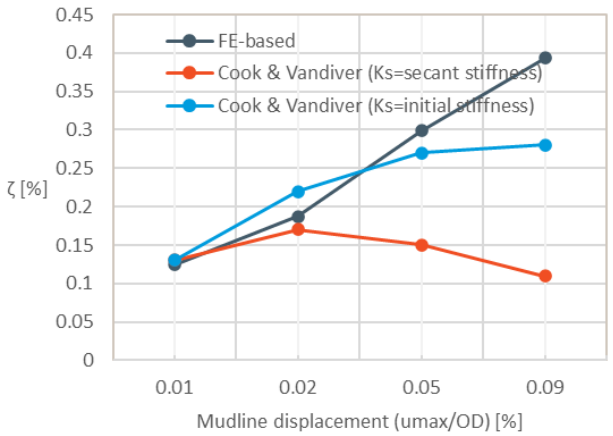

Figure 4. Damping ratio vs. maximum normalized mudline displacements according to (Cook and Vandiver, 1982) and FE calculations.

The increase of damping ratio values with increasing amplitudes of cyclic loading has been also reported in the literature (Malekjafarin et al., 2022). The Cook and Vandiver method, on the other hand, cannot capture this increasing trend properly due to the following factors:

- Utilization of the soil secant stiffness K_s instead of the stiffer loading/unloading K_{ur} stiffness. The stiffness. K_{ur} is more representative of the soil behaviour. For fatigue limit state conditions where pile displacements are very low, K_{ur} is relatively close to the initial stiffness of the springs (K_{ini}). As the mudline displacement increases, the secant stiffness reduces. This reduction is more pronounced for large u_{max}/OD ratios and does not compensate the increase in specific damping ratio ζ_{smd} with increasing strains, leading to an overall decrease of the soil damping ratio.
- Inherent uncertainties in the calculation of shear strains from pile displacements. The correct estimation of the soil shear strains is of paramount importance for the accurate determination of the specific damping ratio and in turn, the soil hysteretic damping.
- The influence of the pile diameter. While the Cook and Vandiver formulation was calibrated and tested against typical pile foundations in the oil and gas industry decades ago, current monopiles with smaller length to diameter ratios behave more rigidly, exhibiting a different deformation mode characterized by rotations along the shaft as well as rotations and lateral

displacements along the base (Burd et al., 2020). By extending Eq. (1) with additional rotational and pile base terms (e.g., rotational stiffness, modal rotations, etc.), more realistic hysteretic damping values could be attained.

4 CONCLUSIONS

In this contribution, a new FE-based methodology based on a free vibration analysis of the wind turbine structure is presented for the estimation of hysteretic soil damping in OWT's. The FE-based damping ratio is compared with that of the Cook and Vandiver methodology. The utilization of the Cook & Vandiver method can result in an underestimation of the hysteretic soil damping depending on the expected monopile deflections and the assumed soil stiffness in its formulation. The main characteristics of the proposed numerical strategy are the following:

- A 3D FE model comprising the tower, monopile and the rotor nacelle assembly.
- The incorporation of the Hardening Soil model with small strain stiffness, capable of reproducing hysteresis loops in the soil via the strain-driven degradation of the small-strain shear modulus.
- Performing dynamic analysis as part of numerical decay tests with selected initial cycle amplitudes at the tower top.
- The generation of damping curves (for each cycle amplitude) from the tower peak displacements and the subsequent exponential fitting to extract the damping ratio.
- Transforming tower displacements to mudline displacements and finding the damping ratio at the desired mudline displacement from the resulting damping ratio-mudline displacement curve.

For the assessed mudline displacements, the proposed methodology consistently predicted increasing damping ratios for increasing cycle amplitudes. To have a baseline, results computed with the Cook and Vandiver method were presented. Results from this method but using instead the secant soil stiffness calculated from the smallest cycle amplitude were also included. For larger mudline displacements, the Cook and Vandiver method failed to capture the positive correlation between cycle amplitudes and damping ratios. On the other hand, by using the soil secant stiffness from the smallest cycle amplitude (u_{max}/OD = 0.01), the gap with the FE-based results was substantially reduced.

Finally, the utilization of the secant or the initial soil spring stiffness, the transformation from pile displacements to soil shear strains and the pile diameter, were identified as potential factors hindering the accuracy of the Cook and Vandiver method for large mudline displacements.

Analysis of different temporary anchor points for construction of 380 kV high-voltage transmission masts

L'analyse des points d'ancrages différentes temporairement pour la construction des pylônes à haute tension de 380 kV

S. Leppla*, J.C. Paninski, R. Freund

**steffen.leppla@fb1.fra-uas.de*

ABSTRACT: For the construction of new high-voltage transmission lines and the improvement of existing lines temporary anchor points are necessary. In engineering practice, basically three different systems are used: deadman structures, counterweights and the so-called Spinnanker. Deadman structures are wood or steel beams or steel pipes, which are buried in the subsoil. The resistance occurs due to the passive earth pressure. For counterweights, large concrete blocks are used to activate the sliding resistance. The Spinnanker consists of an anchor plate and threaded steel bars, which are screwed into the subsoil. The resistance results from the skin friction of the steel bars. Deadman structures and counterweights are two well-known systems, but they cause a lot of tillage and use of material thus have a massive impact on the environment. The Spinnanker is a new construction system, which is minimally invasive especially with regard to soil mixing and soil compaction. Based on a real construction project in Germany these three different temporary anchor systems are analyzed regarding the design and safety concept. Finally, recommendations for the field of application, the construction and the secure and economic design are given.

RÉSUMÉ: En raison de la transition énergétique, la construction de nouvelles lignes électriques à haute tension et l'amélioration des lignes existantes sont nécessaires. Dans la pratique de l'ingénierie, trois systèmes différents sont utilisés : les constructions « homme mort », des blocs en béton et ce qu'on appelle le « Spinnanker ». Les constructions « homme mort » se composent de poutres en acier ou de tuyaux en acier enfouis dans le sous-sol. La résistance est due à la pression passive du sol. Les blocs en béton sont utilisés pour activer la résistance au glissement. Le « Spinnanker » se compose d'une plaque d'ancrage et de tiges filetées vissées dans le sous-sol. La résistance est une combinaison du frottement superficiel de la pression passive du sol. Les constructions « homme mort » et les blocs en béton sont deux systèmes bien connus, mais ils nécessitent beaucoup de travail du sol et d'utilisation de matériaux et ils ont un impact élevé sur l'environnement. Le « Spinnanker » est un système de construction peu invasif, surtout en ce qui concerne le mélange et le compactage du sol. Basés sur un projet de construction réel en Allemagne, ces trois différents systèmes d'ancrage temporaires sont analysés en termes de conception et de concept de sécurité. Enfin, des recommandations concernant le domaine d'application, la construction et la conception sécurisée et économique sont données.

Keywords: Temporary anchor; safety; resource reduction; Spinnanker.

1 INTRODUCTION

Just in Germany, 4,000 km of new high-voltage transmission lines will be approved until the middle of 2025. Therefore, a lot of temporary anchor points are necessary during construction time. These anchor points should be environmentally neutral as possible to save resources, time and money and to avoid unnecessary CO_2-emission. For the design and construction of overhead electricity lines, the regulations in the standard EN 50341 (CEN 2013) have to be considered. This standard deals with the basics for design and dimensioning for the structure of the masts including the different loading cases, electrical requirements, materials to be used, the foundation and requirements for the components. It does not include a preliminary design or the dimensioning of temporary anchor points for all construction stages. Regarding the geotechnical aspects of the design and construction of the masts the standard EN 1997-1 (CEN 2014) has to be considered.

According to EN 1997-1 all relevant geotechnical boundary conditions including the ground and groundwater situation and the regulations for the safety concept have to be considered in all analyses of stability and serviceability. The standard is also to be applied for the design and the construction of temporary anchor points of electricity masts.

2 DEADMAN STRUCTURE

Deadman structures are wood or steel beams or steel pipes, which are buried in the subsoil. The design of deadman structures is not fully covered by the standard EN 1997-1. In engineering practice there exists a design procedure which refers partly to EN 1997-1. Furthermore it is based on a design approach which may overestimate the resistance of the soil.

Due to this, the following design procedure based on ranking domain is recommended. This procedure includes the analysis of all possible geotechnical failure mechanisms:

- horizontal stability
- vertical stability
- inclined sliding stability

Figure 1 shows the principle layout of a deadman structure with the geometric parameters and the characteristic tensions force F_k (kN), which results from permanent and variable loads. Regarding the impact, for a conservative approach the partial factor $\gamma_Q = 1{,}3$ is used.

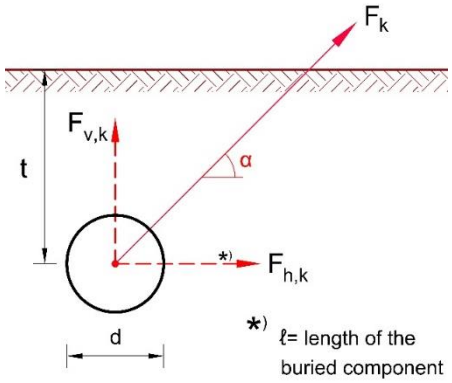

Figure 1. Principle layout of a deadman construction (sectional view).

2.1 Analysis of the horizontal stability

For the analysis of the horizontal stability, the horizontal impact $E_{h,d}$ (kN) is compared to the horizontal earth resistance $R_{h,d}$ (kN). The horizontal impact consists of the horizontal component $F_{h,k}$ (kN) of the tension force F_k (kN) and the active earth pressure $e_{ah,k}$ (kN/m²). All forces are shown in Figure 2.

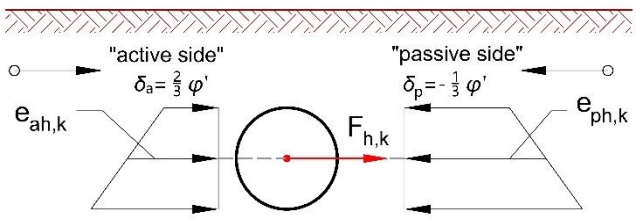

Figure 2. Horizontal components (sectional view).

The total impact $E_{h,d}$ is explained by Equation (1), using the partial factor $\gamma_G = 1{,}2$ for the earth pressure.

$$E_{h,d} = F_{h,k} \cdot \gamma_Q + e_{ah,k} \cdot d \cdot l \cdot \gamma_G \qquad (1)$$

In the analysis of the horizontal stability the resistance $R_{h,d}$ is the passive spatial earth pressure $e_{ph,k}$ (kN/m²), which depends on the length l (m) and the diameter d (m) of the buried component and the friction angle φ' (°) of the soil. The effective length l^{Er} (m) for the spatial earth pressure is defined for the dead load of the soil by Equation (2) and for the cohesion by the Equation (3).

$$l_{pg}^{Er} = l + 0{,}6 \cdot d \cdot \tan\varphi' \qquad (2)$$

$$l_{pc}^{Er} = l + 0{,}3 \cdot d \cdot (1 + 1{,}5 \cdot \tan\varphi') \qquad (3)$$

The design value of the resistance $R_{h,d}$ is described by the Equation (4). The partial factor is $\gamma_{R,e} = 1{,}3$.

$$R_{h,d} = \frac{R_{h,k}}{\gamma_{R,e}} = \frac{e_{pgh,k} \cdot d \cdot l_{pg}^{Er} + e_{pch,k} \cdot d \cdot l_{pc}^{Er}}{\gamma_{R,e}} \qquad (4)$$

The final proof in the analysis of the horizontal stability is as follows:

$$E_{h,d} \leq R_{h,d} \qquad (5)$$

2.2 Analysis of the vertical stability

For the analysis of the vertical stability, the vertical impact $E_{v,d}$ (kN) is compared to the vertical earth resistance $R_{v,d}$ (kN). The vertical impact consists of the vertical component $F_{v,k}$ (kN) of the tension force F_k and of the vertical component of the passive earth pressure $E_{pv,k}$ (kN). The vertical earth resistance $R_{v,d}$ consists of the dead load of the soil G_k (kN) and of the friction force $R_{s,k}$ (kN) in the shear zone above the buried component. All forces are shown in Figure 3.

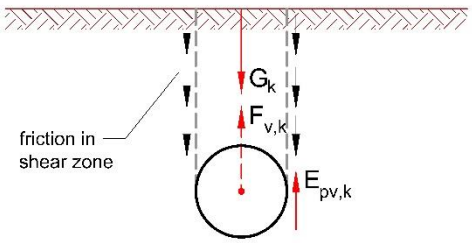

Figure 3. Vertical components (sectional view).

The total impact $E_{v,d}$ is explained by the Equations (6) and (7).

$$E_{v,d} = F_{v,k} \cdot \gamma_Q + E_{pv,k} \cdot \gamma_G \quad (6)$$

$$E_{pv,k} = R_{h,k} \cdot tan\left(\frac{1}{3}\varphi'\right) \quad (7)$$

The dead load of the soil G_k is characterized by the geometry above the buried component, the weight of the buried component $G_{bc,k}$ (kN) and the weight of the soil γ (kN/m³), Equation (8). In the case of groundwater, the weight of the soil changes to γ'.

$$G_k = (\gamma \cdot d \cdot (t-d) \cdot l) + G_{bc,k} \quad (8)$$

The friction force $R_{s,k}$ results from the horizontal earth pressure at rest E_0 (kN) which exists in the shear zone above the buried component. The area of the shear zone is the circumference of the ground view of the buried component. The earth pressure at rest E_0 and the resulting friction force $R_{s,k}$ are defined by the Equations (9) and (10).

$$E_0 = \gamma \cdot (1 - sin\,\varphi') \cdot \left(t - \frac{d}{2}\right) \cdot \frac{t - d/2}{2} \cdot (2 \cdot l + 2 \cdot d) \quad (9)$$

$$R_{s,k} = E_0 \cdot tan\,\varphi' \quad (10)$$

The total resistance $R_{v,d}$ is as follows:

$$R_{v,d} = \frac{G_k + R_{s,k}}{\gamma_{R,e}} \quad (11)$$

The final proof in the analysis of the vertical stability is as follows:

$$E_{v,d} \leq R_{v,d} \quad (12)$$

2.3 Analysis of the inclined sliding stability

For the analysis of the inclined sliding stability, the activated soil body is simplified, not proven, formed as a wedge where the basic side is in the direction of the tension force F_k (kN). At this activated soil body the impact E_d (kN) is compared to the sliding resistance R_d (kN). The impact consists of the tension force F_k and of the inclined component of the active earth pressure $E_{a,\|,k}$ (kN/m). The impact E_d is explained in Equation (13) and (14).

$$E_d = F_k \cdot \gamma_Q + E_{a,\|,k} \cdot \gamma_G \cdot l \quad (13)$$

$$E_{a,\|,k} = E_{ah,k} \cdot cos\,\alpha \quad (14)$$

The sliding resistance R_d consists of the

- friction force $R_{s,G,k}$ (kN) in the sliding surface, which results from the dead load of the soil $G_{\perp,k}$ (kN)
- downslope force of the dead load of the soil $G_{\|,k}$ (kN)
- friction force $R_{s,Ea,k}$ (kN) in the sliding surface, which results from the inclined component of the active earth pressure $E_{a,\perp,k}$ (kN/m)
- friction force $R_{s,c,k}$ (kN) in the sliding surface, which results from the cohesion
- friction force $R_{s,E0,k}$ (kN) in the area A (m²), which results from the earth pressure at rest E_0 (kN)

All forces and the geometry of the sliding block are shown in the Figures 4 and 5.

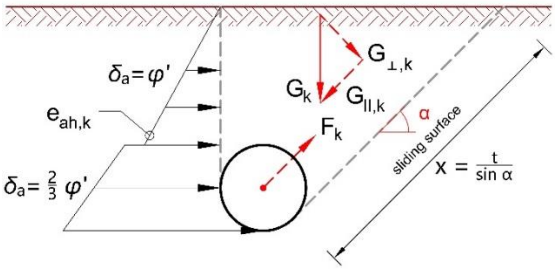

Figure 4. Sliding block (sectional view).

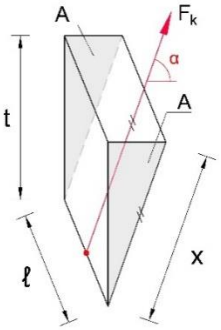

Figure 5. Sliding block (3-dimensional view).

The components of the total resistance R_d are described by the Equations (15) to (20).

$$R_{s,G,k} = G_{\perp,k} \cdot tan\,\varphi' \quad (15)$$

$$G_{\perp,k} = G_k \cdot cos\,\alpha \quad (16)$$

$$R_{s,Ea,k} = E_{a,\perp,h} \cdot tan\,\varphi' \cdot l \quad (17)$$

$$E_{a,\perp,k} = E_{ah,k} \cdot sin\,\alpha \quad (18)$$

$$R_{s,c,k} = c'_k \cdot x \cdot l \quad (19)$$

$$R_{s,E0,k} = 2 \cdot A \cdot E_0 \cdot tan\,\varphi' \quad (20)$$

The total resistance R_d is as follows:

$$R_d = \frac{R_{s,G,k}+R_{s,Ea,k}+R_{s,c,k}+R_{s,E0,k}+G_{\parallel,k}}{\gamma_{R,h}} \quad (21)$$

$$G_{\parallel,k} = G_k \cdot \sin\alpha \quad (22)$$

The final proof in the analysis of the inclined sliding stability is as follows:

$$E_d \leq R_d \quad (23)$$

2.4 Safety and quality assurance

The real load-displacement behavior of deadman structures has not be analyzed completely. This includes small scale and large scale tests in soil for high loads. Regarding the regulations in EN 1997-1 the deadman structure has to be treated as an anchor system. Due to this, in-situ load-displacement tests on each construction site are necessary, if no comparable information is available. For the necessary testing load the regulations for pre-stressed anchor systems have to be considered.

3 COUNTERWEIGHTS

Counterweights consist of large concrete blocks which are positioned on a steel frame on the bottom. To increase the friction between the counterweights and the subsoil, a bedding of gravel material is often installed. For the design procedure the regulations for single foundation elements in EN 1997-1 have to be considered. The main part of the stability is given by the dead load of the counterweight and the friction in the subsoil. Due to this, the following design procedure is recommended. This procedure includes the analysis of all possible geotechnical failure mechanisms:

- uplifting
- sliding stability
- limitation of the eccentricity
- bearing resistance

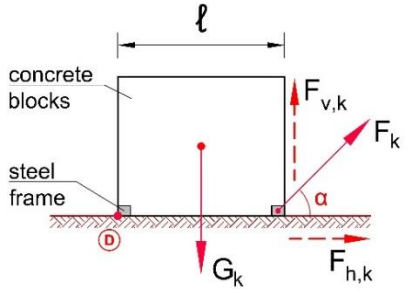

Figure 6. Principle layout of a counterweight.

Figure 6 shows the principle layout of a counterweight with the geometric parameters and the characteristic tensions force F_k (kN), which results from permanent and variable loads. For a conservative approach the partial factor $\gamma_Q = 1{,}3$ is used.

3.1 Uplift

For the analysis of the uplift, the vertical component $F_{v,k}$ (kN) of the tension force F_k is compared to the dead load G_k (kN) of the counterweight. For the design level the partial factors $\gamma_{G,stb} = 0{,}95$ and $\gamma_{Q,dst} = 1{,}30$ are used in the Equation (24) and (25).

$$E_{v,d} = F_{v,k} \cdot \gamma_{Q,dst} \quad (24)$$

$$R_{v,d} = G_k \cdot \gamma_{G,stb} \quad (25)$$

The final proof in the analysis of the uplifting is as follows:

$$E_{v,d} \leq R_{v,d} \quad (26)$$

3.2 Sliding stability

For the analysis of the sliding stability, the horizontal component $F_{h,k}$ (kN) of the tension force F_k is compared to the friction resistance $R_{h,k}$ (kN) below the counterweight. The horizontal impact is as follows:

$$E_{h,d} = F_{h,k} \cdot \gamma_Q \quad (27)$$

The friction resistance is influenced by the angle of friction δ_k in the subsoil below the surface:

$$R_{h,d} = \frac{(G_k - F_{v,k}) \cdot \tan\delta_k}{\gamma_{R,h}} \quad (28)$$

Regarding the plain surface of the prefabricated concrete blocks and the steel frame, the angle of friction in the subsoil should be limited to $\delta_k = 2/3 \cdot \varphi'$. For the partial safety factor of the friction resistance $\gamma_{R,h} = 1{,}1$ should be used. The final proof in the analysis of the sliding stability is as follows:

$$E_{h,d} \leq R_{h,d} \quad (29)$$

3.3 Limitation of the eccentricity

For the analysis of the limitation of the eccentricity, the moments in point D in Figure 6 are calculated. The moments occur due to the vertical component $F_{v,k}$ of the tension force F_k and due to the dead load of the counterweight G_k. The impact moment and the resistance moment are as follows:

$$M_{E,d} = F_{v,k} \cdot l \cdot \gamma_{Q,dst} \quad (30)$$

$$M_{R,d} = G_k \cdot \frac{l}{2} \cdot \gamma_{G,stb} \quad (31)$$

The partial safety factors are $\gamma_{Q,dst}$ = 1,05 and $\gamma_{G,stb}$ = 0,90. Equation (32) shows the final proof. In addition the eccentricity e should not exceed l/3 on the level of the characteristic loads (Eq. 33).

$$M_{E,d} \leq M_{R,d} \quad (32)$$

$$\frac{F_{v,k} \cdot l/2}{G_k - F_{v,k}} \leq \frac{l}{3} \quad (33)$$

3.4 Bearing resistance

The bearing resistance failure is caused by excessive stress in the ground due to the applied load. Very important is to consider the eccentricity e which shortens the length l to l'. This shortened length is the effective length l' = l – (2 · e). The impact V_k (kN) is the dead load of the counterweight G_k reduced by the vertical component $F_{v,k}$ of the tension force F_k. The impact on the design level is described by equation (34).

$$V_d = \left(G_k - F_{v,k}\right) \cdot \gamma_Q \quad (34)$$

The bearing resistance $R_{v,k}$ is influenced by the effective base area of the counterweight, the angle of friction φ' (°), the cohesion c' (kN/m^2) and the inclination of the load. The counterweight does not have any embedment depth. The design value of the bearing resistance is

$$R_{v,d} = \frac{R_{v,k}}{\gamma_{R,v}} \quad (35)$$

4 SPINNANKER

The Spinnanker is a new type of foundation and anchorage system consisting of threaded steel bars that are screwed into the soil. It can be easily installed in both cohesive and non-cohesive soils using a hand-held turning machine. The common models have 6 to 18 threaded bars, which are screwed into the subsoil through a circular anchor plate. Figure 7 shows a Spinnanker type XII / 2.0 / 15. Bars with different diameters 15, 18, 20 and 26 mm can have a length from 2.0 to 8.0 m and are installed with different inclinations. The diameter of the plate, the number and the length of the bars depend on the soil condition and the load. The possible applications are described in Katzenbach et al. (2019a). Figure 8 shows for example the anchoring for installing a new 380 kV high-voltage line.

Figure 7. Spinnanker XII / 2.0 / 15 (12 threaded bars with a length of 2.0 m and a nominal diameter of 15 mm).

Figure 8. Anchoring with Spinnankers for a new 380 kV high-voltage line in Germany.

4.1 Load-deformation behaviour

The load-deformation behavior of the Spinnanker can easily be described by vertical pull-out tests. Figure 9 shows a typical load-displacement curve obtained from a pull-out test. The maximum load was in this case 180 kN at a displacement of only 2.5 mm.

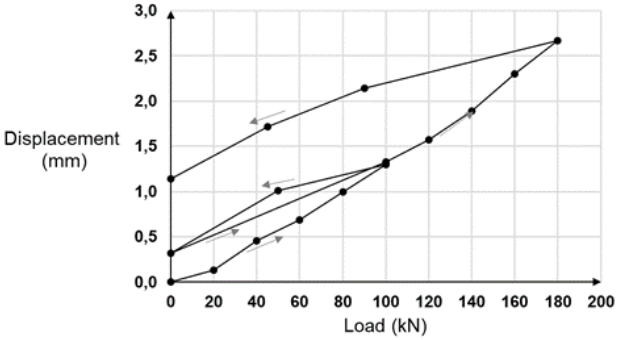

Figure 9. Vertical pull-out test on a Spinnanker XII / 3.0 /15 in fine and medium sand with medium density.

4.2 Design and safety concept

The first step is a preliminary design based on the large number of former load tests. The second step is the final design based on suitability load tests in-situ which leads to the characteristic value of the bearing

capacity $R_{t,k}(\vartheta, n_{Sp})$ in (kN) for an inclined load (inclination ϑ) and/or for a group of multiple Spinnankers (amount n_{Sp}). For the ultimate limit state, the design value of the load bearing capacity is calculated using partial safety factors according to EN 1997-1:

$$R_{d,\vartheta} = \frac{R_{t,k}(\vartheta, n_{Sp})}{\gamma_{s,t}} = \frac{R_{t,k}}{\gamma_{s,t}} \cdot k_\vartheta \cdot k_n \qquad (36)$$

In Eq. (36) the correction factors k_ϑ for the inclination of the load and k_n for the amount of Spinnankers in a group are included. The partial factor for the resistence is $\gamma_{s,t} = 1.15$ based on the results of in-situ load tests. The design resistance $R_{d,\vartheta}$ (kN) should be higher than the design load $E_{d,\vartheta}$ (kN) which correspond to a resulting force in the direction $\vartheta = \alpha$ (°):

$$E_{d,\vartheta} \leq R_{d,\vartheta} \qquad (37)$$

For a conservative approach for the design load $E_{d,\vartheta}$ the partial factor γ_Q = 1,3 is used. A detailed description of the design and safety concept is given in Katzenbach et al. (2019b) and Leppla et al. (2022).

5 COMPARISON OF ANCHOR POINTS

Based on an example from engineering practice the three different temporary anchor points are designed. The boundary conditions are as follows:

- tension force F_k = 120 kN, inclination α = 60 °
- medium dense sand/gravel:
  γ = 19 kN/m^3, φ' = 32.5 °, no groundwater

The results of the design of the three different anchor points are as follows:

- deadman structure:
  steel pipe, diameter d = 406 mm,
  length l = 4 m, depth t = 3 m
- counterweight:
  concrete blocks, total volume 13.8 m^3 and 31.8 tons, ground area a/b = 2.4 m / 2.4 m
- Spinnanker:
  1 x XII / 4.0 / 15 with only 120 kg of steel

6 CONCLUSIONS

As shown, the design concepts of the three different temporary anchor points are significantly different. Regarding the level of safety it has to be pointed out, that for deadman structures and for counterweights no in-situ load tests are carried out in engineering praxis. This leads to uncertainty in the design and the resulting lower level of safety.

In addition, the different efforts for construction regarding the necessary use of resources have to be focused. An optimized design and construction leads to the minimization of the CO_2-emission.

For the design and construction of temporary anchor points, the following aspects and requirements have to be considered:

- All necessary geotechnical parameters have to be detected by a professional soil and groundwater investigation.
- The construction of deadman structures and of counterweights leads to a heavy impact on the environment.
- The design of a Spinnanker is based on in-situ load tests. This leads to a well defined level of safety and an economic optimization.
- Compared to other systems, the Spinnanker leads to a lower emission of CO_2.
- Regarding the technical regulations in EN 1997-1 the bearing capacity of all anchor systems has to be verified by in-situ load tests. Therefore, load tests for deadman structures and counterweights are necessary.

ABSTRACT: This paper reports on large scale tests of monopile foundations for Offshore Wind Turbines (OWT) to be conducted in test site in Zeebruges, Belgium, in the framework of the SAGE-SAND project (*Soil ageing around OWT foundations – from operational response to decommissioning*). The project aims to investigate the evolution of the soil mechanical properties with time, and the alternative use of vibratory driving, to hammering, for installation and decommissioning of monopiles. Four hollow steel monopiles will be installed, by impact hammering and by vibratory driving, at a location where the soil conditions are representative of the Belgian sector of the North Sea. At selected time intervals during the project, the piles will be subjected to lateral loading at a fraction of their lateral capacity. Both the soil ageing effects and the influence of the installation method will be investigated. Herein an overview of the SAGE-SAND field testing program is presented, along with geotechnical information obtained from standard in-situ tests. Cone Penetration Tests (CPTs), as well as geological information and existing boreholes in the vicinity of the project are shown. Available correlations and empirical relationships from the Belgian practice are used to infer the soil stratigraphy and relate CPT data to soil properties necessary to perform predictive numerical simulations. Continuous in-situ tests such as cross hole tests and CPTs to the proximity of the piles throughout the duration of the project will allow the examination and the analysis of the soil ageing process.

RÉSUMÉ: Ce document rend compte de tests à grande échelle de fondations monopieux pour les éoliennes offshore (OWT) à réaliser sur un site d'essai à Zeebruges, en Belgique, dans le cadre du projet SAGE-SAND (vieillissement du sol autour des fondations OWT - de la réponse opérationnelle à la mise hors service). Le projet vise à étudier l'évolution des propriétés mécaniques du sol avec le temps, ainsi que l'utilisation alternative du battage vibratoire, par rapport au martelage, pour l'installation et la mise hors service des monopieux. Quatre monopieux en acier creux seront installés, par martelage et par battage vibratoire, dans un endroit où les conditions du sol sont représentatives du secteur belge de la mer du Nord. À des intervalles de temps sélectionnés pendant le projet, les pieux seront soumis à une charge latérale correspondant à une fraction de leur capacité latérale. Les effets du vieillissement du sol et de la méthode d'installation seront tous deux étudiés. Une vue d'ensemble du programme d'essais sur le terrain SAGE-SAND est présentée ici, ainsi que des informations géotechniques obtenues à partir de tests in situ standard. Des essais de pénétration au cône (CPT), ainsi que des informations géologiques et des sondages existants à proximité du projet, sont également présentés. Des corrélations disponibles et des relations empiriques issues de la pratique belge sont utilisées pour déduire la stratigraphie du sol et relier les données CPT aux propriétés du sol nécessaires à la réalisation de simulations numériques prédictives. Des tests in-situ continus tels que des essais de trou traversant et des CPT à proximité des pieux tout au long de la durée du projet permettront l'examen et l'analyse du processus de vieillissement du sol.

Keywords: Offshore geotechnics; mono-pile foundations; site investigation; large-scale tests.

1 INTRODUCTION

Offshore wind energy, decisive in the global shift towards green energy, is marked by ambitious plans worldwide to expand wind farms for a sustainable, long-term renewable energy supply. The wind farms, consisting of large turbines, hold significant potential to generate multi-gigawatts of electricity. The focus on minimizing costs for offshore turbines is crucial for achieving this long-term vision and requires advanced engineering approaches for design and site-specific optimization, especially for the foundations, that constitute approximately 30% of the total cost (Gavin et al., 2016).

Monopiles are the most commonly used foundation system for Offshore Wind Turbines (OWTs): large-diameter steel tubes which are either impact- or vibratory driven into the seabed. Recent studies conducted to advance design methodologies for monopiles for OWTs result from the findings of the PISA project. As such, a new design method has been developed by combining numerical modelling approaches and findings from large-scale monopile tests conducted at two sites, namely Dunkirk (dense sand) (Byrne et al., 2020) and Cowden (stiff clay) (Burd et al., 2020). The tests mainly focused on monotonic lateral loading and explored the rate effects and cyclic loading. However, previous research efforts have suggested the need for investigating the effect of soil ageing and installation method on the monopiles' response, as described in the following.

The soil ageing phenomenon, often referred to as "set-up," has been studied in the context of driven piles in clay, where the dissipation of excess pore pressures induced by driving leads to a positive gain in capacity with time (Gavin et al., 2016). However, the understanding of the mechanisms of ageing for piles in sand, as well as the quantification of its effect on the monopile's stiffness and lateral capacity, remains still much less explored. Field studies were conducted by researchers at Imperial College London (IC), the Norwegian Geotechnical Institute (NGI), and University College Dublin (UCD), to shed light on the behaviour of monopiles subjected to ageing processes.

All these studies revealed that ageing effects on steel pipe piles may be responsible for an increase in axial capacity with time (Jardine et al., 2005), although with variable growth rates. Karlsrud et al. (2014) attributed this variability to local soil conditions, emphasizing the need for site-specific considerations in understanding ageing effects.

On top of such considerations, environmental concerns regarding noise emissions during pile driving have led to the development of alternative installation methods to mitigate the impact on marine ecosystems.

The Vibro project conducted a major field trial at Cuxhaven involving six instrumented monopiles. The project's findings, as presented by Achmus et al. (2020), indicate that when monopiles in sand are installed by vibro-driving without specific requirements, reduction factors for stiffness during primary loading and unloading should be considered in the design. The study concludes the need for further research to identify optimum installation parameters.

Figure 1. Experimental site for large scale pile testing established for the SAGE-SAND project in Zeebruges, Belgium.

The SAGE-SAND project *"Soil ageing around offshore wind turbine foundations - from operational response to decommissioning"* aims to study the interaction between soil and pile for OWTs, in order to understand the effects of the soil ageing and of the installation process on the lateral behaviour of the foundation system during its lifetime, up to the decommissioning of the pile. For this purpose, an experimental site has been selected at the Port of Antwerp-Bruges in Zeebruges, Belgium (Figure 1).

The main aim of this paper is to show preliminary findings from the research project's initial stage, focusing on the CPT measurements to enhance understanding of the reference site.

2 OVERVIEW OF THE PROJECT

The experimental campaign provides for: an extensive geotechnical site investigation, the pile installation, lateral pile load tests, and at the end, the pile extraction. The geotechnical site characterization includes borings to identify the soil stratigraphy and retrieve samples for laboratory tests (e.g., soil classification, triaxial test), cross-hole tests, inclinometer measurements, Cone Penetration Tests (CPTs), seismic CPTs, and the geophysical method Multichannel Analysis of Surface Waves (MASW).

The piles have a diameter of 2.0 m and an embedded length of 18 m. According to the initial plan

two piles will be vibratory installed, and two piles will be hammered. The dynamic pile response during driving will be measured using accelerometers. The strains along the pile will be continuously measured using optical Fiber Bragg Gratings (FBG's). Piezometric pore water pressures in the vicinity of the piles will detect overpressures, that arise during the driving and can induce liquefaction of the surrounding soil. As the heat from the driving process may influence the chemical and ageing processes in the foundation soil, the temperature distribution will be measured using thermocouples, and the soil plug inside the piles will be monitored.

The long-term monitoring plan includes regular CPTs at the proximity of the piles, repeated cross-hole tests, and pile impedance measurements. The continuous monitoring will be carried out at selected time intervals, following lateral load tests. This way it aims to capture the evolution of soil properties with time, to provide insights crucial to achieve the project's objectives. The present paper focuses on the analysis and interpretation of the CPT campaign.

3 GEOLOGICAL INFORMATION

Preliminary information about the local geology has been obtained from the Databank Ondergrond Vlaanderen (DOV). This is a database that provides geological and geotechnical information from the Flemish subsurface, available via the online DOV Portal (DOV, 2023). The subsoil at the test site consists of Quaternary deposits up to a depth of 22.50 m, Tertiary (Eocene) and Quaternary layers up to a depth of 27.5 m, on top of Tertiary layers. The groundwater is saline. A complete set of data is retrieved from an existing borehole, near the test site (borehole: 1439-BB69-1818, DOV portal).

The samples extracted during the execution of this borehole are available in the Geotheek, the Flemish repository for samples from the subsurface (DOV, 2023). This helped gain an initial understanding of the stratigraphy at the nearby test location. In this regard, eight layers have been identified (starting from the ground surface): silt, fine sand interspersed by silt, silty clay, peat, silty sand, medium sand interspersed by thin lenses of fine sand.

4 CONE PENETRATION TESTS

4.1 Description of the equipment and test locations

Four electrical cone penetration tests (e-CPTs) were conducted at the locations of the piles, as shown in Figure 2. The probes were performed using a 10 cm^2 electric cone. The cone resistance, q_c, and the friction resistance, f_s, are measured at depth intervals of 1 cm. Their ratio, expressed as a percentage, yields the parameter R_f, friction ratio.

Figure 2. CPTs performed at the locations of the piles.

4.2 CPT data and soil layering

The CPTs data are used to determine the stratigraphy of the subsoil and estimate its properties. In particular, the acquired data are interpreted using available empirical methods to estimate the soil engineering parameters, such as strength and stiffness, that are required to conduct installation and lateral load analyses of the test piles. In particular, the subsoil at the test location has been idealized as a layered deposit, where each layer is considered homogeneous, and it is characterised by average constant q_c and R_f values. These values are calculated by omitting the extreme peaks, identified using the statistical method called "interquartile range" to find the outliers of a dataset. Figure 3 shows the CPT data in terms of q_c and R_f, at the four investigated locations S1, S2, S3 and S4, as well as the idealized soil layers. The complete set of the CPT data will be made available on the database titled Databank Ondergrond Vlaanderen (URL:https://www.dov.vlaanderen.be/portaal/?module=verkenner).

5 BELGIAN GUIDELINES FOR CPT DATA INTERPRETATION

The recommendations by the Belgian standard 'NBN EN 1997-1 ANB' were adopted to identify the mechanical properties of the soil layers. The average q_c and f_s values are used to provide such estimates. Table 2 presents the soil effective unit weight γ', the friction angle φ', the undrained shear strength c_u, and effective cohesion c'.

Table 2. Soil mechanical properties per layer according to the Belgian practice (NBN EN 1997-1 ANB).

Layer	γ' (kN/m^3)	φ' (°)	c_u (kPa)	c' (kPa)
1	9	28	-	-
2	8	25	25	2
3	7	23	14	2
4	2	15	20	5
5	9	30	-	-
6	10	35	-	-
7	10	30	-	-
8	10	35	-	-

6 GEOTECHNICAL CORRELATIONS USING CPT DATA

Suitable correlations from the literature have been selected to provide additional CPT-based predictions of the soil parameters.

The total unit weight, γ, was estimated from CPT data using the relationship proposed by Robertson and Cabal (2015):

$$\frac{\gamma}{\gamma_w} = 0.27\ logR_f + 0.36\ log\left(\frac{q_t}{p_a}\right) + 1.236 \quad (1)$$

where γ_w is the unit weight of water, p_a is atmospheric pressure, q_t is the CPT corrected total cone resistance.

To estimate the peak friction angle, φ', the expression by Uzielli et al. (2013), valid for clean quartz sands, was adopted:

$$\varphi' = 25\left[\frac{(q_t/p_a)}{\sqrt{\sigma'_{v0}/p_a}}\right]^{0.1} \quad (2)$$

where σ'_{v0} is the in-situ vertical effective stress.

The soil relative density, D_R, was estimated by the formula proposed by Jamiolkowski et al. (2003), which is valid for clean silica sands:

$$D_R = 100\left[-0.675 + 0.268\ ln\left(\frac{q_c/p_a}{\sqrt{\sigma'_{v0}/p_a}}\right)\right] \quad (3)$$

The overconsolidation ratio, OCR, was evaluated as the ratio between the soil effective yield stress, σ'_p, and σ'_{v0}. To estimate σ'_p, the correlation provided by Mayne (2013) valid for all soils was adopted:

$$\sigma'_p = 0.33(q_t - \sigma_{v0})^m (p_a/100)^{1-m} \quad (4)$$

where σ_{v0} is the total vertical stress, m can be calculated by Eq. (5) as suggested by the author:

$$m = 1 - \frac{0.28}{1 + (I_c/2.65)^{25}} \quad (5)$$

where I_c is the soil behaviour type index as reported in Robertson and Wride (1998) and Robertson (2009).

The following relationship between c_u and OCR, valid for fine-grained soils, was adopted, considering that the compression indices and φ' are not known with confidence (Ladd and DeGroot, 2003):

$$c_u = \sigma'_{v0} 0.22 OCR^{0.8} \quad (6)$$

To estimate the small strain shear modulus, G_0, the well-known relationship between G_0 and the shear wave velocity, V_s, provided by the elasticity theory, has been considered. A number of empirical correlations to estimate the V_s profile using CPT data are available in literature. Herein, the in-situ V_s profiles were estimated using the equation derived by Mayne (2006) which was obtained from a well-documented experimental dataset of saturated clay, silt, and sand sites:

$$V_s = 118.8 \log f_s + 18.5 \quad (7)$$

where V_s is in (m/s) and f_s in (kPa).

A more accurate estimation of G_0 will result from the interpretation of the MASW data and cross-hole tests data.

Table 3 presents the estimated values of the layers' physical and mechanical properties, namely the soil effective unit weight, γ', peak friction angle, φ', relative density, D_R, overconsolidation ratio, OCR, undrained shear strenght, c_u, and small strain shear modulus, G_0.

Table 3. Soil mechanical properties per layer according to correlations for the CPT interpretation at the test site.

Layer	γ' (kN/m³)	φ' (°)	D_R (%)	OCR (-)	c_u (kPa)	G_0 (MPa)
1	9	-	-	18	20	89
2	7	-	-	3	13	66
3	7	-	-	3	23	59
4	8	-	-	5	42	104
5	9	39	53	3	-	98
6	10	42	70	3	-	130
7	9	38	49	2	-	104
8	10	42	69	2	-	132

Note that values for the soil mechanical properties are not reported for the layer types that fall outside the applicability range of the adopted correlations. Detailed analyses are included in the geotechnical report titled "Interpretation of CPT results for the SAGE-SAND test site in Zeebrugge" (Letizia et al., 2023). By comparing the estimated parameters presented in Tables 2 and 3, large differences in values can be observed. This discrepancy can be attributed to the fact that the Belgian guidelines provide a rather conservative estimation of the soil parameters to be used in design based on the experience of the local soils.

7 CONCLUSIONS

This study presents an analysis of geotechnical data obtained from the SAGE-SAND project's site CPT campaign. Specifically, the geotechnical interpretation of four CPTs conducted at the site in Zeebruges, Belgium, is presented. The research project aims to quantify the impact of the soil ageing and installation process, namely impact hammering and vibratory driving, on the lateral capacity and stiffness of monopiles for offshore wind turbines, as well as on extractability of such foundations during the decommissioning phase. This work focuses on the geotechnical characterization of the test site, and provides its soil stratigraphy by interpreting CPTs using the Belgian design guidelines and correlations from the existing literature. Additional tests which include geophysical methods (MASW), cross-hole tests, seismic CPTs and extensive laboratory tests are currently ongoing to best identify the soil properties to be used consequently to simulate the pile installation and make predictions of the lateral monopile response.

ACKNOWLEDGEMENTS

The academic consortium KU Leuven – UCLouvain – ULiege is grateful for the financial support provided by the Energy Transition Fund (Energietransitiefonds, ETF2022), via the project SAGE-SAND Soil ageing around OWT foundations – from operational response to decommissioning.

ABSTRACT: Mechanical energy storage can cope with the intermittent power supply of renewable energy sources (e.g. solar and wind). Concurrently, the green transition requires carbon capture and utilization technologies. This paper presents a novel concept of underground impermeable capsules formed by CO_2 hydrates, which can be used to pressurize gas and/or fluids (water, air, and/or carbon dioxide) for energy storage. Such capsules can be used for Pumped-Hydro Compressed Carbon Dioxide Energy Storage; in which water is compressed against pressurized gas in the capsule. This "green" use of gas hydrates can deliver both energy storage and carbon utilization objectives, in onshore and offshore applications. The paper first presents the construction phases and working principles of this underground mechanical energy storage. Next, temperature-pressure requirements for CO_2 gas hydrate stability are outlined, identifying a depth range of 30 m – 200 m as ideal for hydrate capsule creation. Finally, a simplified mechanical model based on elasticity is developed to quantify energy storage as a function of capsule geometry and material behavior.

RÉSUMÉ: Le stockage mécanique de l'énergie peut faire face à l'alimentation électrique intermittente des sources d'énergie renouvelables (par exemple, solaire et éolienne). Parallèlement, la transition verte nécessite des technologies de captage et d'utilisation du carbone. Cet article présente un nouveau concept de capsules souterraines imperméables formées d'hydrates de CO_2, qui peuvent être utilisées pour pressuriser du gaz et des fluides (eau, air et/ou dioxyde de carbone) en vue du stockage d'énergie. De telles capsules peuvent être utilisées pour le stockage d'énergie du dioxyde de carbone comprimé-hydro-pompé; dans lequel l'eau est comprimée contre le gaz sous pression dans la capsule. Cette utilisation « verte » des hydrates de gaz peut atteindre à la fois les objectifs de stockage d'énergie et d'utilisation du carbone, tant dans les applications terrestres qu'offshore. Le document présente d'abord les phases de construction et les principes de fonctionnement de ce stockage mécanique souterrain d'énergie. Ensuite, les exigences de température et de pression pour la stabilité des hydrates de CO_2 sont décrites, identifiant une plage de profondeur de 30 m - 200 m comme idéale pour la création de capsules d'hydrates. Enfin, un modèle mécanique simplifié basé sur l'élasticité est développé pour quantifier le stockage d'énergie en fonction de la géométrie de la capsule et du comportement des matériaux.

Keywords: Energy storage; gas hydrates; geotechnical engineering; carbon utilization.

1 INTRODUCTION

The EU has set a target of achieving a minimum of 40% renewable energy by 2030. Such movement towards renewable sources requires a capability of energy storage to accumulate surplus production, to be discharged when demand is greater than output (Guney and Tepe, 2017).

One sustainable way to store renewables is Underground Mechanical Energy Storage (UMES), which could level demand and production by pumping/discharging pressurized fluids into/from an

underground natural or man-made reservoir. There are two main approaches for underground energy storage: (*i*) Underground Pumped Hydroelectric Storage (UPHS), in which surplus production is stored as gravity (potential) energy by lifting a manmade soil mass ("overburden") when inflating with water a buried geomembrane-lined bag (Norlyk et al., 2020; Olsen et al., 2015); (*ii*) Compressed Air Energy Storage (CAES) using compressors to convert renewables into exergy as compressed air reservoirs at constant volume (isochoric) or constant pressure (isobaric) that is, then, expanded across a turbine to recover electricity (Budt et al., 2016). Proof-of-concept studies have investigated UPHS for shallow man-made membrane-lined reservoirs in sandy overburden, with difficulties in preventing straining of the lining used for the man-made reservoir (Olsen et al., 2015). On the other hand, CAES using underground air reservoirs is not competitive due to geological restrictions and uncertainties/variabilities of underground spaces affecting its airtightness (Budt et al., 2016). A hybrid approach of Pumped-Hydro Compressed Air Energy Storage (PH-CAES) has been studied (Pottie et al., 2020). Concurrently, recent studies proposed innovative thermo-mechanical closed-cycle energy storage having Carbon Dioxide (CO_2) as working compressed fluid in Compressed Carbon Dioxide Storage (CCDS) (Manzoni et al., 2022). Thus, there is scope to combine Carbon Capture, Utilization, and Storage (CCUS) with UMES to reduce the carbon dioxide in the atmosphere and mitigate climate change.

This paper presents a novel concept for energy storage based on man-made CO_2 hydrate capsules that serve as pressurized underground reservoirs for compressed fluids; this unites the objectives of UMES and CCUS. The paper is composed of four sections. Firstly, the construction and working principle are conceptually presented. Secondly, the feasibility of the CO_2 hydrate capsules is studied. Thirdly, the relative portion of energy storage in the domain is analyzed by a simple mechanical model. Finally, the key research questions required for further advancement of the suggested approach are presented.

2 PROPOSED UMES CONCEPT

Figure 1 illustrates the steps of construction and operation of the proposed concept of UMES using pressurized CO_2 gas hydrate capsules to store energy. While illustrated for offshore conditions, this solution can also be employed onshore.

To overcome the shortcomings of natural reservoirs, it is proposed to construct a (nearly) impermeable capsule using CO_2 gas hydrate in permeable porous soil deposits at intermediate depths of 10 m – 200 m. First, a spherical (filled) body is formed of CO_2 hydrate from the "creation" well through seepage in a porous medium (e.g. coarse-grain soil with an appropriate coefficient of permeability), as shown in Figure 1a. Then, the inner volume of the spherical hydrate body is dissociated to remain with soil and water within an external thick and relatively impermeable boundary, illustrated in Figure 1b. The disassociation would be triggered by a reduction in pore pressures and/or heat conduction through the well; the thermal-pressure conditions under which CO_2 gas hydrate can form and remain stable are discussed in the subsequent section. The thickness of the hydrate layer (forming the capsule) may be regulated by both the duration of a controlled hydrate formation and later dissociation processes.

As hydrates can reduce the permeability of sandy soil by a factor of 1000 for a volumetric hydrate saturation of 50% (Minagawa et al., 2005), the spherical hydrate shell structure practically forms an impermeable barrier.

Prior to standard operations, the man-made vessel (i.e., the capsule embedded in the deformable ground) may be internally pressurized to increase the energy storage capability of the system. The water inside the man-made hydrate structure can be pressurized or replaced by compressible gas (Figure 1c) depending on the storage approach: namely, (*i*) entire water removal and gas injections for the deploying compressed gas storage; (*ii*) water injections to use the capsule for underground pumped hydro storage; (*iii*) the water in the inner volume is partially replaced by pressurized gas, allowing for a hybrid solution in which water is compressed against gas to allow the use of hydraulic turbines. Thus, there are multiple possible applications of CO_2 gas hydrate capsules.

Furthermore, either air or CO_2 may be used as working gas. The use of CO_2 instead of air offers a four-fold advantage: CO_2 can serve as a self-healing material (recreating and sealing hydrate within tension-induced cracks), it will enhance efficiency (minimizing exergy losses) as it has ease of compression compared to air (Astolfi et al., 2022) and minimal dissolution in water at the operating pressure and temperature ranges (Shindo et al., 1995). Also,

using CO_2 as a construction material may benefit the carbon footprint.

The optimal envisioned application would be hybrid Pumped-Hydro Compressed Carbon Dioxide Energy Storage. During operations, see Figure 1d, the injection of water into the well would store mechanical energy in the compressed gas and water, and strain energy in the deformable capsule and ground (i.e. the vessel components). The stored energy is recovered by discharging the pressurized water across a turbine, exploiting efficient turbine/pump systems currently used in above-ground pumped hydro storage.

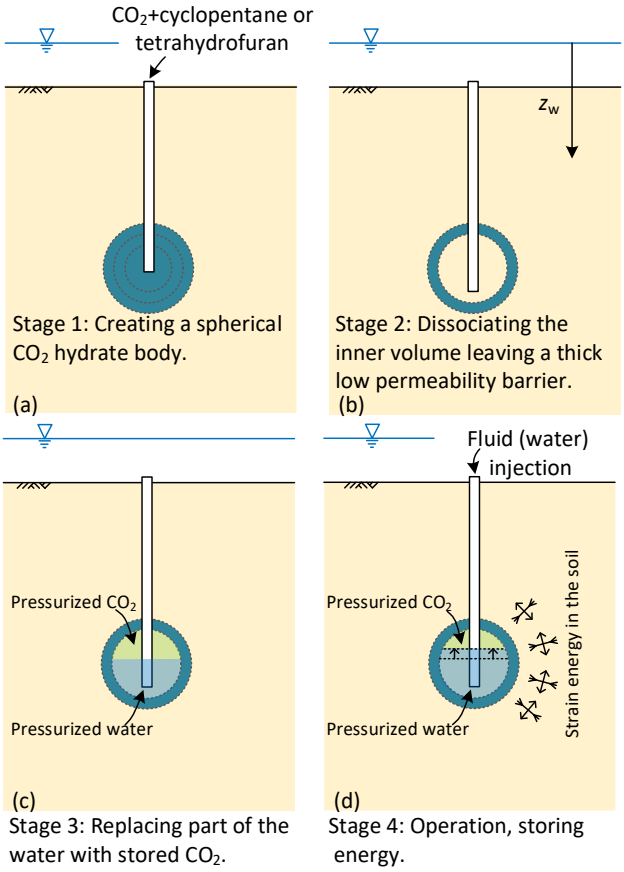

Figure 1. Hydrate capsule formation and operation.

3 STABILITY REQUIREMENTS OF CO_2 GAS HYDRATES

CO_2 gas hydrates require high pressures and low temperatures to be stable, with an exponentially increasing trend between dissociation pressure and temperature. For instance, Herslund et al. (2012) reported CO_2 gas hydrates being stable at 10°C for pressures greater than 4 MPa. This stability condition would not be compatible with the envisioned application at intermediate depths. However, the use of promoters such as cyclopentane or tetrahydrofuran (or a mixture of which) with concentrations of up to about 5 % of the water by mass, can reduce the hydrate formation pressure to values less than 1 bar (=100 kPa) at 13 °C (Herslund et al., 2014) and less than 4 bar (=400 kPa) at 19 °C.

Figure 2 shows the hydrate phase equilibrium together with the pressure-temperature profile of the groundwater in an offshore environment for a location in the North Sea with seabed depth H_w = 10 m or 80 m: the hydrate is stable when water pressure is greater than the disassociation pressure at a given temperature. As can be seen, pressure and temperature conditions for the stability of CO_2 gas hydrate capsules are met for a depth, below water table (z_w), ranging from 30 m to 400 m, approximately. On the other hand, CO_2 gas hydrates with promoters may not be stable at shallow depths (due to a combination of high temperatures and low pressures) or at water depths greater than 500 m (due to the increase in water temperature with depth and the exponential increase in dissociation pressure with temperature).

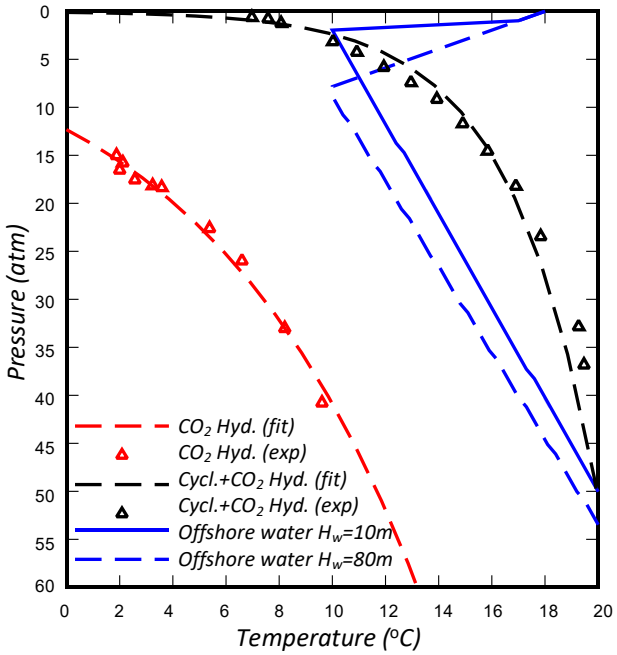

Figure 2. CO_2 hydrate stability condition versus offshore water and temperature profiles.

Therefore, when adopting cyclopentane or tetrahydrofuran promoters, vessel systems based on CO_2 gas hydrates are suitable for intermediate depths only. Furthermore, the internal temperature conditions within the vessel must be kept within the bounds of the hydrate's phase transformation curves throughout the operation to avoid impacting the formed capsule. Also, for offshore applications, water salinity and shallow

water temperature need to be considered. Jensen et al. (2011) reported that salinity (3.5 wt % NaCl solution) shifted the P-T curve by 2°C (leftwards in Figure 2); if considering a similar shift in CO_2 gas hydrates, the feasible depth range for capsule creation will reduce to 200 m. Future works will explore feasibility depths for onshore conditions.

4 A SIMPLIFIED MODEL FOR ENERGY DIVISION

This section presents a simple model to evaluate the energy storage ratios among the various system components.

To this aim, we assume that the entire system is elastic, and does not involve yielding. In addition, we assume that the internal soil (enclosed by the capsule) is found under homogenous and isotropic state. This condition could be considered correct for fully air or water saturated, and a fair estimation for the mixed condition. Under these conditions, one can consider a four-part system, as illustrated in Figure 3.

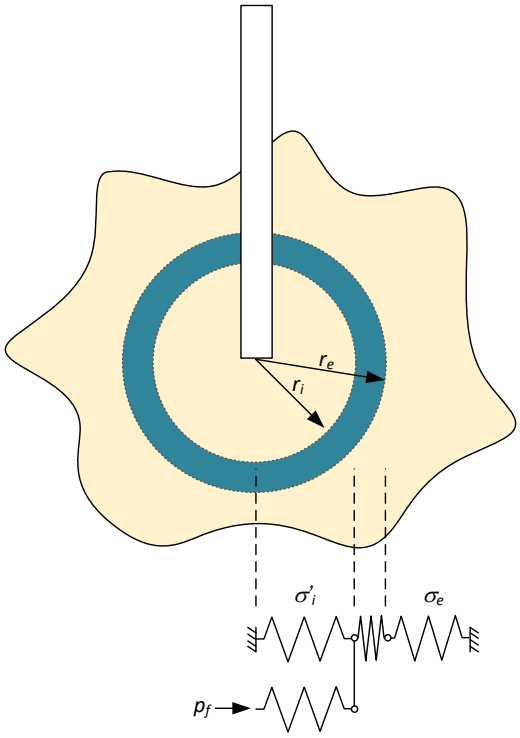

Figure 3. Simple model for evaluating the stress condition.

Considering an infinite elastic domain beyond the external boundary of the capsule, one can relate the pressure change at the boundary to the displacement of the outer boundary as follows:

$$u_e = \frac{\Delta\sigma_e}{4G_s} r_e \qquad (1)$$

where u_e is the displacement at the outer boundary at the distance r_e, $\Delta\sigma_e$ is the change of radial stress at the outer boundary (positive in compression), G_s is the shear modulus of the soil. Note that no volumetric strains develop at this outer region, and consequently no changes in pore pressure occur.

Applying the governing equations of elasticity to the hydrate bearing soil section, with the total stress boundary condition at its two boundaries results in:

$$u_h(r) = \frac{r_e^3 r_i^3 (\Delta\sigma_i - \Delta\sigma_e)(1+\nu) + 2r^3(1-2\nu)(r_i^3\Delta\sigma_i - r_e^3\Delta\sigma_e)}{4\,G_h r^2 (r_e^3 - r_i^3)(1+\nu)} \qquad (2)$$

where G_h is the shear modulus of the hydrate bearing soil. In general hydrate bearing soils exhibit significantly larger stiffness (e.g. Klar et al., 2010; Uchida et al., 2012) as well as dilatancy (e.g. Pinkert, 2016; Cohen and Klar, 2019), although this is somewhat irrelevant to the elastic solution presented here.

Assuming a uniform and isotropic stress condition in the inner region results in the following equation:

$$u_i = -\frac{\Delta\sigma'_i}{3\,K_s} r_i = -\frac{\Delta\sigma_i - \Delta p_f}{3\,K_s} r_i \qquad (3)$$

where p_f is the uniform fluid or gas pressure, and K_s is the bulk stiffness of the soil skeleton in the internal body. Overall, there are 4 unknowns ($u_i, u_e, \Delta\sigma_i, \Delta\sigma_e$) and 4 equations that allow for a solution to be established (Eq. 1., Eq. 2 applied at $r = r_i$ and at $r = r_e$ with the values of u_i and u_e, and Eq. 3).

Eq. 4 and 5 (below) provide the solution for the case in which the Poisson's ratio of the hydrate bearing soil is 1/2 (representing an impermeable undrained in terms of total stresses):

$$\Delta\sigma_i = \frac{4\left(G_s r_i^3 + G_h\left(r_e^3 - r_i^3\right)\right)}{(4G_h + 3K_s) r_e^3 - 4(G_h - G_s) r_i^3} \Delta p_f \qquad (4)$$

$$\Delta\sigma_e = \frac{4G_s r_i^3}{(4G_h + 3K_s) r_e^3 - 4(G_h - G_s) r_i^3} \Delta p_f \qquad (5)$$

The final displacement, u_i and u_e can be calculated by substituting the above stress changes in to Eqs. 1 and 3, or alternatively in to Eq. 2 with the associated radii. The strain energy stored in each region is as follows. For the inner zone:

$$E_{inner} = \frac{6K_s \pi r_e^6 r_i^3}{\left((4G_h + 3K_s) r_e^3 - 4(G_h - G_s) r_i^3\right)^2} \Delta p_f^2 \qquad (6)$$

For the hydrate bearing soil:

$$E_{hbs} = \frac{8G_h\pi r_e^3 r_i^3 (r_e^3 - r_i^3)}{\left((4G_h+3K_s)r_e^3 - 4(G_h-G_s)r_i^3\right)^2}\Delta p_f^2 \qquad (7)$$

and for the outer region:

$$E_{outer} = \frac{8G_s\pi r_e^3 r_i^6}{\left((4G_h+3K_s)r_e^3 - 4(G_h-G_s)r_i^3\right)^2}\Delta p_f^2 \qquad (8)$$

Again, these expressions assume a Poisson's ratio of 1/2 only for the hydrate bearing soil. At the limit cases where only water (or other fluid) is pressurized the energy stored in the fluid would be:

$$E_{fluid} = \frac{2\pi r_i^3}{3\frac{K_f}{n}}\Delta p_f^2 \qquad (9)$$

where K_f is the bulk stiffness of the fluid and n is the soil porosity. Eq. 9 is a rough estimate of the change in the stored energy of gas if the change in pressure (p_f) is small and K_f is taken as p_g (for ideal gas).

For partially water and gas filling conditions, K_f can be replaced by an equivalent stiffness of $K_{eq} = K_w K_g / \left(S_w K_g + S_g K_w\right)$ where K_w and K_g are the bulk stiffnesses of the water and gas, and S_w and S_g are the volumetric fractions of water and gas in the capsule ($S_w + S_g = 1$). Under this condition, there is still a clear proportionality between the components of energy storage that can be examined.

Figure 4 shows the relative part of each region in energy storage as a function of the radii of the hydrate boundaries for material properties relevant for water saturated inner region and for mixed filling condition with $K_{eq}/n = 0.5G_s$. In practice r_e/r_i would be close to 1 for large capsules and in the range of 1.2 to 2 for small capsules, suggesting that for water saturated inner region most of the energy will be stored in the soil for large capsules, and largely in the hydrate bearing soil for small capsules. Clearly, Figure 4 does not reveal information about the storage capacity but merely on the division between the components.

When K_f is associated with fully gas saturated, the ratios effectively become such that all the energy is stored in the gas, with almost no contribution from the soil. This is also true for the mixed water-gas condition, as any small amount of gas greatly reduces the equivalent stiffness (as can be evaluated by K_{eq}, or in Figure 4 for the mixed condition in which the gas stores more than 90% of the energy). This suggests that for gas storage the suggested approach simply results in a subsurface porous gas container.

The above spherical 'elastic' model is limited but could be the basis for the extension and inclusion of hydrate fracturing, soil yielding, and even healing aspects (by recreation of hydrates in formed cracks).

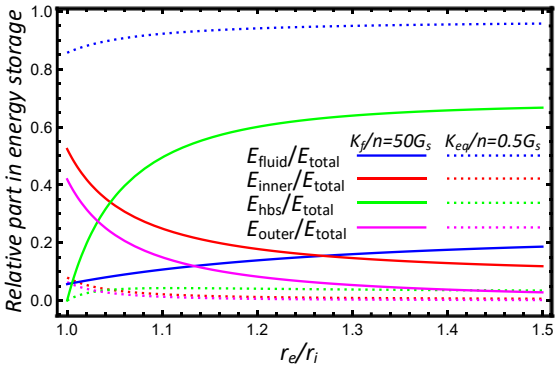

Figure 4. Relative part in energy storage for case in which $\frac{K_f}{n} = 50G_s$ *(full) and* $\frac{k_{eq}}{n} = 0.5G_s$ *(dashed),* $G_h = 10G_s$, $K_s = 1.67G_s$.

It is expected that it would be beneficial to induce high pressure, as part of the construction stage, to crack the hydrate and allow for reformation of hydrate in the formed fractures. Upon release of the induced pressure, the hydrate capsule (shell structure) would become prestressed, allowing for substantial pressure containment capacity during the operational stage. Therefore, during the first pressurization cycle, yielding of soil can increase the maximum operational fluid pressure for greater storage capacity.

5 SUMMARY AND DISCUSSION

This paper introduced a novel approach for Underground Mechanical Energy Storage (UMES) systems using CO_2 hydrates to create an impermeable vessel that can be internally pressurized by a mix of fluids (water, air, and/or carbon dioxide). The proposed concept of Pumped-Hydro Compressed Carbon Dioxide Energy Storage has the ambition to unite energy storage and carbon utilization objectives for the construction of the pressurized vessel, while exploiting efficient turbine/pump systems currently used in above-ground pumped hydro storage.

The construction phases, working principles, and requirements for hydrate stability were outlined. Then, a simplified mechanical model based on elasticity was suggested and used to quantify energy storage as a function of capsule geometry and material behavior. This may be considered a first step for the preliminary design of case studies.

To further advance this innovative concept and address critical knowledge gaps, the following research questions must be explored: (*i*) can spherical

hydrate be formed in real condition or gas buoyancy will hinder the ability to form capsules, (*ii*) what are the limits on pressurization in terms of hydrate and soil yielding, and can those be mitigated by healing processes of hydrate reformation in fractures, (*iii*) how large can the capsules be and what is the duration of their construction, (*iv*) does the thermal changes associated with gas storage impact the hydrate structure and to what extent, (*v*) what is the energy efficiency during operations as the result of the pressure-volume relationship at the inlet. To address these aspects, future works will span small-scale experiments and computer simulations.

It is worth noting that over the last 20 years extensive research has been carried out on geomechanical aspects of gas hydrates bearing sediments, although for a completely different objective of gas production. It is believed that the research knowledge and numerical tools developed in these prior studies (e.g. Klar et al., 2013) could be fostered towards analyzing the innovative energy storage solution presented in this paper.

ACKNOWLEDGEMENTS

The authors would like to express their deep appreciation to DTU Offshore and the BIRD Foundation for their interest and financial support. The authors would also like to thank Hans Horikx and Charlotte Nørgaard Larsen for the discussion on the topic and for providing the environmental data.

Three-dimensional characterization of non-uniform deformation in drying fine sediments: An x-ray CT study

Caractérisation tridimensionnelle de la déformation non uniforme dans le séchage des sédiments fins: Une étude par tomographie à rayons X

ABSTRACT: Desiccation-induced cracks in fine sediments comprises soil strength, elevate hydraulic permeability, and undermine the integrity of geotechnical structures. The drying-induced shrinkage is typically constrained at boundaries, fostering non-uniform shrinkage and promoting desiccation crack formation. This study employs sequential X-ray computed tomography (CT) scans to investigate non-uniform deformation in saturated bentonite during the drying process. Internal glass bubbles serve as markers, enabling the characterization of three-dimensional (3D) internal deformation. A particle tracking algorithm, enhanced by using an Artificial Neural Network, facilities the estimation of glass bubbles displacement fields between scans. Results indicate that sidewall adhesion contributes to non-uniform deformation during drying, fostering desiccation crack formation near the sidewall.

RÉSUMÉ: Les fissures induites par la dessiccation dans les sédiments fins compromettent la résistance du sol, augmentent la perméabilité hydraulique et sapent l'intégrité des structures géotechniques. Le retrait dû au séchage est généralement contraint aux limites, favorisant un retrait non uniforme et encourageant la formation de fissures de dessiccation. Cette étude utilise des balayages séquentiels en tomographie par rayons X (CT) pour étudier la déformation non uniforme dans le bentonite saturé pendant le processus de séchage. Des bulles de verre internes servent de marqueurs, permettant la caractérisation de la déformation interne en trois dimensions (3D). Un algorithme de suivi de particules, renforcé par un réseau neuronal artificiel, facilite l'estimation des champs de déplacement des bulles de verre entre les balayages. Les résultats indiquent que l'adhésion de la paroi latérale contribue à la déformation non uniforme lors du séchage, favorisant la formation de fissures de dessiccation près de la paroi latérale.

Keywords: Desiccation crack; fine sediments; x-ray CT; particle tracking.

1 INTRODUCTION

Desiccation cracks in fine sediments form due to the drying-induced shrinkage and weaken the functionality of various geotechnical structures (Novak et al., 2000), such as embankment dams (Atique et al., 2009), shallow foundations (Lozada et al., 2015), and landfill liners (Omidi et al., 1996). More frequent severe drought events are expected to occur due to climate change and will intensify desiccation cracks.

For the last few decades, researchers have adopted laboratory tests (Corte & Higashi, 1964), numerical simulations (Amarasiri et al., 2011), and field characterization (Philip et al., 2002) to develop a better understanding of desiccation crack formation. Soil shrinkage is driven by elevated matric suction and influenced by boundary constrictions. At pore-scale, desiccation crack is formed by air invasion in water-saturated fine sediments (Shin & Santamarina, 2011; Zhao & Santamarina, 2020). It is anticipated that boundary restrictions induce non-uniform deformation, lead to local pore enlargement, and promote desiccation crack formation (Weinberger, 1999). Laboratory tests adopted digital camara to characterize the morphology of desiccation cracks and quantify the impact of substrate friction on desiccation crack formation (Decarlo & Shokri, 2014). Results show that more extensive cracks form due to the increased substrate friction (Costa et al., 2008). However, there is limited experimental studies on the internal non-uniform deformation within drying fine sediments.

This study adopts X-ray computed tomography (CT) to quantify internal deformation within drying fine sediments. Micron glass bubbles were embedded in a saturated bentonite sample to serve as tracking markers. During drying, multiple X-ray scans were collected to characterize the internal deformation. We adopted a particle tracking method enhanced by using

an Artificial Neural Network (ANN) to link glass bubbles between scans based on their location and morphology information. The three-dimensional (3D) displacement fields offer insights into non-uniform deformation resulted from sidewall adhesion and its impact on desiccation cracks formation.

2 EXPERIMENTAL METHOD

2.1 Material and sample preparation

We adopted bentonite with a liquid limit of *LL*=375%, as determined by fall-cone tests. Bentonite powders were hydrated by deionized water to achieve an initial water content of 375%. Glass bubbles were adopted to serve as tracking markers to monitor the internal deformation during the drying process. These glass bubbles are hollow glass spheres with a diameter ranging from 40 to 80 μm with a bulk density of 0.1 to 0.15 g/cm^3 (Gurit). Glass bubbles were mixed with saturated bentonite at a mass ratio of about 1.67%. The mass ratio was chosen to have an average distance between glass bubbles equals to three times the bubble diameter. Glass bubbles were gently mixed with saturated bentonite to avoid damage.

The container for drying tests had an inner diameter (*d*) of 8mm, a thickness (*t'*) of 2mm, and a height (*h*) of 10mm, as illustrated in Figure 1(a). The container is made of acrylic, which is transparent to X-ray. The sidewall was treated to increase the adhesion with bentonite sample. We polished sidewall using 400CW sandpaper and then coated it with PVA (Polyvinyl alcohol) to change the surface wettability from hydrophobic to hydrophilic(Trantidou et al., 2017). Subsequently, the mixture of bentonite and glass bubbles was injected into the container slowly using a small syringe to minimise the trapped gas bubbles.

2.2 Scanning procedure

The sample underwent drying in an environmental chamber at a constant temperature of 23℃ and at a relative humidity around 50%. Figure 1(b) shows the evolution of water content with drying time. Three high-resolution X-ray CT scans were conducted at pre-defined water contents to investigate the non-uniform deformable characteristics. The water content for scanning was selected based on preliminary tests to investigate non-uniform deformation before and after desiccation crack. The sample was covered during X-ray CT scans so that the water content remained unchanged.

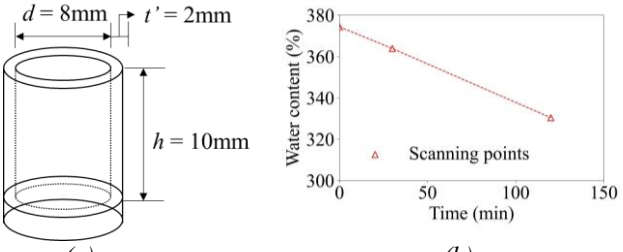

Figure 1. (a) Container for drying tests. (b) Drying curve and three scanning points.

2.3 Image processing

Figure 2 (a-c) shows grey-scale slices of the X-ray CT image for Scan-1 to Scan-3. A noticeable contrast was evident among the glass bubbles (air), bentonite, and acrylic container. To minimize image noise, we applied a median filter of size 3×3×3 voxels twice. Then, glass bubbles were separated from both bentonite and container with the threshold determined from Otsu's method (Otsu, 1979). The three-dimensional morphology and location of individual glass bubbles were obtained. The location data of each glass bubble is defined by the *x*, *y*, and *z* coordinates of its centroid. The morphology was quantified for both particle size and particle shape. Particles size parameters include volume (*V*) and surface area (*SA*), where particle shape parameters are sphericity (*SP*), aspect ratio (*AR*). More details of image processing and shape analysis were described by Zhao and Wang (Zhao & Wang, 2016).

2.4 Particle tracking algorithm

This study adopted the particle tracking algorithm enhanced by using an Artificial Neural Network (ANN) (Xu et al., 2023). The algorithm adopts both particle location and morphology to link bubbles between scans. A summary of the procedure is shown as follows:

First, we defined the unified coordination systems based on the base of container and six bubbles near the base. Then, the centroid parameters of all bubbles were consistently adjusted to ensure a unified coordinate system for three scans. After that, we manually linked 1,098 pairs of glass bubbles to set up the trained ANN model by using the parameter combination including *x*, *y*, *z*, *V* and *SP*, which has a highest accuracy 97.58%. The trained ANN model was applied to link bubbles between three scans, with a spatial position threshold to efficiently track all the glass bubbles (total 28,504) involved in our research. The ANN particle tracking successfully linked the majority of glass bubbles. A flittering was employed to the displacement data to remove tracking errors.

3 RESULTS

The first drying stage induced primarily vertical shrinkage in Scan-2 (Figure 2a – 2b). Due to the existence of sidewall adhesion, the vertical displacement in the middle of the sample is much larger. Eventually, a crack formed at near the sidewall and resulted in the horizontal shrinkage in Scan-3 (Figure 2c).

Figure 2 (d) displays the projection of displacement vectors on the vertical plane (x-z) at the middle section between Scan-1 and Scan-2. Vertical displacement reduced gradually from the sample surface to the base of container. Also, more pronounced displacement occurred in the centre, especially near the sample surface. The mean vertical displacement within the top 10% of the sample decreased from 0.36 mm at the centre to 0.17 mm near the sidewall. These results underlined the evident non-uniform displacement occurring on the sample surface with significant sidewall adhesion prior to crack formation. Figure 2 (e) shows a three-dimensional view of the displacement field between Scan-1 and Scan-2. The pronounced displacement was especially evident in the central of the surface, while there were smaller displacement on both sides due to the adhesion between the sidewall and the sample.

Figure 2 (f) shows the projection of displacement vectors on the vertical plane (x-z) at the middle section between Scan-2 and Scan-3. The crack formed on the left side of the sample resulted in large horizontal displacement in addition to the vertical displacement. For instance, within the top 10% of the sample, the horizontal displacement near the crack varied between 0.05mm and 0.10mm. The horizontal displacement gradually decreased as it approached the right side. Also, significant vertical displacement was observed, with the absence of sidewall adhesion influence on the left side due to the crack formation. The overall displacement field indicated a shrinkage towards the lower right corner.

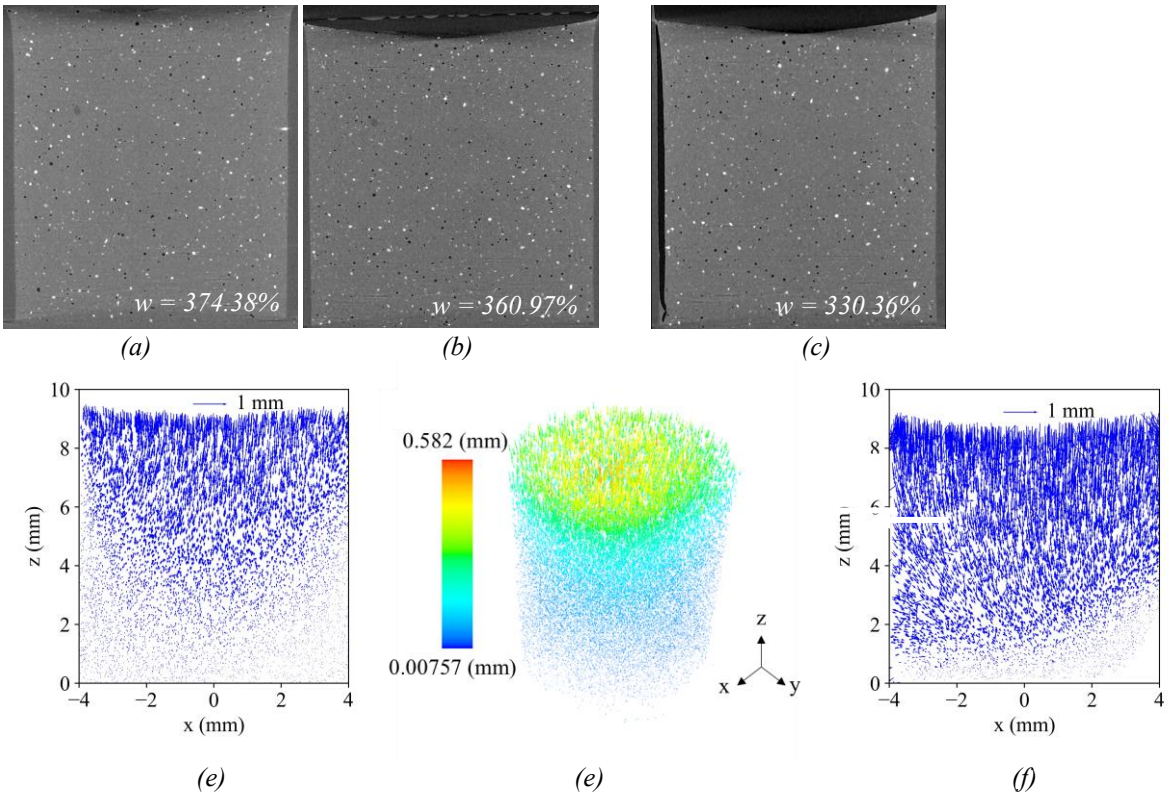

Figure 2. Non-uniform deformation and desiccation crack formation. (a)~(c) Vertical slices of Scan-1 to Scan-3. (d) Vertical projection of displacement field from Scan-1 to Scan-2. (e) 3D view of displacement vectors from Scan-1 to Scan-2 (f) Vertical projection of displacement field from Scan-2 to Scan-3.

4 CONCLUSIONS

This study investigated the non-uniform deformation of a drying bentonite sample. Glass bubbles were embedded in saturated bentonite to serve as tracking markers, while X-ray CT scans was employed to monitor internal deformation. The glass bubbles were tracked with an ANN model to quantify the three-dimensional displacement field before and after desiccation crack formation. The internal deformation before desiccation crack is dramatically affected by the adhesion between the bentonite and the container sidewall. A much larger vertical displacement

occurred in sample centre, while the vertical displacement was constrained at the sidewall. Desiccation crack formed near the sidewall lead to significant horizontal displacement, in addition to the vertical shrinkage observed in the sample.

ABSTRACT: The driveability and axial capacity of driven piles depend critically on their geometry, end conditions and the degree of drainage they experience during driving. This paper summarises the installation characteristics of 41 impact-driven piles driven for the ALPACA joint industry project (JIP). The installed piles covered open- and closed-ended steel tubular, sheet and reinforced square concrete piles with a wide range of diameters (from 139 mm to 1.8 m), wall thickness ratios (14 to 72), and embedment length-to-diameter ratios (6 to 40). Analyses that applied parameters interpreted from parallel piezocone penetration and dissipation tests indicated that pore-pressures of several MPa developed beneath large open-ended piles during rapid driving and led to surprisingly low shaft resistances. However, the slower driving of the closed-ended concrete and sheet piles permitted far higher degrees of dissipation and led to far greater shaft resistances. Signal matching analyses demonstrate how the End of Driving (EoD) shaft resistances were affected strongly by de-structuration of the chalk and the relative depth of the pile tip. The EoD shaft resistances corresponded closely with predictions made applying the short-term Chalk ICP-18 Soil Resistance to Driving (SRD) formulae. An updated base resistance formula was proposed that correlates with pile wall thickness ratio.

RÉSUMÉ: La capacité de battage et la capacité axiale des pieux battus dépendent essentiellement de leur géométrie, de conditions d'extrémité et du degré de drainage pendant le battage. Cet article résume les caractéristiques d'installation de 41 pieux battus par impact pour le projet industriel commun ALPACA, incluant des pieux tubulaires en acier à extrémités ouvertes et fermées, des tôles et des pieux carrés en béton armé, avec des diamètres (139 mm à 1,8 m), des rapports d'épaisseur de paroi (14 à 72) et de longueur d'ancrage par diamètre (6 à 40). Des analyses utilisant des paramètres interprétés à partir d'essais de pénétration et de dissipation de piézocônes parallèles ont indiqué que des pressions interstitielles de plusieurs MPa se développaient sous de grands pieux à extrémité ouverte lors d'un battage rapide et conduisaient à des résistances d'arbre étonnamment faibles. Cependant, l'enfoncement plus lent des palplanches et du béton à extrémité fermée a permis des degrés de dissipation beaucoup plus élevés et a conduit à des résistances d'arbre bien plus grandes. Les analyses d'appariement des signaux démontrent comment les résistances de l'arbre en fin de battage (EoD) ont été fortement affectées par la déstructuration de la craie et la profondeur relative de la pointe du pieu. Les résistances des arbres EoD correspondaient étroitement aux prédictions faites en appliquant les formules à court terme de Chalk ICP-18 Soil Resistance to Driving (SRD). Une formule de résistance de base mise à jour a été proposée, en corrélation avec le rapport d'épaisseur de paroi du pieu.

Keywords: Chalk; impact driving; chalk resistance to driving (CRD); axial capacity; signal matching.

1 INTRODUCTION

Chalk is a high-porosity, calcareous, variable soft biomicrite found in large areas of North West Europe and other regions worldwide (Mortimore, 2012).

Large open-ended driven piles are employed to support a wide range of onshore and offshore infrastructure at chalk sites. However, their driveability has proven challenging to predict. Refusal has been reported on driving through high density chalk while strikingly low average shaft resistances (sometimes well below 20 kPa) can be developed on driving through low-to-medium density chalk, attributing to uncontrolled self-penetration (or 'runs') to far greater-than-expected depths (Carotenuto et al., 2018). Buckley et al. (2021) proposed a short-term 'Chalk ICP-18' Resistance to Driving (CRD) approach based on back-analyses of onshore and offshore

driving records of open-ended piles with respective length-to-diameter and wall thickness ratios of $5 \leq L/D \leq 40$ and $17 \leq D/t_w \leq 67$ driven in structured low-to-medium density chalks with corrected cone resistances (q_t) broadly between 10 and 20 MPa. They also suggested that the annular base resistances (q_b) developed during driving amount to around $0.6q_t$.

Jardine et al. (2023a, b) report how the significant uncertainties and challenges involved in designing driven pile foundations to sustain axial and lateral, monotonic and cyclic loading in chalk were addressed in the major ALPACA (Axial-lateral pile analysis for chalk applying multiscale field and laboratory testing) and ALPACA Plus joint industry research projects. Forty-one instrumented piles were driven at the well-characterised St Nicholas at Wade low-to-medium density chalk site in Kent, UK (Vinck et al., 2023) and comprehensive testing undertaken that led to new design guidelines for all the above loading cases.

This paper summarises the key phenomena observed during driving with dynamic instruments mounted on all piles and the findings obtained from rigorously conducted stress wave record numerical matching analyses. The performance of the Chalk ICP-18 CRD predictive approach was checked against the extended dataset, and the base driving resistance formula updated to account for wall thickness ratio.

2 PILE INSTALLATION OBSERVATIONS

Table 1 summarises the ALPACA and ALPACA Plus ranges for pile diameter D (139 mm – 1.8 m), slenderness ratio (L_p/D) (6 – 40), wall thickness ratio (D/t_w) (14 – 72), tip conditions, geometry and shaft materials. Also listed are the hammer masses, non-dimensional average velocities V (= vD/c_h), upper bound full drainage elapsed times and end-of-driving average shaft resistances (τ_{avg}^{EoD}) back analysed from stress-wave matches. All piles were monitored with above-ground pile driving analyser (PDA) strain gauges and accelerometers; 16 were instrumented with paired Fibre Bragg Grating optical strain gauge strings embedded along their shafts (Buckley et al., 2020).

All the open-ended piles drove in a fully coring manner with internal chalk columns that extruded and rose well above ground level at the end of driving, confirming relatively little outward volume displacement into the stiff surrounding chalk mass. Figure 1 shows how the volume displaced above ground compared to that of the embedded steel, V_{pag}/V_{steel}, fell systematically with L_p/D; open-pile cores rarely rise above ground level in sands and clays.

Driving the open-tubular LD and SD piles to target depths with the employed hammers required 9 to 55 blows per 250 mm and total driving times of 2 to 14 minutes. Relatively hard driving was required for (i) the 200 mm square concrete piles, with up to 308 blows/250 mm over up to 81 minutes and (ii) the sheet piles with up to 100 blows/250 mm and ≈ 20-minute driving times, leading to relatively low V values. These piles' slow driving is likely to have led to greater degrees of drainage that attributed to higher τ_{avg}^{EoD} (83.3 and 37.1 kPa respectively) average shaft resistances than the 24.8 kPa of open-ended piles.

Table 1. ALPACA and ALPACA Plus driven pile installation: pile geometries, conditions, hammer details, ranges of normalised velocity V, upper bound full drainage elapsed times and end-of-driving (EoD) average shaft resistances (τ_{avg}^{EoD}).

Pile numbers, codes and material	D (mm)	t_w (mm)	R^* (m)	L_p (m)	L_p/D	Hammer (ram mass)	Norm. V (= vD/c_h)	Upper bound t_{95} (min)	τ_{avg}^{EoD} (kPa)

Notes: D listed for concrete and sheet piles based on equivalent area; t_w: pile wall thickness; R: equivalent radius for open-ended piles ($= (R^2 - R_i^2)^{0.5}$); R and R_i: outer and inner radius, respectively; c_h: coefficient of horizontal consolidation.*

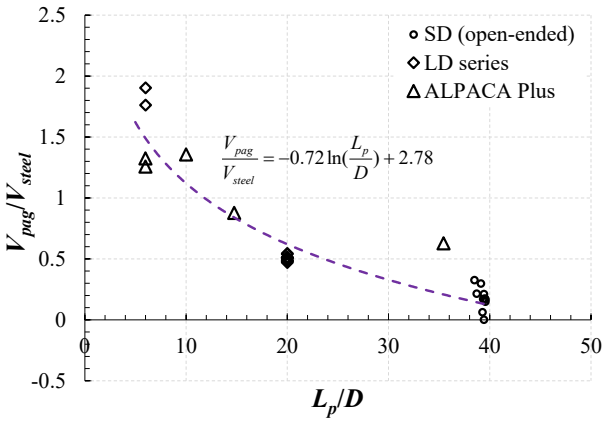

Figure 1. Variation of the ratio between the above-ground chalk plug volume (V_{pag}) and embedded steel volume (V_{steel}) against L_p/D.

3 DRIVING RESISTANCE PREDICTIONS

3.1 ALPACA shaft and base CRD formulae

Buckley et al. (2020) show that internal shaft resistances are likely to be far lower than apply externally to piles driven in chalk. The overall shear resistances are therefore considered in Chalk ICP-18 as the sum of the external and internal shaft stresses and treated as applying only on the external pile shaft. The overall shear resistances available at any level on the shaft, τ_{rzi}, are determined through Equation (1), in which σ_{ri}' denotes radial effective stress during installation and δ_{ult}' interface shear resistance angle determined from Bishop ring shear interface tests and typically taken as 32° (Vinck, 2021).

$$\tau_{rzi} = \sigma_{ri}' tan\delta_{ult}' \quad (1)$$

The local radial effective stress (σ_{ri}') and base bearing pressure (q_b) are defined as functions of relative pile tip depth (h), corrected cone resistance (q_t), equivalent radius (R^*) and D/t_w:

$$\sigma_{ri}' = 0.031 q_t \left(\frac{h}{R^*}\right)^{-0.481\left(\frac{D}{t_w}\right)^{0.145}} \quad (h/R^* \geq 6) \quad (2)$$

$$R^* = \left(R^2 - R_i^2\right)^{0.5} \quad (3)$$

$$q_b = q_t (D/t_w)^{-0.175} \quad (4)$$

3.2 Performance of the method in predicting field behaviour

The performance of the Chalk ICP-18 shaft CRD method was assessed systematically against the dynamic stress-wave matches of the ALPACA and ALPACA Plus piles' instrumented driving records, as well as independent cases collated and analysed by Vinck (2021).

Overall comparison of the total EoD shaft load between the predictions for shaft resistance Q_s integrated from the above expressions and the signal-matching outcomes, indicated a fortuitously unbiased mean calculated-to-measured (Q_c/Q_m) ratio of 1.00 and a coefficient of variation (CoV) of 0.38 for the open-ended piles listed in Table 1. The latter CoV, which should be recognised when developing upper and lower bound CRD profiles for hammer selection and pile fatigue analyses, reflects natural variabilities of chalk conditions and driving operations as well as uncertainties inherent in stress wave matching.

Further testing of the approach by Vinck et al. (2023) at the Sauchay medium density chalk test site near Dieppe in France also showed good agreement with mean Q_c/Q_m of 0.99 and CoV of 0.19.

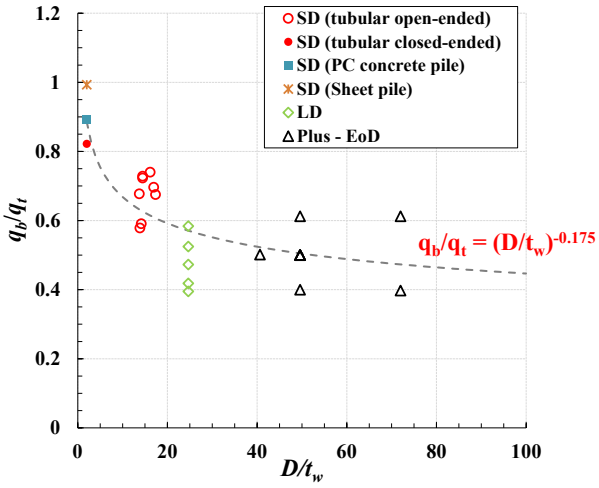

Figure 2. Normalised bearing pressure (q_b/q_t) against piles' D/t_w at end-of-driving (Note: q_b evaluated over closed-ended piles' full areas and open-ended piles' steel annuli; D/t_w taken as 2 for closed-ended piles).

However, Jardine et al. (2023b) and Vinck et al (2023) proposed from their analyses that the base driving resistance formula required updating. Figure 2 plots the signal-matched End-of-Driving base resistance (q_b) values normalised by q_t against D/t_w, showing a declining trend that can be expressed by power-law Equation (4). This updated method leads to

a better and more conservative fit to the data than the Chalk ICP-18's tentatively suggested $q_b/q_t \approx 0.6$.

Two examples from the signal matching analyses are shown in Figure 3. The shaft resistance profiles derived from signal matching back analyses are compared with predictions from Equations (1)-(3) for both relatively long (L_p/D = 20) and short (L_p/D = 6) open steel, 508mm outside diameter piles (LD5 and 13 respectively). Two q_t profiles are also shown, as established in CPT soundings made close to both piles.

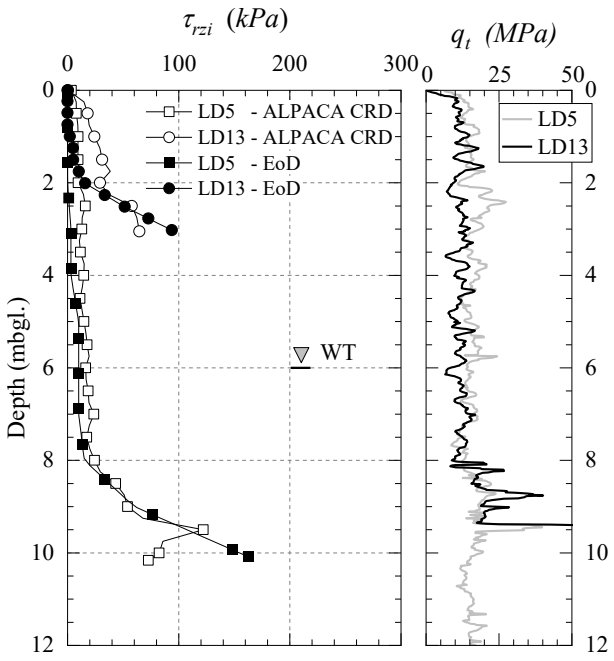

Figure 3. Profiles of CPT resistance and shaft friction from EoD PDA analysis against CRD prediction for two LD piles (D =508 mm, D/t_w =25).

4 CONCLUSIONS

(1) Predicting pile's driveability in chalk is crucial to many onshore and offshore projects.

(2) Comprehensive research was undertaken in the ALPACA and ALPACA Plus campaigns on 41 instrumented piles to (i) improve fundamental understanding of driving resistances and (ii) calibrate new predictive approaches. Axial driving resistances were found to depend critically on pile geometry, end conditions, CPT resistance and any drainage during installation.

(3) Closed-ended sheet and concrete piles experienced relatively hard driving that permitted higher degrees of drainage and higher driving resistances.

(4) Rigorous stress wave analyses confirmed that the Chalk ICP-18 resistance to driving (CRD) method led to unbiased shaft predictions for the St Nicholas at Wade (SNW) piles and generally good matches in other independent cases. The test analysis also allowed an improvement of the method's formulation for base resistance to driving.

The contribution of ductile cast-iron piles to a more sustainable deep foundations industry

La contribution des pieux en fonte ductile à une industrie plus durable des fondations profondes

F. Lopez*, E. Steinlechner
Tiroler Rohre GmbH, Hall in Tirol, Austria

**freddy.lopez@trm.at*

ABSTRACT: As addressed by the UN Secretary-General, António Guterres, at the opening of the Climate Implementation Summit at COP27 (Sharm el-Sheikh, Egypt) in 2022, climate change is not only an essential challenge of our century but the defining issue of our age. Any hope of limiting temperature rise to 1.5°C means achieving global net-zero emissions by 2050. The built environment and with it the construction industry is worldwide responsible for 39% of greenhouse gas emissions (CO_2), therefore it is our responsibility as part of the construction industry to take stronger actions and effective accountability. Wherever we are and whichever our position might be, our actions can produce large positive changes. The following technical paper presents an overview of the contribution of ductile cast-iron piles to achieve a more sustainable deep foundations industry, by reducing considerably the embodied carbon footprint of the implemented solutions. It is not too late yet, but we all need to redouble efforts in order to bend the global emissions curve. It is the fight of our lives and we will lose, unless we work together. The use of innovative and sustainable materials can definitely help the building sector to face successfully today´s existential challenges.

RÉSUMÉ: Comme l'a déclaré le Secrétaire général des Nations unies, António Guterres, lors de l'ouverture de la conférence sur les changements climatiques dite COP 27 (Charm el-Cheikh, Égypte), le changement climatique n'est pas seulement un défi essentiel de notre siècle, mais aussi l'enjeu fondamental de notre époque. Tout espoir de limiter la hausse de la température globale à 1.5°C implique d'atteindre zéro émission nette mondiale d'ici 2050. L'environnement bâti et avec lui l'industrie de la construction sont responsables à hauteur de 39% des émissions de gaz à effet de serre (CO2) dans le monde. C'est donc notre responsabilité, en tant qu'acteur de l'industrie de la construction, de prendre des mesures plus fermes et de rendre compte de manière efficace. Où que nous nous situions et quelle que soit notre position, nos actions peuvent produire d'importants changements positifs. Cet article technique présente l'ensemble des contributions des pieux battus en fonte ductile pour parvenir à une industrie plus durable des fondations profondes, en réduisant considérablement l'empreinte carbone intrinsèque des solutions mises en œuvre. Il n'est pas encore trop tard, mais nous devons tous redoubler d'efforts pour infléchir la courbe des émissions mondiales. C'est le combat de notre vie et nous le perdrons si nous ne travaillons pas ensemble. L'utilisation de matériaux innovants et durables peut indiscutablement servir le secteur du bâtiment dans le but de relever avec succès les défis existentiels d'aujourd'hui.

Keywords: Sustainability; reduction of carbon footprint; ductile cast-iron piles.

1 GREENHOUSE GAS EMISSIONS AND CLIMATE CHANGE

The work of scientists and researchers around the world report changes beyond the natural variation of temperatures on land and in the ocean, as well as abnormal trends in the timing of seasons, rainfall patterns and occurrence of extreme climate events, which affect millions of people globally. The scientific community acknowledges the irrefutable link between the human-caused greenhouse gas (GHG) emissions and the global climate change, observed in the last decades.

In response to this, a legally binding international treaty on climate change - the *Paris Agreement* - was adopted by 196 parties in 2015, pursuing efforts to limit global warming to 1.5 °C by the end of the 21st century (compared to preindustrial levels). To achieve this goal, global emissions must reach net-zero by 2050 (Climate Watch, 2023).

2 THE ENVIRONMENTAL IMPACT OF THE BUILT ENVIRONMENT

The built environment, consisting of buildings and infrastructure, is responsible for a large share of the

human-made global environmental impact, including approx. 40% of the global energy consumption, 50% of all raw material extraction, 33% of all potable water usage and 35% of all waste generation, as well as 39% of the carbon emissions (AIB and IGBC, 2022).

2.1 GHG emissions

It is estimated that the world emissions reach approx. 48 billion metric tons of GHG (measured in CO_2e) each year and the built environment accounts for almost 39% of them (Figure 1), a figure comprising both *operational carbon* (resulting from heating, cooling, lighting, etc.) and *embodied carbon*, or emissions resulting from the manufacturing of materials, construction processes and end of life cycle phases of all buildings and infrastructure (Figure 2).

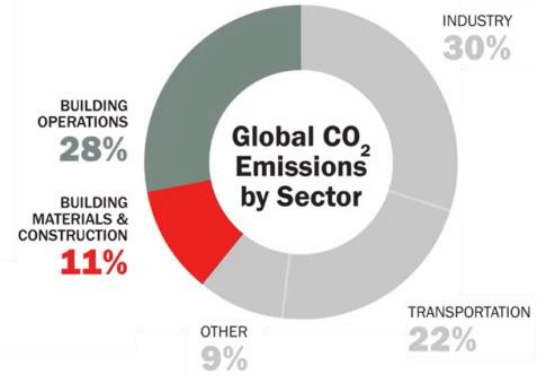

Figure 1. Breakdown of operational and embodied carbon (Architecture 2030, 2023).

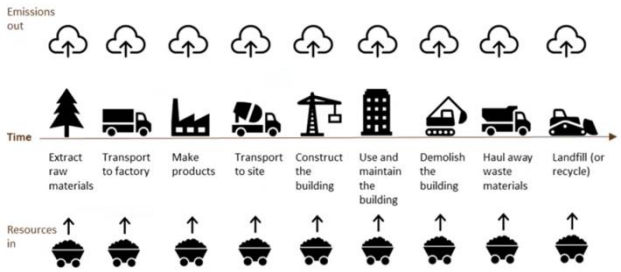

Figure 2. Life cycle phases of a building (Athena Institute, 2019).

2.2 Importance of embodied carbon

The embodied carbon emissions have largely been overlooked historically but contribute around 11% of all global carbon emissions (Figure 1). Carbon emissions released before the building or infrastructure begins to be used, sometimes called *upfront carbon*, will be responsible for half of the entire carbon footprint of new construction between now and 2050 (WGBC, 2019). Taking into account the embodied carbon, the construction industry is the biggest offender when it comes to global emissions.

While the construction industry has made great strides on the *operational front* in recent years (decarbonisation of electricity and gas grids, more efficient heating/cooling systems, etc.), the *embodied carbon front* will be responsible for the majority of the carbon emissions associated with global new building and infrastructure (Architecture 2030, 2023).

2.3 The response of the construction industry

Parallel to the reduction of operational carbon, the construction industry has acknowledged that efforts must now rapidly increase to tackle embodied carbon emissions at a global scale, too. In this context, different global initiatives such as *Advancing Net Zero* (World Green Building Council), *Envision* (Institute for Sustainable Infrastructure, USA), *Level(s)* (European Commission), etc. originated within the construction sector to decarbonize the construction industry by 2050.

Because the embodied emissions of a building or infrastructure project are locked-in once the project is constructed and cannot be taken back or reduced, the focus of the construction industry is being set on minimizing the upfront carbon to the greatest extent possible and to reduce, or as a last resort, offset all remaining embodied carbon in order to achieve net zero across the life cycle of any building or infrastructure asset (WGBC, 2019). Although Emissions can be reduced at any point of a project development stage; the opportunities to limit and/or reduce upfront embodied carbon are greater at the earliest stages (HM Treasury, 2013). As a project progresses, it becomes more challenging to make design changes to obtain the same outcome (Figure 3).

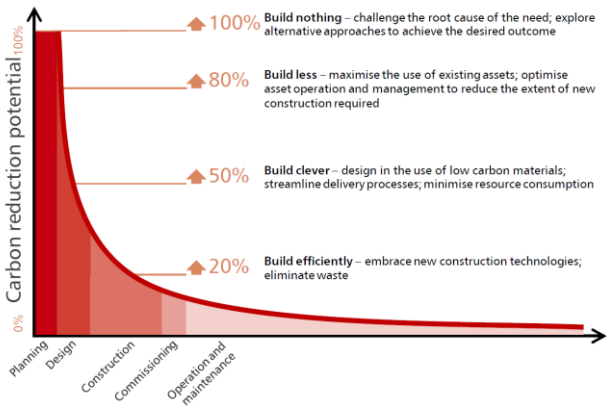

Figure 3. Carbon reduction curve (HM Treasury, 2013).

While it is not always possible to follow the "*build nothing*" approach, interventions to existing building and infrastructure assets to re-use them ("*build less*" approach) can result in considerable

reductions. The "*build clever*" and "*build efficiently*" approaches, mainly related to the selection of lower carbon materials and the adoption of new techniques that eliminate waste (such as off-site manufacturing), are applicable to new buildings and infrastructure and result in important reductions (HM Treasury, 2013).

3 EMBODIED CARBON IN DEEP FOUNDATIONS

Deep foundations are integral to the built environment and the broader civil engineering and construction industry. The positive impacts of reducing carbon emissions are commendable reasons to change the way the deep foundation industry operates (Martin, 2022). The first step to reduce the embodied carbon in deep foundations is to quantify the carbon footprint of the designed and built solutions. Based on the quantification, it is possible to compare and contrast different technical approaches within a project, identifying the sources that drive the upfront carbon emissions (i.e. materials) and to implement optimizing measures to effectively reduce them and/or mitigate their impact. A very helpful tool is the *Carbon Calculator*, developed by the European Federation of Foundation Contractors (EFFC, UK) and the Deep Foundations Institute (DFI, USA), using verifiable and standardised data to estimate the upfront carbon of special geotechnical works.

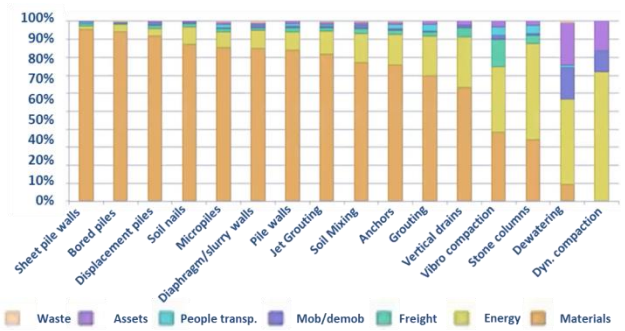

Figure 4. Contribution of different emission categories to the total carbon footprint of special geotechnical works (Martin, 2022).

The assessment of different case studies (Figure 4) shows that for most techniques in the deep foundation industry, the largest impact on the total carbon footprint of the implemented solutions came from materials (Martin, 2022), such as cement and steel, both materials with a high global warming potential (Figure 5).

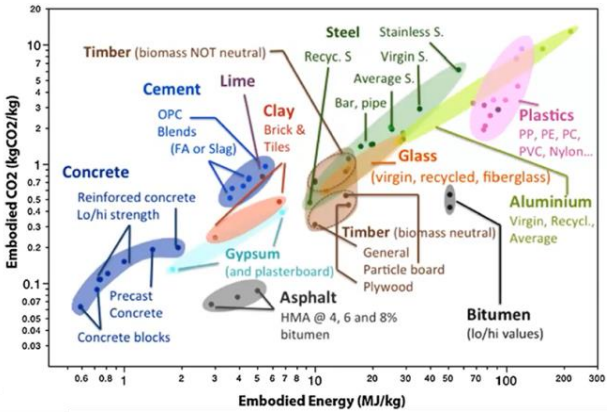

Figure 5. Embodied Carbon and embodied energy for different construction materials (Barcelo et al, 2014).

4 DUCTILE IRON PILES

Ductile iron piles (DIPs) are low vibration, driven, full-displacement piles, installed using a medium-sized excavator and a hydraulic breaker hammer with a modified shank that seats into the pile socket (bell) for driving, using the hammer's percussive energy (Figure 6). DIPs are used to transfer loads from the superstructure into the lower soil layers and/or to limit deformations, developing skin friction and end-bearing capacity (Lopez and Steinlechner, 2023).

Figure 6. Execution of ductile iron piles (DIPs).

4.1 Embodied carbon of DIPs

The pile elements are produced using 100% of recycled materials (steel scrap), which are smelted in a furnace with the help of coke as a reaction and reduction agent (Bau EPD GmbH, 2022). Due to the use of 100% recycled materials in the production and the potential implementation of additional measures to reduce the carbon intensity of the manufacturing process (i.e. re-use of waste heat, exhaust air and water treatment, use of renewable energy, etc.) result in further reductions of the system´s total carbon footprint, enabling DIPs to fall under the category of low carbon materials.

4.2 A comparative analysis

In 2017, two technical proposals for the deep foundations of a new production and logistics warehouse in Germany (Figure 7) were compared.

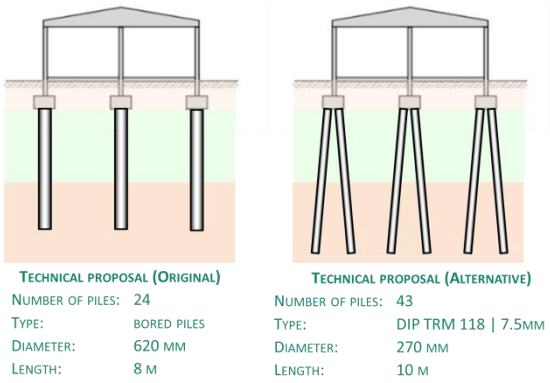

Figure 7. Technical proposals for the comparative analysis (modified after Gschösser, 2018).

The results of a life cycle analysis for both alternatives (bored piles and grouted DIPs) are summarized in Table 1. Compared to the bored pile solution, the execution of DIPs presented a reduction of about 29% in the embodied carbon emissions. In addition, the DIP proposal saved approx. 25% of construction costs and 60% of execution time.

Table 1. Embodied carbon analysis (Gschösser, 2018).

[2)] Transport concrete: 30 km / transport DIPs: 300km

5 SUMMARY AND FINAL REMARKS

Buildings and infrastructure are currently responsible for 39% of global carbon emissions, thus, decarbonising the construction sector is one of the most cost effective ways to mitigate the worst effects of climate breakdown, however, the pace and scope of decarbonisation efforts must be radically increased, collaborating across the whole construction value chain to develop and deploy more low embodied carbon alternatives, required to achieve the scale of change needed (WGBC, 2019). Deep foundations are an integral part of the built environment; therefore sustainability should also be a key consideration in the industry. Ductile iron piles fall into the category of low carbon materials, due to the use of 100% recycled materials and the implementation of potential improvements in their manufacturing process. DIP solutions comply with the core philosophy of embodied carbon reductions (Figure 4), allowing to build clever and efficiently, contributing to a more sustainable deep foundations industry.

3D Thermo-mechanical analysis of a real-world thermally activated piled foundation

Analyse thermo-mécanique 3D d'une fondation en pieux activés thermiquement d'un cas d'étude réel

A. Lupattelli, D. Salciarini*
Department of Civil and Environmental Engineering, University of Perugia, Perugia, Italy
**diana.salciarini@unipg.it*

ABSTRACT: The work presents the results of a Three-Dimensional (3D) thermo-mechanical analysis, carried out through the COMSOL Multiphysics finite-element code, to investigate the effects of the heating/cooling cycles on the response of a real case of bored and cast-in-place piled foundation, where all the piles have been equipped with pipes to operate as heat exchangers with the ground. Referring to the available data on the building design and to the results of thermal property tests performed on soil samples, a 3D model of the soil-foundation system has been reconstructed. To obtain realistic operational conditions, a uniform mechanical pressure acting on the slab top surface has been imposed, while a transient heat conduction simulation has been conducted by adopting a simplified temperature harmonic function, representing the average air temperature in the Italian area, both on piles and at the ground surface. By dividing the foundation piles into subgroups, two configurations of pile thermal activation have been analyzed to optimize the system performance. The comparison between layouts reveals very similar trends, with pile's stresses and displacements predominantly influenced by the mechanical load. Energetically, the heat flux per unit of pile surface remains almost unchanged in the two considered cases, despite one layout experiencing alternate years of inactivation, with the soil temperature restores to the initial conditions.

RÉSUMÉ: Le travail présente les résultats d'une analyse thermo-mécanique tridimensionnelle (3D) réalisée à travers le code aux éléments finis COMSOL Multiphysics afin d'étudier les effets des cycles de chauffage/refroidissement sur la réponse d'un cas concret de fondation en pieux forés et coulés en place, où tous les pieux ont été équipés de tuyaux pour fonctionner comme échangeurs de chaleur avec le sol. En se référant aux données disponibles sur la conception du bâtiment et aux résultats des tests de propriétés thermiques effectués sur des échantillons de sol, un modèle 3D du système sol-fondation a été reconstruit. Pour obtenir des conditions opérationnelles réalistes, une pression mécanique uniforme agissant sur la surface supérieure de la dalle a été imposée, tandis qu'une simulation de conduction de chaleur transitoire a été réalisée en imposant une fonction harmonique de température simplifiée, représentant la température moyenne de l'air en saison chaude dans la région italienne, tant sur les pieux qu'à la surface du sol. En subdivisant les pieux de fondation en sous-groupes, deux configurations d'activation thermique des pieux ont été analysées pour optimiser les performances du système. La comparaison entre les configurations révèle une tendance cohérente, avec des valeurs principalement influencées par la charge mécanique. Énergétiquement, le flux de chaleur par unité de surface de pieu reste relativement stable, malgré une configuration connaissant des années alternées d'inactivation, lorsque la température du sol revient aux conditions initiales inchangées.

1 INTRODUCTION

Nowadays the growth in the consumption of fossil fuels in the building sector has become increasingly impacting. Therefore, numerous efforts are being made to find alternative technologies that allow the use of renewable energy. The heat contained in the most superficial layers of the Earth's crust, called low-enthalpy geothermal energy, can be effectively exploited as renewable and available energy in various applications: among these, Energy Piles (EPs) associate the traditional mechanical function to the energetical one by exchanging heat with the ground (Brandl, 2006; Ravera et al., 2024), allowing for satisfying a large part of the energy needs of a building, and providing for heating and cooling according to seasonal needs (Rotta Loria et al., 2020; Gerola et al., 2023). Extensive research, experimental sites, and real project monitoring demonstrated the feasibility of EPs (Bourne-Webb et al., 2022; Cecinato and Salciarini, 2022; Lupattelli et al., 2023a, 2023b, 2024), leading to the adaptation of this solution for a large number of buildings. Nevertheless, this technology's potential remains underestimated,

hindering its wider adoption: key barriers include the limited availability of specific technical information and lack of long-term performance assessments. It is essential to demonstrate the EPs' suitability in terms of thermal efficiency and geo-mechanical impact: pilot case studies could draw lessons from existing small-scale or community-scale projects, applying these insights to improve future projects on a larger scale.

Based on this perspective, a real case study of an energy-piled foundation located in Umbria (central Italy) has been modeled and analyzed to examine the soil-foundation Thermo-Mechanical (TM) response under the hypothesis of different activation layouts.

2 DESCRIPTION OF THE CASE STUDY

The case study of a private building located in Umbria (central Italy) is presented, whose project has been provided by the Owner (Figure 1).

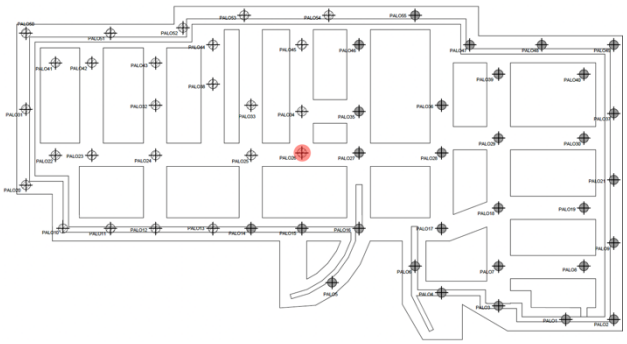

Figure 1. Plan of the building foundation: piles of 8.5 m length in light grey; piles of 10 m length in dark grey; reference pile highlighted in red.

The building, a two-story house, is founded on n. 55 bored and cast-in-place concrete piles, characterized by length varying from 8.50 m (n. 25 piles) to 10 m (n. 30 piles), and a diameter of 0.50 m. Besides the structural function, to supply the heating and cooling needs of the building for about 290 m^2 living area, all the piles have been equipped with pipes for the circulation of a heat-carrying fluid.

2.1 Soil properties

The foundation soil consists of a homogeneous layer of clayey silt with medium consistency. Given the presence of a water table close to the ground surface, the soil is assumed to be fully saturated. To study the thermal characteristics of the soil involved in the heat exchange process during the EGs operation, Thermal Property (TP) tests have been conducted on soil samples by means of two experimental facilities: a Hot Disk TPS 2500S apparatus, and an ATT DM 340 SR climatic chamber. Thermal conductivity λ_s, and volumetric specific heat $C_{p,s}$ (with nominal error of 3%, and 7%, respectively) of the samples have been measured according to the ISO 22007-2 standard. The soil thermal expansion coefficient β_s, and the thermal diffusivity α_s have been derived from the literature for typical fine-grained soils.

3 THERMO-MECHANICAL ANALYSIS

3.1 Geometry and discretization

Using the *"COMSOL Multiphysics"* Finite Element (FE) numerical code, the geometry of the entire foundation has been modeled in the central part of a homogeneous soil volume, and it has been discretized with 502588 tetrahedral elements (Figure 2), using mesh refinement for the foundation.

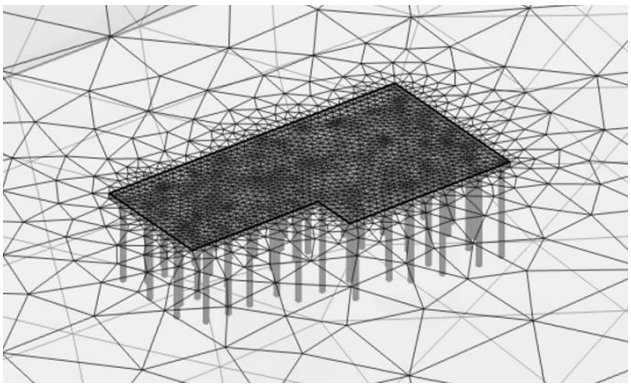

Figure 2. 3D View of domain spatial discretization.

The bottom and later boundaries of the domain have been placed at a depth of 50 m from the ground surface and at 100 m from the slab lateral edges, respectively. Piles have been modeled as a linear elastic material, while the soil has been modeled as a linear elastic-perfectly plastic material. To simulate fully saturated conditions in the fine-grained soil, the material has been characterized by thermo-physical properties accounting for the fluid and solid phases.

3.2 Initial and boundary conditions

The pile-soil interface has been considered as perfectly rough (full adhesion), and no soil-pile interface elements have been introduced. Fixed displacements have been assumed at the base of the soil volume, and horizontal displacements have been constrained for the symmetry vertical planes. A uniform pressure of 25 kPa has been applied to the slab (according to the actual project), to simulate the weight of the elevated structure. Thermal insulation has been adopted on the symmetry vertical planes, as well as at the bottom of the soil volume, and at the slab top surface.

To simulate the seasonal operation of the EPs, a simplified balanced seasonal variation of the carrier fluid temperature has been considered, since the real thermal needs of the building have not been made available. The temperature of each pile has been increased and decreased by applying a harmonic function (15±10°C), according to two different scenarios of activation (Figure 3): *i)* the entire foundation is thermally activated, and *ii)* the foundation is divided into two pile subgroups A (25 piles), and B (30 piles).

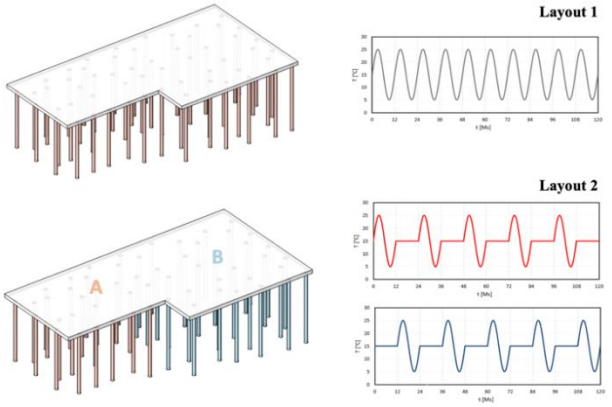

Figure 3. Pile subgroup activation according to two different scenarios (layouts 1 and 2).

3.3 Numerical simulation program

A 3D, FE model of the soil-foundation system has been prepared to conduct long-term analyses. Two simulations have been carried out to assess the influence of the adopted EP activation layout (Figure 3):

- layout 1 (reference case): all foundation piles are heated and cooled for 10 consecutive years (6 months of heating and 6 months of cooling);
- layout 2: the two subgroups are alternate-year activated, *i.e.*, pile subgroup A is activated in years 1, 3, 5, 7, and 9 (6 months of heating and 6 months of cooling), while pile subgroup B is activated in years 2, 4, 6, 8, and 10 (6 months of heating and 6 months of cooling).

4 RESULTS AND DISCUSSION

The mechanical response of a central pile of the foundation slab has been analyzed in terms of vertical stress and displacements along the pile axis, and at depths of z_1=2.5 m, z_2=5 m, and z_3=7.5 m. Also, the energy performance has been analyzed in terms of the time evolution of the conductive heat flux across the pile lateral surface. The following sign convention is used here: compressive stress, upward displacements, and heating flux are considered positive.

4.1 Effect of activation of layout 1

The TM effects induced in the soil-pile system by the operation of the energy foundation according to layout 1 are presented in the following for the selected pile (Figure 4a,b).

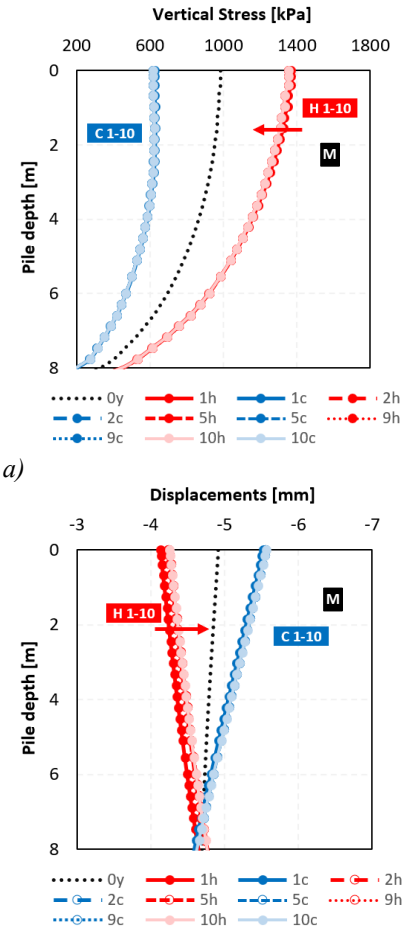

Figure 4. a) Vertical stresses, and b) displacements distribution along the reference pile axis during thermal cycles.

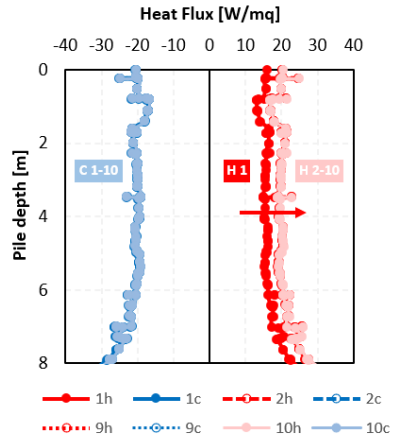
The initial application of the mechanical load results in a pile compression of about 1000 kPa and induces a downward displacement of 5 mm (represented by the black dashed curves, labeled with M). At the end of the first heating and cooling cycles, the temperature in the near soil reaches 20°C and 10°C, respectively, and then stabilizes due to the progressive cycles. Heating, along with the rigid constraint offered by the foundation slab and the mechanical load applied, determines a significant increase in global vertical compression (+400 kPa) within the pile (black dashed curves, labeled with M). During the first cooling phase, the process is reversed, and the pile experiences a reduction in the vertical stress, while remaining under compression (–400 kPa). Heating is responsible for a partial uplift of the

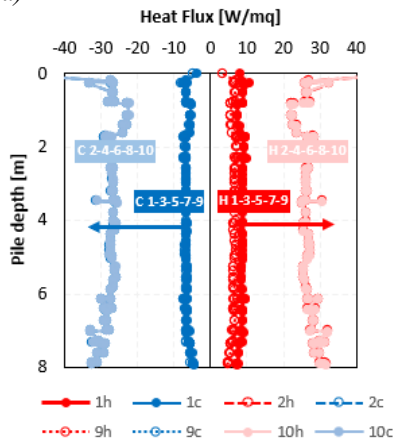
pile due to the expansion (of about +1 mm), while the opposite occurs during cooling, as pile displacements start increasing downward (of about –0.5 mm).

4.2 Effect of activation of layout 2

This second set of numerical simulations aimed at assessing the influence of the thermal activation of layout 2 (Figures 5 and 6). The results are shown for a reference pile, belonging to subgroup B.



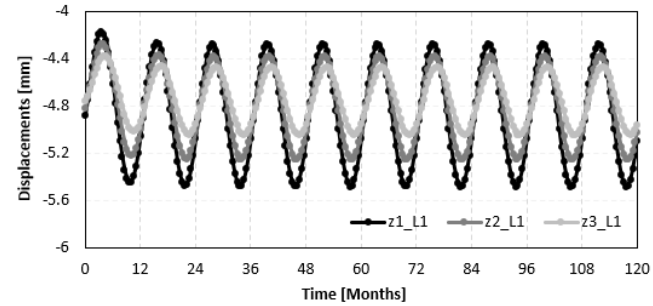
a)



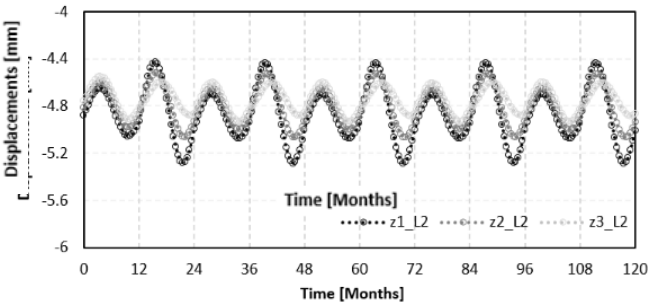
b)

Figure 5. Heat flux along the pile lateral surface during thermal cycles for a) layout 1, and b) layout 2.

From a first comparison, and from an energy point of view, there are no substantial changes between the two scenarios. Heat flux per unit pile surface taken at soil-pile interface, during years 2-4-6-8-10 (when the pile is active for both layouts), shows increased values for heating (+25 W/m^2) and cooling phases (–25 W/m^2) in layout 2 with respect to layout 1 (+22 W/m^2 and –22 W/m^2, respectively). This difference is very limited likely due to the same temperature distribution registered within the soil. The slight increase of the heat flux can be attributed to the temperature recovery to unchanged initial conditions during the years of pile inactivity in layout 2, which brings thermal exchange benefits in the following year of thermal activation.



a)



b)

Figure 6. Time evolution of vertical displacements at selected pile depths z_1, z_2, and z_3 for a) layout 1, and b) layout 2.

From a mechanical perspective (Figure 6), layout 1 exhibits higher displacements during the first thermal cycle. At the beginning of the analysis the soil volume has a uniform initial temperature T_0, and because of variations in temperature distribution between the cycles, the thermal field undergoes significant modifications, leading to a change in the initial conditions for the subsequent heating and cooling cycles. The better mechanical performance can be attributed to the case of alternate activation (layout 2). Indeed here the thermal induced displacements are slightly lower compared to layout 1, with about ± 0.6 mm of displacements compared to ± 0.4 mm of layout 1 (Figure 6).

5 FINAL REMARKS

A 3D model of an energy-piled foundation case study has been shown, and the TM response of a reference pile has been analyzed in two activation scenarios.

The recorded values of vertical stress and displacements were observed to be primarily influenced by the applied mechanical load, with the thermal load contributing to a comparatively minor values fluctuation. From the comparison, the heat flux per unit of pile surface does not change significantly, although the pile and soil in layout 2 are subjected to alternate years of temperature recovery due to the

inactivation. Considering the pile lateral surface, which varies according to its length, the global heating and cooling thermal power, extracted for each cycle, will be certainly greater preferring layout 1. Conversely, the mechanical performance of layout 2 is slightly better in terms of vertical displacements during cycles. However, stresses and displacements registered in layout 1 fit perfectly into the capacity of the single pile.

Improved predictions might be obtained by knowing the actual energy needs of the building, which is currently not available.

ACKNOWLEDGEMENTS

The Authors would thank CIRIAF of Perugia, for support in carrying out laboratory thermal tests. Part of the work presented was carried out within the scope of COST Action CA21156 "FOLIAGE", PRIN 2022 Project "GEOREFIT" (CUP: E53D23002670006), and CETP 2022 "LEG-DHC" (CUP: B97G22000940003).

ABSTRACT: In Portugal, road pavements as well as their foundation are mostly built with natural aggregates, usually crushed, with high economic and environmental impacts. However, the attempt to use excavation materials has become more frequent, whenever they meet the requirements for that use, either in the foundation or in the granular layers of road pavements. Nevertheless, it often happens that the materials found on the construction site do not meet the requirements to be reused, in many situations because they are fine clayey materials. One way to make it possible to reuse those materials is to improve their properties to fulfil the requirements of use. In this work, two clayey sand soils were characterized, in its natural state and after mixing it with plastic waste and sisal fibres, respectively. Mixtures with 1%, 2% and 3% of plastic waste and with 0.5%, 1.0% and 1.5% of sisal fibres with 15 mm length were characterized. Laboratory tests were performed to assess their ability to improve soil properties for embankment construction and pavement layers. The bearing capacity ratio was determined using California Bearing Ratio (CBR) test. An increase in the bearing capacity ratio was achieved with plastic waste stabilization. Reduction in the bearing capacity ratio was observed in the specimens stabilized with sisal fibres. Increase in the bearing capacity ratio was more effective for high penetration values. The dry unit weigh decreased with the increase in plastic waste / sisal fibre content.

RÉSUMÉ: Au Portugal, les revêtements routiers ainsi que leurs fondations sont pour la plupart construits avec des granulats naturels, généralement concassés, avec des impacts économiques et environnementaux élevés. En revanche, la tentative d'utiliser des matériaux d'excavation est devenue plus fréquente, chaque fois qu'ils répondent aux exigences de cet usage, soit dans les fondations, soit dans les couches granulaires des revêtements routiers. Cependant, il arrive souvent que les matériaux trouvés sur la ligne ne répondent pas aux exigences pour être réutilisés dans les travaux. Une façon de rendre possible la réutilisation de ces matériaux est d'améliorer leurs propriétés pour répondre aux exigences d'utilisation. Dans ce travail, deux sols argilo-sableux ont été caractérisés, respectivement à l'état naturel et après mélange avec des déchets plastiques et des fibres de sisal. Des mélanges contenant 1%, 2% et 3% de déchets plastiques et 0,5%, 1,0% et 1,5% de fibres de sisal d'une longueur de 15 mm ont été caractérisés. Des tests en laboratoire ont été effectués pour évaluer leur capacité à améliorer les propriétés du sol pour la construction de remblais et les couches de chaussée. La capacité portante a été déterminée à l'aide du test CBR. Une augmentation de la capacité portante a été obtenue grâce à la stabilisation des déchets plastiques. Une réduction de la capacité portante a été observée sur les échantillons stabilisés avec des fibres de sisal. Le poids unitaire sec a diminué avec l'augmentation de la teneur en déchets plastiques/fibres de sisal.

Keywords: Soil stabilization; CBR test; plastic waste; sisal fibres; road embankments.

1 INTRODUCTION

There is a need to significantly reduce waste production and increase recycling rates. Many wastes and industrial by-products can benefit from more reuse and recycling solutions reducing the life cycle impacts. However, since natural fibres are readily available and less expensive, soil can also be stabilized with them.

Soil stabilization using waste materials or natural fibres as an additive can have technical and environmental advantages. Some researchers have studied the use of waste materials, mainly produced from plastic wastes (Paramkusam et al. 2013) and natural fibres (Fonseca da Silva, et al., 2019) in soil stabilization.

The plastic wastes can be used for stabilization as plastic strips, plastic flakes, or fibres. Plastic wastes included, as example, plastic strips of HDPE or PET from bottles (Rawat and Kumar 2016; Babu and Chouksey 2011), shredded labels of PE and PP from packages (Gardete et al. 2017), flakes from grounded PET bottles (Gardete and Luzia 2017).

Natural fibres can have different origins, such as sisal, coconut, jute, rice straw, bamboo, linen, and cut into different lengths, from 5 mm (Wu, et al., 2014) to 75 mm (Fonseca da Silva, et al., 2019) and used in different percentages, from 0.25% (Manjunath et al., 2013) to 2.0% (Mohammed, et al., 2022).

From the stabilization with several types of waste materials, it was observed that the percentages of

waste addition achieving best results are generally lower than 2% (Choudhary et al. 2010; Rawat and Kumar 2016; Paramkusam et al. 2013). From stabilization with natural fibers it was observed that the percentages of fiber addition that achieve better results are, generally, less than 1% (Nguyen and Indraratna, 2023). Nevertheless, some authors refer percentages up to 1.5% (Mohammed et al., 2022). With regard to fiber length, the optimal value varies between 10 mm (Maity et al., 2018) and 15 mm (Mohammed et al., 2022).

Stabilization with plastic waste materials and with natural fibres increased the resistance and the shear strength parameters of the soil measured in CBR tests, unconfined compression tests and simple shear tests (Hejazi et al. 2012, Nguyen and Indraratna, 2023).

2 MATERIALS

2.1 Soils

Two clayey sand soils (A and B) were used. Visually, the soils are reddish-brown with a significant quantity of fines and evident plastic behaviour. Plastic waste was mixed with the clayey sand soil A, with nearly 50% passing the No. 200 sieve. Sisal fibres were mixed with the clayey sand soil B, with nearly 37% passing the No.200 sieve.

At this point it should be said that for each of the tests referred to in the following sections, two specimens were tested. The results presented correspond to the average of the results for each of the specimens.

The gradation for both soils is presented in Figure 1 (LNEC, 1966a).

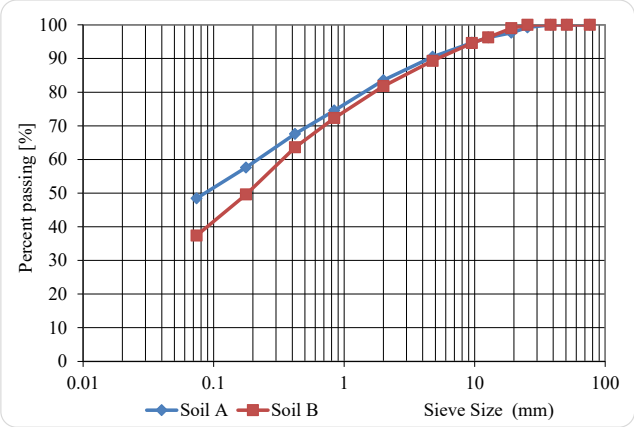

Figure 1. Gradation curves.

The following properties of the soils were characterized, liquid limit, plastic limit, sand equivalent, organic matter content and methylene blue value. The results are presented in Table 1.

Table 1. Soil properties.

Property	Standard	Soil A	Soil B
Liquid Limit [%]	NP 143 (IGPAI, 1969)	31.6	27.2
Plastic Limit [%]		20.6	20.7
Sand Equiva-lent [%]	LNEC E 199 (LNEC, 1967a)	14.4	44.6
Organic Matter Content [%]	NLT-117 (IRANOR, 1977)	2.48	3.00
Methylene Blue Value [g/100g]	NF P18-592 (AFNOR,1990)	0.8	0.5

Table 2 presents the classification of the two soils according to USCS (ASTM, 2006). and AASHTO (LNEC, 1970) classifications.

Table 2. Soil classification.

Classification	Soil A	Soil B
USCS (ASTM, 2006).	SC- Clayey sand	SC-SM – Silty clay sand
AASHTO (LNEC, 1970)	A-6-(3)	A-4(1)

Modified Proctor compaction test was used to determine MDD (Maximum Dry Density) and OMC (Optimum Moisture Content) of the soils. The test procedures followed standard LNEC E 197 (LNEC, 1966b). Soil A presented an OMC of 12.7% and MDD of 19.2 kN/m^3 and Soil B presented an OMC of 11.6% and MDD of 19.6 kN/m^3, Figure 2.

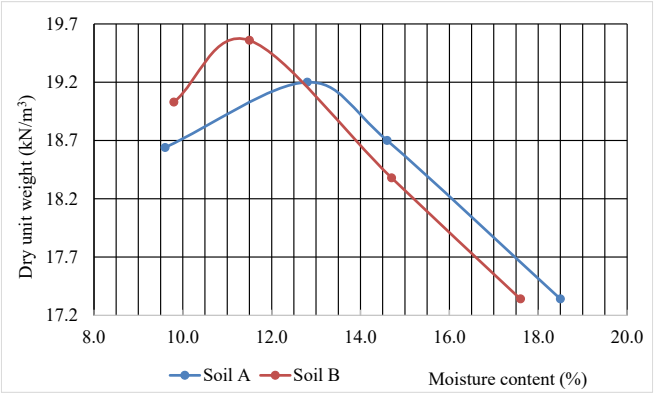

Figure 2. Modified Proctor test results.

2.2 Plastic waste and sisal fibres

2.2.1 Plastic waste

Plastic waste came from the industry and is used as it was provided without any modification. It was selected for having low recycling and reuse value. The plastic waste used was provided by plastic recycling

company Ecoiberia - Reciclados Ibéricos, S.A.. The plastic waste used was made from shredded labels in PE and PP. The flakes are highly flexible, very thin (estimated thickness from 30 to 60 µm), irregular shape and size mostly between 1.0 and 2.0 cm^2, some flakes are creased, Figure 3. The flakes are made from assorted materials and colors, therefore this type of waste has low interest for recycling.

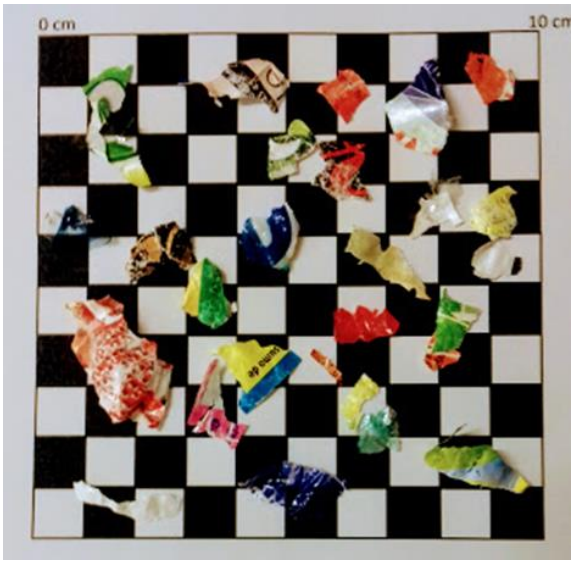

Figure 3. Waste plastic flakes.

2.2.2 Sisal fibres

The sisal fibers used were purchased in a commercial store and are generally used for civil construction work associated with plaster. Sisal fibers generally have an average diameter of 150 µm and a density of 1.35 g/cm^3 (Mohammed et al., 2022) and were cut to 15 mm in length, Figure 4.

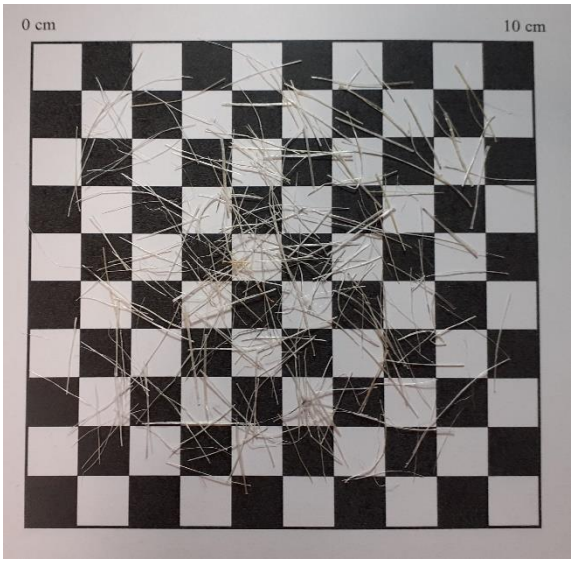

Figure 4. Sisal fibres.

3 SOIL STABILIZATION

3.1 Mixing

The soils were mixed with both plastic waste and sisal fibres by hand. The contents of plastic waste used were 1%, 2% and 3%, weight of waste / dry weight of soil and for sisal fibre were 0.5%, 1.0% and 1.5%, weight of sisal fibre / dry weight of soil. The values for 0% waste / sisal fibre content are referred to the original soils without stabilization. For the stabilization plastic waste / sisal fibres were added to the dry soils. These were mixed until a visually homogeneous mixture was observed. The water content for all specimens compacted corresponded to the OMC of the original soils (soil A for plastic waste and soil B for the sisal fibers). Water was added and mixture proceeded until a good dispersion of the water in the mixture was observed.

A homogeneous mixture was easy to achieve when using the waste plastic flakes. Flakes are easily dispersed in the soil and a visually homogeneous dispersion was observed.

With sisal fibers it was a little more complicated to mix, particularly for the higher percentage of fibre. Even so, a mixture with good homogeneity was achieved.

All specimens were compacted with 55 blows/layer (like the Modified Proctor Test specimens).

Two specimens were tested for each waste plastic / sisal fibre percentage.

3.2 CBR test results

CBR test procedures followed standard LNEC E 198 (LNEC, 1967b). In Figure 5 are presented the relative compaction (dry density of the specimen / MDD) values for CBR specimens. As expected, higher plastic waste/sisal fibre content lead to lower relative compaction.

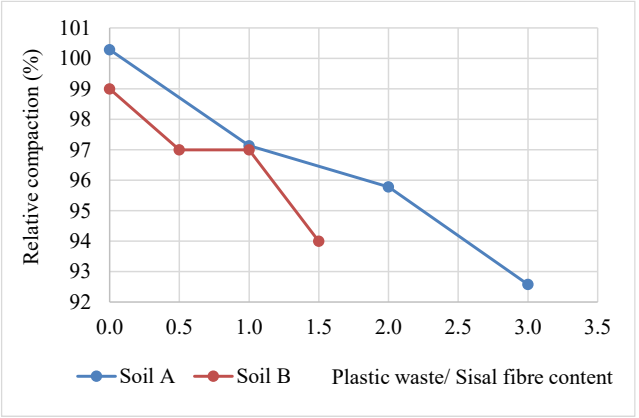

Figure 5. Relative compaction in CBR specimens.

In Figure 6 and Figure 7 the Force-Penetration curves from the CBR test are presented. The effect of the stabilization is more evident for high penetrations. For penetration values higher than 10 mm stabilization with 1% and 2% of plastic flakes provided better result than the original soil. Stabilization with sisal fibres shows that the original soil presented better performance until 6.0 mm of penetration. After 6.0 mm it was observed a change in the trend with a reduction of performance. Whereas mixtures with 1.0% and 1.5% of fibres maintained a practically linear trend up to 12 mm of penetration.

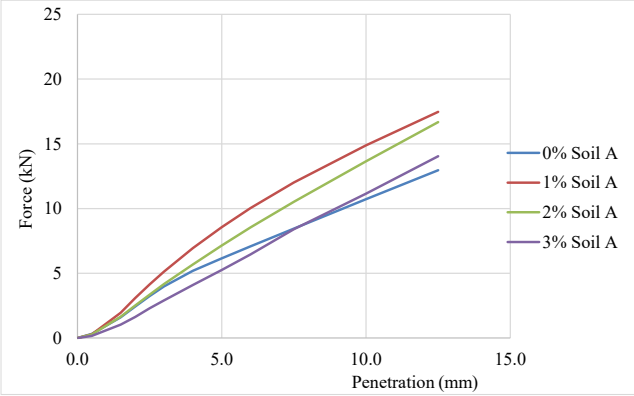

Figure 6. Force-penetration curves for soil A stabilized with waste plastic flakes.

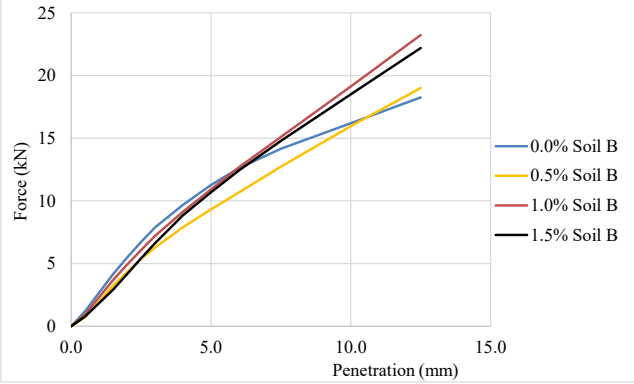

Figure 7. Force-penetration curves for soil B stabilized with sisal fibres.

The CBR values obtained for 2.5 mm and 5.0 mm penetration are presented in Figure 8. For both soils CBR values for 5.0 mm penetration were higher. Stabilization with plastic waste increased CBR values until 1% content but after this value CBR values decreased with increasing plastic waste content. For 1% plastic waste content CBR at 5.0 mm penetration increased from 14% to 19% (36% increase), and CBR at 2.5 mm penetration increased from 11% to 14% (27% increase). No increase in CBR was observed for sisal fibre stabilization. The original soil achieved higher CBR2.5 and CBR5.0 values. The CBR values decrease for 0.5% of sisal fibers, increasing to 1%, to 55%, very close to the natural soil, and decreasing again to 1.5%.

The results obtained in Figure 6 and Figure 7 show that the improvement in soil behavior obtained by stabilization with plastic waste / sisal fiber is more evident for high penetration values (greater than 5 to 6 mm). Therefore, this improvement in behavior is not captured in the CBR values (determined for 2.5 and 5 mm of penetration), Figure 8. As a consequence, it is also observed that the CBR values for 5 mm present a more favorable trend than those for 2.5mm. Despite observing an improvement in soil behavior through the analysis of force-penetration curves, in the CBR values only for stabilization with plastic waste, an increase in CBR values was obtained compared to the original soil, in this case to a percentage of 1%.

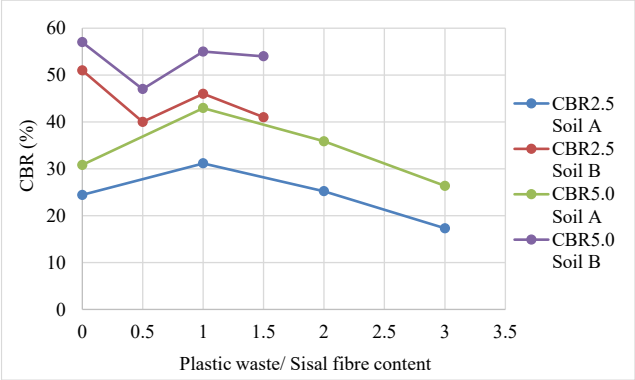

Figure 8. CBR2.5 and CBR 5.0 values.

4 CONCLUSIONS

Waste plastic flakes and sisal fibres were used for the stabilization of two clayey sand soils, Soil A and Soil B. Contents of 1%, 2% and 3% of plastic waste and 0.5%, 1.0% and 1.5% of sisal fibres were used. Results show a decrease in the relative compaction with increasing plastic waste or fibre content. Stabilization with waste plastic flakes increased CBR by more than 20% when compared to the original soil. Optimum waste plastic flakes content was 1%. CBR values decreased for higher contents. CBR values generally decreased with the addition of sisal fibres. However, for 1% of fibers the CBR value, 55%, is close to the CBR of natural soil, 57%. For 1.5% the CBR decreases again. This maybe could be explained by the fact that the mixture with sisal fibers is less homogeneous.

The use of waste materials and natural fibres for soil stabilization can be interesting options. Waste plastic flakes showed better results, the dispersion in the soil was easy and increased CBR values for percentages close to 1%. Sisal fibres were more complicated to mix, with low homogeneity achieved and CBR values generally decreased.

ABSTRACT: Anthropic activities significantly contribute to the release of CO_2 into the atmosphere, which worsens global warming and accelerates climate change. To address these issues, geological storage in depleted oil reservoirs is seen as a potential solution to mitigate these effects. However, there is a lack of information on the application of this technique in the Golfo San Jorge Basin in Argentina, as well as geomechanical studies on its rocks. This study aims to characterize the geomechanical properties of rocks from the Salamanca, Castillo and Pozo D-129, formations under the influence of supercritical carbon dioxide injection. The studied samples were obtained from reservoir analogues exposed at the outcrop. Core plugs were used to assess the variation in the rock's mechanical behaviour when exposed to a CO_2-rich environment during 30-day periods, by performing Uniaxial Compressive Tests in both pristine and carbonated states. Additional analyses including X-ray diffraction (DRX) and mercury intrusion porosimetry (MIP) were conducted to evaluate the modifications produced in the microstructure. Notably, significant variations in mechanical parameters and porosity were observed in the studied formations. This article discusses the interaction between rock and supercritical CO_2, considering its chemical composition, to contribute to a better understanding of the potential for geological storage in the Golfo San Jorge Basin.

RÉSUMÉ: Les activités anthropiques contribuent de manière significative à la libération de CO_2 dans l'atmosphère, ce qui aggrave le réchauffement de la planète et accélère le changement climatique. Le stockage géologique dans des réservoirs de pétrole épuisés est considéré comme une solution potentielle pour atténuer ces effets. Cependant, on manque d'informations sur l'application de cette technique dans le bassin du Golfo San Jorge en Argentine, ainsi que d'études géomécaniques sur ses roches. Cette étude vise à caractériser les propriétés géomécaniques des roches des formations de Salamanca, Pozo D-129 et Castillo sous l'influence de l'injection de dioxyde de carbone supercritique. Les échantillons étudiés ont été obtenus à partir d'analogues de réservoirs exposés à l'affleurement. Des carottes ont été utilisées pour évaluer la variation du comportement mécanique de la roche lorsqu'elle est exposée à un environnement riche en CO_2 pendant des périodes de 30 jours, en effectuant des essais de compression uniaxiale à l'état vierge et à l'état carbonaté. Des analyses supplémentaires, notamment la diffraction des rayons X (DRX) et la porosimétrie par intrusion de mercure (MIP), ont été effectuées pour évaluer les modifications produites dans la microstructure. Notamment, des variations significatives des paramètres mécaniques et de la porosité ont été observées dans les formations étudiées. Cet article traite de l'interaction entre la roche et le CO_2 supercritique, compte tenu de sa composition chimique, dans le but de contribuer à une meilleure compréhension du potentiel de stockage géologique dans le bassin du Golfo San Jorge.

Keywords: Carbon dioxide geological storage; supercritical CO_2; Golfo San Jorge Basin; depleted oil and gas reservoirs; geomechanical property evolution.

1 INTRODUCTION

According to the Intergovernmental Pannel on Climate Change, during the past 100 years, an increase of 1.1ºC has been produced in the World's mean temperature (IPCC, 2023). Bearing in mind that climate change is produced due to the increase in the emission of greenhouse effect gases (GHG), and that at least 75% of them are represented by carbon dioxide (CO_2), it would be reasonable to think that by reducing the emissions of CO_2, this phenomenon would be mitigated. Among the available alternatives, capturing and storing CO_2 in the subsurface, is being considered as a way of reducing the concentration of this GHG in the atmosphere, while replacements for fossil fuels are developed.

CO_2 underground storage consists of capturing the CO_2 directly from its emission source (industries) for its further injection into an underground rock stratum. The formation chosen as reservoir, must be studied deeply enough to assure it is adequate. The feasibility of using a certain stratum as a CO_2 reservoir is determined by the evolution of the rock's geomechanical and hydro-chemical properties when exposed to a supercritical CO_2 ($scCO_2$) rich environment. The final objective is to ensure the reservoir's integrity in both short and long terms. Among the properties looked after in a possible CO_2 store, porosity, permeability, composition, and strength are of special interest (Bradshaw et al., 2007, and Hawkes et al., 2004).

In Argentina, there are several underground formations considered as possible CO_2 stores. Some of the potential underground reservoirs are Neuquina Basin, Claromecó Basin and Golfo San Jorge Basin (GSJB) (Grasetti et al., 2022, Laskowski et al., 2023). The three of them are characterized for being oil and gas reservoirs, being of particular interest for this study the Golfo San Jorge Basin (GSJB), since it stands out for containing reservoir rocks in different formations such as Salamanca, Castillo and Pozo D-129.

The main aim of the presented research is to fill the lack of information available in terms of geomechanical and chemical characterization of some GSB Basin formations and to technically consider their potential as possible CO_2 reservoirs. In this context, the results obtained from developing a series of laboratory tests on both pristine and carbonated rocks are presented, showing the evolution produced in their properties after the 30-day and 60-day aging.

2 MATERIALS AND METHODS

2.1 Geological context

The three different groups of rocks studied correspond to Salamanca, Castillo, and Pozo D-129 formations, which are all part of the Golfo San Jorge Basin (GSJB). Figure 1 shows a resume of the geological context of GSJB. The Pozo D-129 Fm. is the basal unit of the Chubut Group, which contains some tight reservoirs that serves as a source of oil and gas (Paredes et al. 2022). The depositional environment is associated with lacustrine and deltaic systems (Allard et al., 2018). The overliying Castillo Fm. represents traditional reservoirs of the petroleum system associated to the Chubut Group, consisting mainly of fluvial and paleosoils deposits (Paredes et al. 2015). A common feature of both rocks is the presence of varying amounts of tuffaceous material, associated with resedimented volcanic ash. The main lithologies are tuffaceous sandstone and tuff. (Cortes et al., 2024). On the other hand, the Salamanca Fm. is the shallowest oil reservoir of the basin, depleted at present and formed of marine sediments. The analyzed rock is a well-sorted glauconitic sandstone (Foix 2009).

These reservoir rocks are proposed as possible CO_2 stores as they meet the properties mentioned by Bachu (2000), presenting high porosity and permeability values (Cortés et al. 2024). Besides, the contrasting geological framework allows for the evaluation of different controls like the lithological composition and the diagenetic evolution.

2.2 Pristine and carbonated cores

To analyse the evolution produced in the properties of the different rocks due to their exposure to a CO_2-rich environment, it is necessary to obtain a group of representative specimens. Even when it would be ideal to obtain reservoir depth samples, this was economically not feasible, so it was proposed as a first approach, to obtain outcrop samples. Once in the laboratory, from these samples, cores with a 38 mm diameter and 76 mm height were obtained following the ASTM D 4543 – 01 specifications. From the samples obtained, half of them were separated and stored as pristine samples, and the other half were selected to expose them to $scCO_2$. Having completed the separation of the cores, the ageing process began.

Firstly, the cores were saturated in water by submerging them for 24 hours. This is an important step since water inside the rock facilitates the diffusion of CO_2. Secondly, they were disposed of in a tray holder, and introduced in the carbonation cell (Figure 2), where the CO_2-aging procedure was meant to be completed. Thirdly, the gas inlet was allowed until the carbonation cell was filled, a moment in which the temperature and pressure conditions were established to ensure the supercritical state of the CO_2 (60ºC temperature and 10 MPa pressure). The cell's conditions were maintained constant for 30 days. Finally, both the temperature and pressure were taken to environmental conditions carefully, to avoid the cracking or even fracture of the carbonated cores due to abrupt changes. The extracted cores were stored in a constant temperature and humidity chamber, covered in 40 μm polyethylene film, to maintain their properties invariant in time.

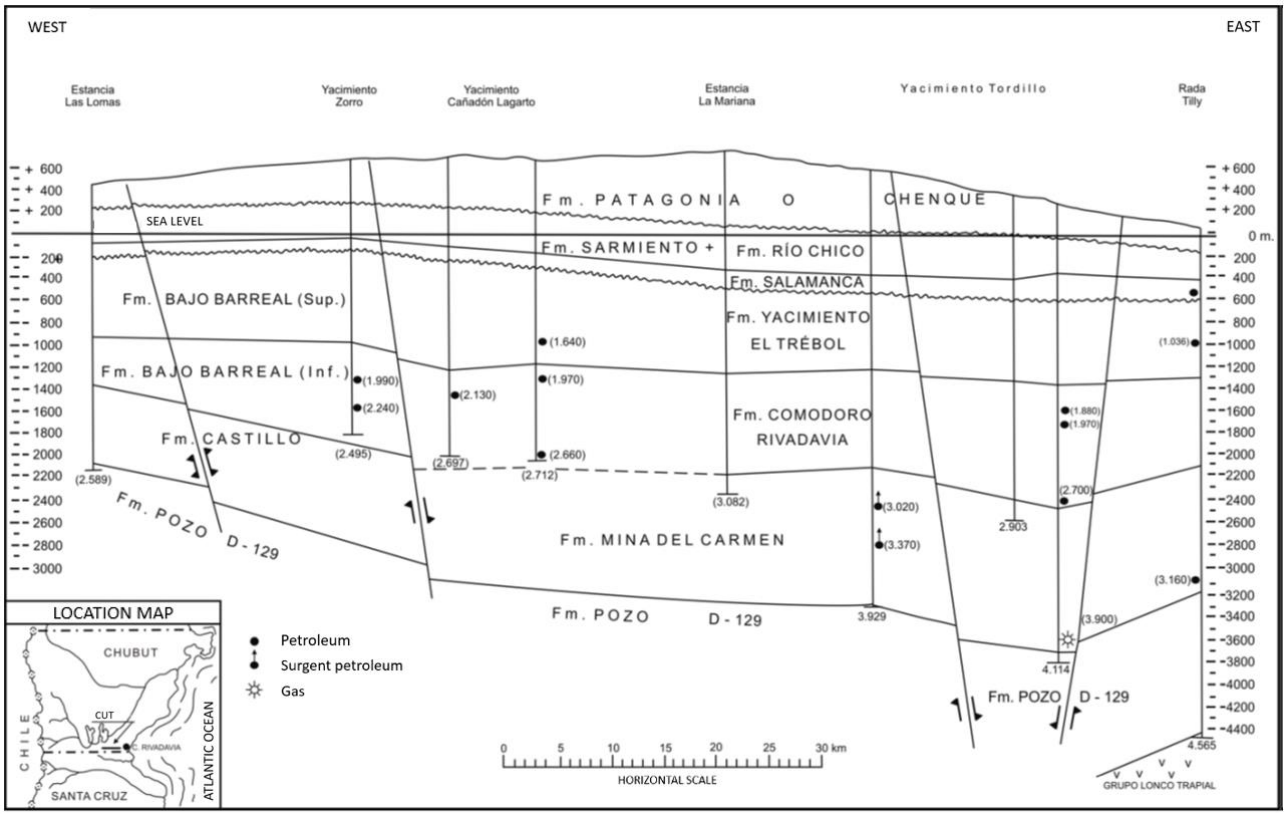

Figure 1. Golfo San Jorge Basin distribution of studied Formations (Sciutto et al., 2008).

Figure 2. Specimens in tray holder and carbonation cell.

2.3 Mechanical properties determination

The importance of analysing the evolution produced in the mechanical behaviour of the reservoir rock proposed as CO_2 underground storage, lies in verifying its long-term integrity. It is in this context, that a series of Uniaxial Compressive Tests, following the ASTM D 3148 – 02 specifications, were performed in both pristine and carbonated rock cores corresponding to the three formations. The results obtained from these tests were tenso-deformational curves which allowed making a complete comparison between the mechanical and elastic properties of the rocks before and after their exposure to $scCO_2$.

2.4 Microstructural properties determination

To reach a better understanding of the results obtained from performing the Uniaxial Compressive Tests, the variation produced in the microstructural properties due to CO_2 injection was analysed. The tests chosen for this research were the Mercury Intrusion Porosimetry (MIP) and the X-Ray Diffraction (XRD). With the results derived from the first group of tests, the available pore volume for CO_2 storage would be estimated, giving this a first approach to determine if the rock is a good reservoir alternative or not. On the other hand, the results obtained from the XRD, would allow to understand the trapping mechanisms being developed in each rock.

3 RESULTS AND DISCUSSION

3.1 Uniaxial compressive strength

The stress–strain curve obtained from performing Uniaxial Compressive Tests on Salamanca Fm. shows a significant reduction of Uniaxial Compressive Strength in carbonated cores at 30 days as is shown in Figure 1. Also is observed that the sample becomes more ductile after the $scCO_2$-aging.

Figure 3 shows the comparison for all lithologies, and formations, showcasing the evolution of Uniaxial Compressive Strength (UCS) for both pristine and

carbonated cores. After subjecting the Sandstone from the Salamanca Fm. to ageing with supercritical carbon dioxide for 30 days, a notable decrease of approximately 40% in Uniaxial Compressive Strength (UCS) is evident. However, in the Tuffaceous Sandstone samples and the Tuff from Castillo and D-129 Fms., this reduction is less pronounced, ranging from 20 to 22%. The trend of UCS reduction persists in rock samples aged for 60 days, though the results remain inconclusive due to the limited number of tests conducted. Various authors have highlighted variations in strength, which depend upon the composition of the rocks. Typically, carbonates exhibit more significant alterations, while results for carbonate-cemented sandstone appear ambiguous, and silica-cemented sandstone tends to undergo minor changes (Vilarrasa et al., 2019). The predominance of carbonate cement within the Salamanca Fm. (Laskowski et al., 2024) and the identification of zeolitic cement in the D-129 Fm. (Olazabal, pers. com.) and samples from the Castillo Fm. (Tunik et al., 2015), explains the variations in strength observed, both before and after $scCO_2$ carbonation, between the studied formations.

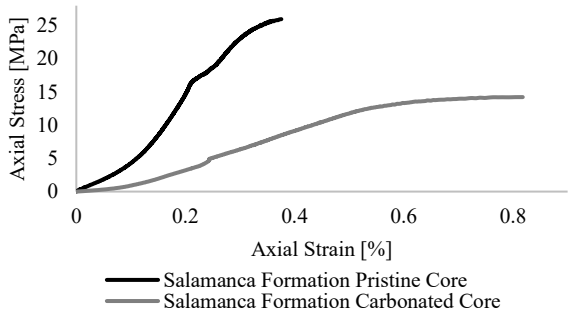

Figure 2. Example of results of stress – strain curve obtained from performing Uniaxial Compressive Tests on Salamanca, in both pristine and carbonated cores at 30 days.

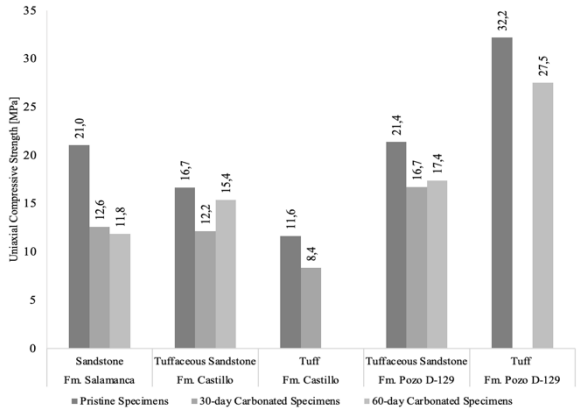

Figure 3. UCS on Salamanca, Castilla and Pozo D-129 Fms, in both pristine and carbonated cores at 30 and 60 days.

3.2 Porosity variations after $scCO_2$-exposure

Mercury Intrusion Porosimetry (MIP) tests were carried out to examine the porosity changes in the chosen reservoir rock induced by supercritical carbon dioxide ($scCO_2$). In general, the sandstone demonstrated a reduction in porosity following exposure to a CO_2-rich environment as is shown in Table 1. MIP porosity of sandstone from Salamanca Fm. is approximately 10.66%, while post-aging porosity is 9.65%. The tuffaceous sandstone from the Castillo Formation and the Tuff of the D-129 Formation exhibit mean values of MIP porosity of approximately 19%, with post-aging porosity measuring 17%.

A detailed examination of Figure 4 revealed changes in the pore size distribution of sandstone from Salamanca Fm. The Differential Intrusion-Pore Diameter curves indicated a notable increase in the volume of smaller pores (40-90 nm), rising from 30% to 45%, alongside a decrease in the larger pores (800-4000 nm) from 30% to 10%.

Table 1. Porosities were obtained for the different rocks studied.

Specimen Characterization		CO_2 exposure time [days]	
		0	30
Formation	Lithology	Porosity [%]	
Fm. Salamanca	Sandstone	10,66	9,65
Fm. Castillo	Tuffaceous Sandstone	19,79	17,05
Fm. Pozo D-129	Tuff	19,30	17,05

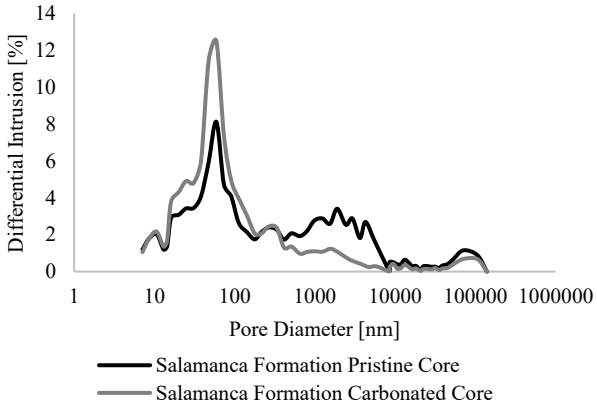

Figure 4. Results of Differential Intrusion-Pore Diameter obtained from performing MIP tests on Sandstone from Salamanca Fm. in both pristine and carbonated cores.

3.3 X-Ray diffraction

XRD analysis demonstrated that the rocks from Castillo and D-129 Fm. generally contain variable amounts of quartz, potassic feldspar, plagioclase, and clays such as kaolinite and illite. Small amounts of

jarosite and analcime are also present in some of the samples.

The treated samples exhibited insignificant changes in potassic feldspar, kaolinite, and illite, except for a 2% reduction in illite observed only in the tuffaceous sandstone of the Castillo Fm. Similarly, analcime displayed minimal changes, but the variation was almost 7%.

The most significant alterations were observed in quartz and plagioclase. In most cases, quartz content decreased, while plagioclase increased in the treated samples. This trend aligns with the measurements of silica and aluminium obtained by portable XRF (Cortés et al., 2024). The reduction in silica and quartz content in the carbonated samples, as determined by XRF and XRD measurements, respectively, may be attributed to the corrosion of quartz crystals (Rathnaweera et al., 2015) or the dissolution of clay minerals (Rathnaweera et al., 2015). However, it is more conventional for feldspars to react before quartz.

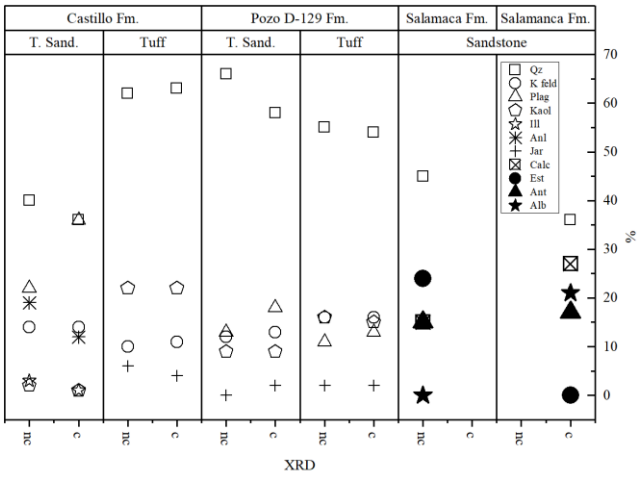

Figure 5. Mineral composition of carbonated and non-carbonated samples determined by XRD. Qz= Quartz, K feld= Potassium feldspar, Plag= Plagioclase, Kaol=Kaolinite, Ill=Illite, Anl=Analcine, Jar=Jarosite. Cal = magnesic calcite, Est = sodic estilbita, Ant = anorthite, Alb=albite.

Remarkably, the quantity of potassic feldspar remained relatively stable, while the amount of plagioclase increased. Both observations pose geological inconsistencies due to the inert nature of quartz and the exclusive magmatic genesis of plagioclase. This increase is attributed to the dissolution of minerals more soluble than plagioclase, leading to an increase in its relative content as stated by Yang et al. (2022). This also could be attributed to the sampling process, which may be influenced by the potential heterogeneity of the formation. Another aspect to remark on is the high quartz content which is inconsistent with previous petrographic studies as stated by Cortés et al. (2024).

The treated samples of Sandstone from Salamanca Fm. exibihit changes in magnesic calcite, sodic estilbita and albite. The effects of glauconite reaction to CO_2 may be a major control in the associated geochemical process (Fu et al. 2015). These changes are affecting the porous matrix and its strength. Further clarity on this uncertainty will be obtained through in-depth analyses, such as thin sections or Scanning Electron Microscope images.

4 CONCLUSIONS

The research emphasizes findings across mechanical, petrophysical, and chemical evolution of the glauconitic sandstone of Salamanca Fm. and tuff and tuffaceous sandstone Castillo and Pozo D-129 Fms for pristine and supercritical CO_2-aged samples at 30 and 60 days.

The evident alteration in the chemical composition of the treated specimens indicates a consequential influence on both mechanical strength and porosity. The drop in mechanical strength is evident across all three analyzed lithologies following CO_2-aging. However, despite the impact on mechanical strength, the samples exhibit a decrease in porosity. Further examination, particularly through thin sections and Scanning Electron Microscopy (SEM), is imperative to elucidate the underlying geochemical reactions and mineralogical changes. The scope of tests is being broadened, encompassing triaxial tests, to delve deeper into the mechanical behaviour and explore the evolution of microstructures under conditions mimicking CO_2 underground storage.

Testing methodologies to evaluate waste-based liners

Méthodologies de test pour évaluer les revêtements à base de déchets

ABSTRACT: Improper waste disposal and management due to industrial activity may lead to soil and groundwater contamination. Thus, the development of methodologies for mitigating waste generation and its valorisation should be investigated to reduce environmental impacts, create waste-based products, and fulfil sustainable development goals. When malfunctioning, earthworks can negatively impact the environmental, besides clayey soils have mechanical issues, and represent high costs of logistics depending on the region, in addition to geosynthetics being still a costly solution. Therefore, recent investigations are using industrials by-products for construction purpose. This research reviews the literature of the main wastes used as liner materials, and their laboratorial tests program to evaluate their potential for liner. Furthermore, a flowchart was designed to optimize the valorisation process depending on the waste availability, and a table developed within the tests over the literature available.

RÉSUMÉ: Une élimination et une gestion inappropriées des déchets dues à l'activité industrielle peuvent entraîner une contamination des sols et des eaux souterraines. Ainsi, le développement de méthodologies pour atténuer la production de déchets et leur valorisation devrait être étudié pour réduire les impacts environnementaux, créer des produits à base de déchets et atteindre les objectifs de développement durable. En cas de dysfonctionnement, les terrassements peuvent avoir un impact négatif sur l'environnement, de plus les sols argileux présentent des problèmes mécaniques, et représentent des coûts logistiques élevés selon les régions, de plus les géosynthétiques restent une solution coûteuse. Par conséquent, des études récentes utilisent des sous-produits industriels à des fins de construction. Cette recherche passe en revue la littérature sur les principaux déchets utilisés comme matériaux de revêtement, ainsi que leur programme d'essais en laboratoire pour évaluer leur potentiel pour l'imperméabilisation des terrassements. De plus, un organigramme a été conçu pour optimiser le processus de valorisation en fonction de la disponibilité des déchets, et un tableau a été développé pour organiser les tests selon la littérature disponible.

Keywords: Industrial wastes; methodology for liner material; laboratory and in-situ tests; geotechnical applications.

1 INTRODUCTION

Liner materials are usually made of compacted clay liners (CCL) or geosynthetic clay liners (GCL), mainly used as layers of low hydraulic conductivity (k) and environmental protection barriers in landfilling, roads, channels, dams, reservoirs, and wastewater lagoons and ponds (Bouazza, 2002; Kerry Rowe et al., 2022). Suitable liners' properties can be summarized mainly as having low k, less than or equal to 10^{-9} m/s, enough strength to support the weight of the disposed/transported solid/liquid materials, deformation during service without cracking or rupture, self-healing properties, and chemical compatibility with the materials.

Depending on the region, natural clays exploration creates logistics' issues and environmental impacts, besides, geosynthetics still represents a costly solution, justifying the use of alternative materials, for use as waterproofing in earthworks. Furthermore, there are several industrial by-products as mining tailings (Maritsa et al., 2016; Pastore 2003; Marchiori et al., 2022a), furnace slags (Masri et al., 2019; Bennett et al., 2011; Liu et al., 2022; Herrmann et al., 2010), fly ashes (von Maubeuge et al., 2015; Marchiori et al., 2023b), and water treatment sludges (Baghbani et al., 2023, Marchiori et al., 2021, 2022b), which seem to have chemical and mechanical properties for that application. The reuse or valorisation of industrial by-products is within the circular economy directives and United Nations' Agenda for Sustainable Development Goals since it allows reduction of construction costs, helps preserve natural resources, decreases the production of synthetic materials and lead to sustainable new geomaterials design.

In addition, there was identified lack of specific methodologies to classify certain types of waste materials as geomaterials (Kerry Rowe et al., 2022), mainly over geotechnical, chemical, and environmental characterization, long-term behaviour of materials, mechanical properties, chemical and mineralogical composition, and leaching evaluation (Agamuthu, 2013; Devarangadi and Shakar M, 2021; Marchiori et al., 2020). Thus, this paper aims to review the literature, select the main laboratorial and in-situ test programs, and propose a laboratorial program to evaluate industrial by-products as liner geomaterial.

2 METHODOLOGY

A review of the literature was performed gather testing methodologies used for producing and assessing liner alternative materials. The chosen database was Scopus, and the main tests were selected in order to create Figure 1 and Table 1.

3 RESULTS

The process to qualify a waste material as a sustainable barrier should comprise careful sampling, identification, and characterization according to physical, chemical, mechanical, and hydraulic parameters, and the need of additives and/or geosynthetics materials to mitigate environmental impact without performance loss. The following subsections present the main concerns on the mentioned characteristics. Table 1 summarizes testing programs used by different authors. The flowchart in Figure 1 organizes the proposed methodology for waste valorisation as liner material.

3.1 Sampling and identification

The most concern about sampling is due to contamination, all the care with the samples must be done in order to do not contaminate it. It is very important to understand and analyze all the industrial processes that generate the by-products to understand some components in further identification (Kerry Rowe et al, 2022). Sample treatment can be included, like dehydration and sieved, but calcination should be avoided due to gas release.

Chemical compactibility and potential negative environmental impacts are the most important worries when dealing withh waste containment facilities. The composition through X-ray fluorescence (XRF) and mineralogical composition with X-ray diffractures (XRD) should be done to identify the possiblity of contamination in the sample. Besides, microstructure assessment with scanning electron microscopy (SEM), computed tomography (CT) scan and mercury intrusion porosimeter (MIP), in addition to thermogravimetric analysis (TGA) and Fourier transformed infrared (FTIR) linked to leaching potential for chemical detections (Marchiori et al., 2020). Physical identification includes the analysis of particle size distribution by sieve or laser equipment, and material classification, besides specific gravity measurements (Herrmann et al., 2010; Liu et al., 2022). The soil characterization should assess Atterberg limits and compaction characteristics within Proctor tests (Maritsa et al., 2016).

3.2 Geocomposite development

Specific gravity plays an important role in the chosen ratios of soil-waste when is searching for a suitable waste-based liner. Waste incorporation percentage must be defined according to the parameters to reach linked to its density (Marchiori et al., 2023a).

3.3 Geotechnical assessment

3.3.1 Mechanical performance

With those preliminary physical and chemical identification, and further geocomposite design, the mechanical evaluation can be done, basically understanding deformation over tension application, and the main tests to be develped are one-dimensional oedometric consolidation and consolidated-undrained (CU) triaxial shearing test to simulate liner conditions (Marchiori et al., 2022b, 2023b).

3.3.2 Hydraulic conductivity

The main parameter of liners is the hydraulic conductivity (k), permeability characterization must be comprised due to the required low k, less than or equal to 10^{-9} m/s. Intermediate- to large-scale experiments can be done, and the methodology for experimental liner development should be designed according to hydrogeological and geotechnical aspects of the selected site, besides economical and environmental impact of the area. Intelligent compaction should be addressed and permeability testing must be conducted (Bouazza, 2002).

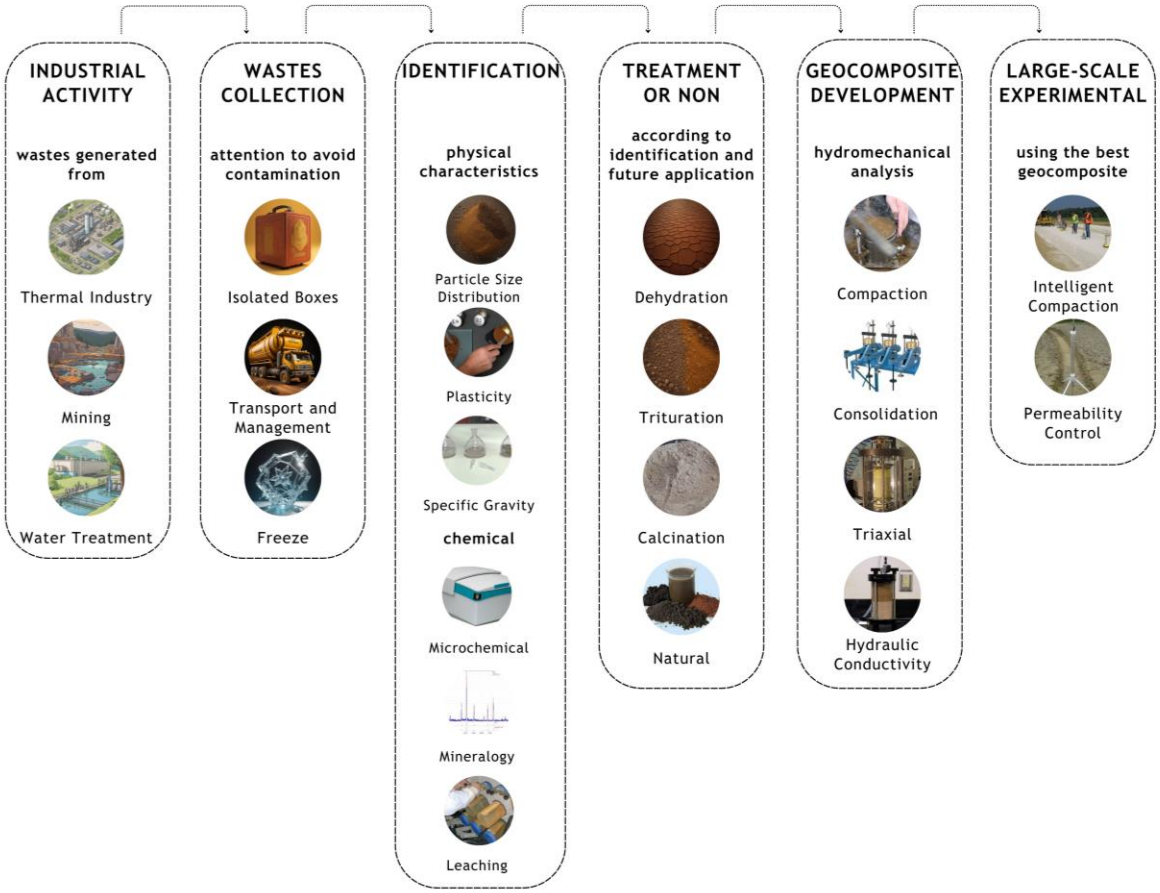

Figure 1. Schematic process for waste-based liner material evaluation.

4 CONCLUSIONS

The flowchart presented here aims to complement rather than invalidate other methods. It focuses on reducing the need for repeated laboratory work and emphasizes key factors and parameters for creating waterproof liners from waste materials. As a result, the information provided in this study, which covers environmental, physicochemical, and geomechanical tests, appears to facilitate the use of wastes with soils for liner production as alternative geomaterials.

Numerical analysis of monopiles supporting offshore wind turbines exposed to scour and cyclic loading

Analyse numérique des monopieux supportant des éoliennes offshores exposées à l'affouillement et aux charges cycliques

C. Menéndez-Vicente*, S. López-Querol
University College London, London, United Kingdom
**carlos.vicente.19@ucl.ac.uk*

ABSTRACT: Offshore wind turbines founded on monopiles are exposed to geohazards such as scour that threaten their long-term stability and serviceability. An active seabed changes the foundation conditions of these structures, which directly affects the soil-structure stiffness and its performance under environmental (cyclic) loading composed of wind and sea waves. This study aims to investigate the effects of scour under cyclic loading. A numerical approach with finite element analysis in Abaqus was applied. To simulate the long-term strain accumulation with load cycles, a hypoplastic constitutive model to reproduce the sand behaviour was implemented. Through these simulations, the ratcheting phenomenon based on increasing deformations with the number of cycles, has been simulated for sandy soils. The results quantify the effect of higher scour depths causing an increase of the displacement incremental rate per load cycle, which leads to larger maximum and residual displacements. This evidences the long-term risk for monopiles exposed to scour and cyclic loading in terms of serviceability and economic viability, due to a potential lifetime reduction given their vulnerability to excessive tilt. This study intends to raise awareness about the importance of considering scour during the design and operation of offshore wind turbines exposed to an active seabed.

RÉSUMÉ: Les éoliennes offshore fondées sur des monopieux sont exposées à des géorisques tels que l'affouillement, qui menacent leur stabilité et leur fonctionnalité à long terme. Un fond marin actif modifie les conditions de fondation de ces structures, ce qui affecte directement la rigidité du système sol-structure et son comportement sous une charge environnementale (cyclique) composée de vent et de vagues. Cette étude vise à examiner les effets de l'affouillement sur un monopieu soumis à une charge cyclique. Une approche numérique avec une analyse par éléments finis dans Abaqus a été appliquée. Pour simuler l'accumulation de déformations à long terme avec cycles de charge, un modèle constitutif hypoplastique simulant le comportement du sable a été implémenté. Ainsi, le phénomène de ratcheting de sols sableux, qui est basé sur l'augmentation des déformations avec l'augmentation du nombre de cycles, a été simulé. Les résultats quantifient l'effet que des profondeurs d'affouillement plus importantes entraînent une augmentation du taux de déplacements incrémentiels par cycle de charge, ce qui conduit à des déplacements maximaux et résiduels plus importants. Ceci met en évidence le risque à long terme pour les monopieux exposés à l'affouillement et aux charges cycliques en termes d'aptitude au service et de viabilité économique, en tenant compte d'une réduction potentielle de la durée de vie en raison de leur vulnérabilité à un basculement excessif. Cette étude vise à sensibiliser à l'importance de la considération de l'affouillement lors de la conception et de l'exploitation d'éoliennes offshore exposées à un fond marin actif.

Keywords: Offshore wind turbines; scour; monopiles; soil-structure interaction; finite elements analysis.

1 INTRODUCTION

Offshore Wind Turbines (OWT) are rapidly being installed worldwide due to the high demand for clean and renewable energy. These structures are exposed to waves and currents, which cause scour around piled foundations. Normally, scour protection such as rock armour is installed to prevent erosion. Nonetheless, non-protected foundations may develop scour holes, which reduce the embedment length and weaken the lateral capacity of monopiles. Cyclic loading caused by wind-wave loads leads to a degradation of the foundation material (often sands), which produces long-term strain accumulation and ultimately irreversible tilting (i.e. serviceability and structural damage). Moreover, this stiffness reduction may lead to a shift in the natural frequency towards the forcing frequencies and an increase in fatigue damage.

To numerically simulate OWT monopiles exposed to cyclic loading, complex constitutive models to replicate the long-term stress-path dependent strain accumulation of granular materials such as sands are needed. Hypoplasticity (von Wolfersdorff, 1996;

Niemunis and Herle, 1997) was implemented successfully by Askarinejad et al. (2022) for sands to reproduce their results obtained through centrifuge testing for a monopile with scour protection. The present paper intends to analyse the opposite: the effect of scour on monopiles exposed to cyclic loading. With a series of simulations for different scour depths S, the impact of cyclic loading is analysed through a hypoplastic constitutive law of the sand surrounding the scoured piled foundation.

2 METHODOLOGY

2.1 Numerical model

A finite element (FE) model based on the study of Askarinejad et al. (2022) was developed in Abaqus. The domain consists of a symmetric half soil-pile system with a pile diameter of $D = 1.8$ m (Figure 1). For comparison purposes, a further FE model with a large-diameter monopile ($D = 7.5$ m) was also modelled. Regarding the boundary conditions, the lateral faces were constrained in normal direction, whereas the bottom plane was fixed in all directions. The pile was modelled for simplicity with an elastic constitutive behaviour using solid bodies (instead of tubular structures) with equivalent masses and flexural stiffnesses (López-Querol et al., 2020). Table 1 shows the material properties, where D is the diameter of the pile, t is the thickness of the tubular profile, ρ is the density, v is the Poisson's ratio, E is the Young's modulus, and I is the moment of inertia. For the pile embedded in the soil, a sand fill of the tubular section was considered, whereas the upper part was modelled as a hollow cylinder. Dry densities were considered in analogy to Askarinejad et al. (2022); nonetheless, the findings are also applicable to submerged conditions. For the soil-pile interface, a fully rough condition was applied. The scour hole was modelled for simplicity as an inverted cone with a range of scour depths $S = \{0; 0.5D; 1.0D\}$ that may be found on the field (Whitehouse et al., 2011) and a slope angle equivalent to the soil's friction angle.

Table 1. Pile elastic properties.

Type	D [m]	t [m]	ρ [t/m^3]	v [-]	E [GPa]	I [m^4]
pile filled with sand						
tubular	1.8	0.031	7.86	0.2	210	0.0674
solid	1.8	-	2.397	0.2	27.51	0.5153
hollow structure						
tubular	1.8	0.031	7.86	0.2	210	0.0674
solid	1.8	-	0.532	0.2	27.47	0.5153

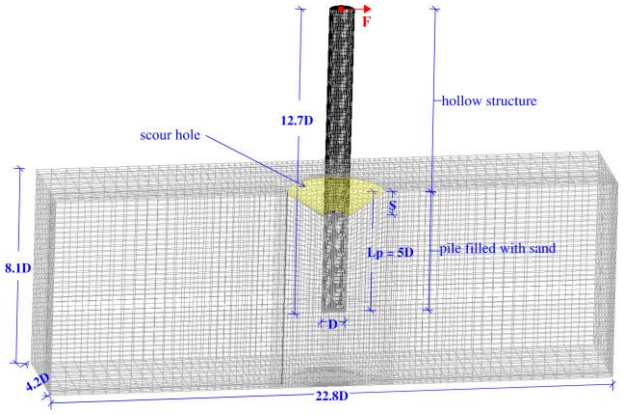

Figure 1. Mesh of the scoured soil-pile system used for FE analysis in Abaqus (adapted from Askarinejad et al., 2022).

2.2 Constitutive model

To reproduce the cyclic soil response, a hypoplastic constitutive model was implemented. This allows a strain and stress-path dependent stiffness adaptation for the simulation of strain accumulation under loading, unloading and reloading stress paths (von Wolfersdorff, 1996; Niemunis and Herle, 1997). With the hypoplastic model, the ratcheting phenomenon (i.e. cumulative plastic deformation, with a constant increment per cycle; Cuéllar, 2011) in sand was simulated. Readers are referred to Askarinejad et al. (2022) for further details about the implementation of hypoplasticity. A drained Geba sand was used with the parameters shown in Table 2 (Azúa-González et al., 2019). These parameters correspond to a fine sand with a d_{50} of 0.12 mm and a relative density of 0.63.

Table 2. Hypoplastic model for Geba sand (Azúa-González et al., 2019).

von Wolffersdorff´s model parameters							
φ'	h_s	n	α	β	e_{i0}	e_{c0}	e_{d0}

IS model parameters							
m_R	m_T	R	β_R	χ			
[-]	[-]	[-]	[-]	[-]			
5.5	3.9	10^{-4}	0.3	0.7			

2.3 Validation

The results obtained through centrifuge testing in Askarinejad et al. (2022) were used for validation. The numerical model described previously was subjected to a horizontal cyclic load applied on the top of the structure with a magnitude of 100 kN and a load frequency of 1 Hz with $N = 10$ load cycles.

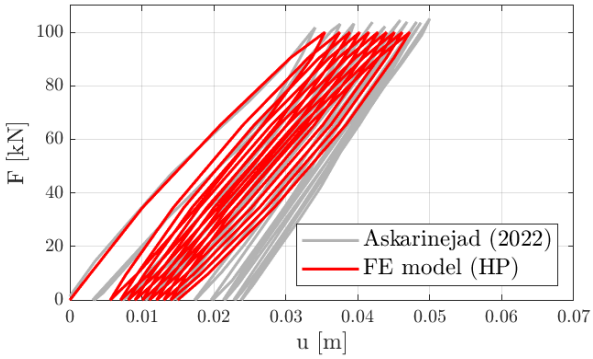

Figure 2. Validation results with hypoplasticity vs. centrifuge results from Askarinejad et al. (2022).

The FE model with hypoplasticity yielded similar results compared to those presented by Askarinejad et al. (2022). Figure 2 shows the horizontal displacements u at the top of the structure (loading point) plotted against the loading force F. A good agreement of the results with the centrifuge data is found, especially for the first load cycles. Hence, the hypoplastic model was considered validated and applied for further investigations of scour affecting the lateral soil-pile response under cyclic loading.

3 RESULTS AND DISCUSSION

The FE model described previously was subjected to a cyclic load with an amplitude of $F = 50$ kN at the top of the structure and a frequency of $f = 1$ Hz during $N = 10$ cycles as a simplified horizontal load representing a wind-wave resultant. For simplicity, only one-way load cycles were considered. Figure 3 and Figure 4 show the dimensionless load-displacement curve for different scour depths $S = \{0; 0.5D; 1.0D\}$ for the small and the large diameter monopiles respectively. A similar behaviour is observed for both models. In Figure 4 it is seen that the higher scour depth ($S = 1.0D$) moves away from the cases with $S = \{0; 0.5D\}$, evidencing the (large diameter) monopile vulnerability to scour compared to the small diameter monopile. The scour depth is linked with D, i.e. a higher D causes a higher absolute S. The displacements were recorded at the loading point (i.e. the top of the structure). The load was normalized by the dead load of the tubular pile ($V = m_{pile}\, g$) and the displacement was normalized by D. Figure 6 shows the soil horizontal stresses (σ_{11}) and the horizontal displacements (u_1) for $S = 0.5D$. Figure 5 shows the evolution of the maximum displacements with N. As expected, the accumulated displacements increase with increasing scour depth due to the loss of lateral bearing capacity given the shorter embedment length and the material degradation with increasing cycling.

It is seen from Figure 5 that the displacement accumulation increases at a higher rate with increasing scour depth. The incremental rate $(u_{N=10} - u_{N=1})/u_{N=1}$ increases from 13% (for $S = 0$) to 19% (for $S = 1.0D$) in the first ten cycles. This confirms that scoured monopiles are more vulnerable to cyclic loading compared to non-scoured monopiles or those with scour protection. Figure 6 (u_1) shows that plastic displacements remain after a series of cycles at the top and bottom of the pile, suggesting a permanent tilt for a combined action of scour and cyclic loading. The simulations are limited by the computational power required, which restricts the number of cycles that can be simulated in a reasonable amount of time.

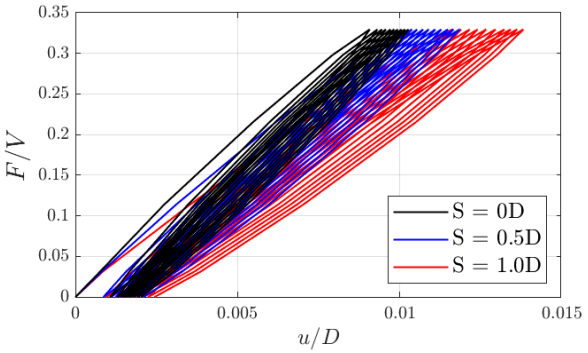

Figure 3. Load-displacement curve for S = {0; 0.5D; 1.0D} with D = 1.8 m.

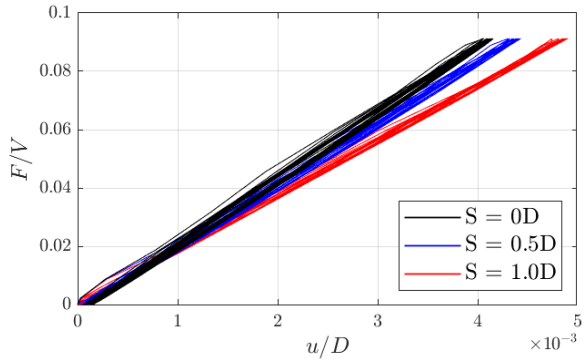

Figure 4. Load-displacement curve for S = {0; 0.5D; 1.0D} with D = 7.5 m.

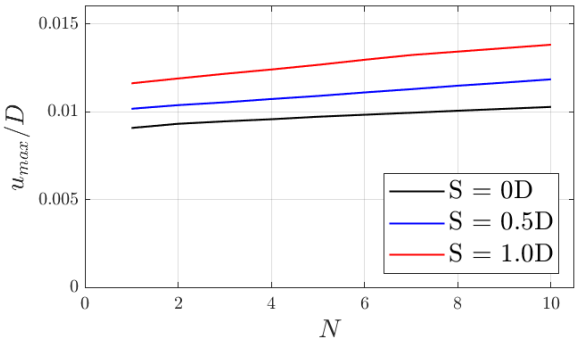

Figure 5. Evolution of maximum displacements with load cycles N for S = {0; 0.5D; 1.0D} with D = 1.8 m.

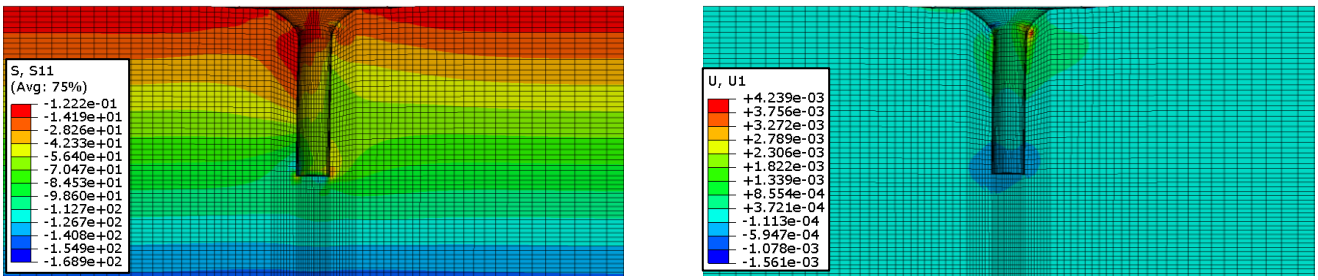

Figure 6. (l) Horizontal stresses (σ_{11}) in kPa; and (r) displacements (u_1) in m for S = 0.5D (scale factor: 50).

Future work will focus on investigating the long-term tendency of cycling and scour. To this end, Niemunis et al. (2005) proposed the high-cycle accumulation (HCA) model for number of cycles $>10^3$ and moderate or small strains, which may also be appropriate for offshore applications.

4 CONCLUSIONS

This paper studied the combined action of scour and cyclic loads obtaining the following conclusions:

- Hypoplasticity has shown to be an appropriate constitutive law to simulate cyclic loading in sands, including cycle-dependent permanent displacements and the ratcheting phenomenon for the explored cyclic loading conditions.
- As expected, the maximum and residual displacements increase with increasing *S*. However, this study demonstrates that also the displacement incremental rate increases with *S*. For the analysed monopile (S = 1.0D), during the first cycles the displacement incremental rate $(u_{N=10} - u_{N=1})/u_{N=1}$ reaches 19%, compared to only 13% for the S = 0 case.
- This study shows the vulnerability of scoured monopiles in terms of serviceability and economic viability. Hence, it is concluded that scour requires substantial consideration during design and, particularly, close monitoring of scour development and corresponding structural performance during operation.

ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the expertise provided by Prof R. Simons (UCL), Dr J. Harris, and Dr N. Tavouktsoglou (HR Wallingford).

ABSTRACT: This communication focuses on the behaviour of buried steel pipes submitted to surface loading such as traffic loading. A laboratory small-scale model has been developed to better understand the soil-pipe interaction. The final objective is to assess the existing design method, and develop them if required.The test set-up consists in a rigid tank with metric dimensions, filled with sand. Real steel pipes are scaled down at 1/3 on the length, leading to the relevant use of 100 mm diameter aluminium pipes. No gas pressure is simulated within the pipes, as it is then an unfavourable condition regarding the effect of surface loading on the pipe. Surface loading with up to 1000 cycles is applied using a vertical actuator acting on a plate. The procedure includes an extensive instrumentation, in particular strain gauges on the pipe and inner displacement sensors,. The experimental campaign permitted to assess the effect of the pipe radial stiffness (by varying the pipe thickness) on the pipe response due to monotonic then cyclic surface loading. The small-scale experimental results were upscaled at the real structure scale and compared to the existing design practice, to highlight its limits and the importance of taking the soil-pipe interaction into account.

RESUME: Cette communication porte sur le comportement des canalisations en acier enterrées soumises à des charges de surface telles que les charges de trafic. Un modèle réduit de laboratoire a été développé pour mieux comprendre l'interaction sol-canalisation. L'objectif final est d'évaluer les méthodes de dimensionnement existantes et de les améliorer si nécessaire. Le dispositif d'essai consiste en une cuve rigide de dimensions métriques, remplie de sable. Les canalisations en acier prototypes sont réduites à 1/3 de leur longueur, ce qui conduit à l'utilisation de canalisations en aluminium de 100 mm de diamètre. Des charges de surface jusqu'à 1000 cycles sont appliquées sur une plaque par un verin vertical. La procédure comprend une instrumentation extensive, en particulier par des jauges de déformation sur la canalisation et des capteurs de déplacement interne. La campagne expérimentale a permis d'évaluer l'effet de la rigidité annulaire de la canalisation (en variant son épaisseur) sur la réponse de la canalisation due aux charges de surface monotones puis cycliques. Les résultats expérimentaux en échelle réduite ont été extrapolés à l'échelle de la structure réelle et comparés aux méthodes de dimensionnement existantes afin d'en mettre en évidence les limites et l'importance de prendre en compte l'interaction sol-canalisation.

Keywords: Physical modeling; soil structural interaction; buried structures; gas transportations pipelines.

1 INTRODUCTION

Most of gas infrastructures are buried. During their lifetime, they can be affected by additional loads (roads, railways or embankments) compared to the design load cases, transmitted through the ground. Pipeline network operators then have to guarantee the integrity of the pipes and to accurately assess the stress increase in the pipe due to these additional surface loads. Based on the pioneering works by Marston & Anderson (1913) on rigid pipes and Spangler & Shafer (1938) on flexible pipes, it is well-known that the stress assessment is highly related to a soil – pipe interaction problem.

More recent improvements in the design methods lie on the reliable determination of the horizontal earth pressure (Scarino, 2003) or in the introduction of a parabolic distribution of the vertical load (Tian et al., 2015). Some of these improvements are in use nowadays, such as in the in-house software RAMCES from GRTgaz (one the French gas operator) used to predict the internal stresses inside a pipe, as well as its deformations to decide acceptability of various overloads. The results of the current experimental

study will be compared to the results from RAMCES predictions.

2 MATERIAL AND METHODS

The main interest of carrying lab testing (contrary to field testing) is to ensure controlled environnement and variables, with a good repeatability from one test to another. Subsequent sections will describe briefly the protocol and the materials used in the tests, while more details can be found in Mertz, 2023.

2.1 Test tank

The experimental campaign is carried out in a test tank (Figure 1), with dimensions 1 × 0.93 × 1.90 m^3, filled with sand and equipped with a vertical electric jack to apply a model surface loading.

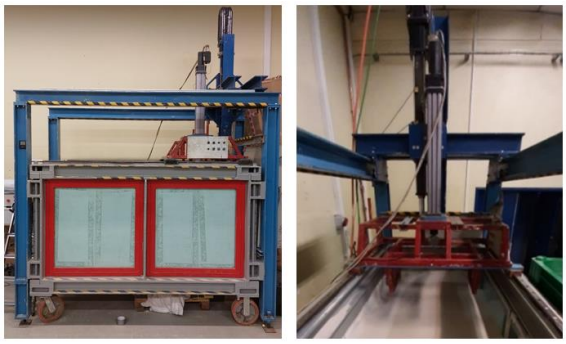

Figure 1. Tank (left) and loading system (right).

The soil used to fill the tank is a siliceous fine sand, uniform and poorly graded, denominated as Fontainebleau NE34 sand. Some of the sand characteristics are presented in Table 1, after Andria-Ntoanina et al. (2010). Filling is done by multiple layers, three of 0.2 m and one of 0.15 m, for a total sand thickness of 0.75 m, with he pipe center being 30 cm deep. Compaction is achieved for each layer using a vibrating plate, as shown on Figure 2, reaching a relative density of around 72 %.

2.2 Pipes

The pipelines used by GRTgaz are mainly made of steel, with nominal diameters ranging from 80 mm to 1200 mm, and thicknesses from 3 mm up to 30 mm. Such structures are not convenient to work with in lab conditions (in term of weight and size for handling, as well as required force to be applied during experiments). Thus, the choice has been made to work with small-scale model. Such scaling needs to be done with care, to avoid introducing bias in the model (scale-effect).

Table 1. Fontainebleau NE34 characteristics.

$d_{50}(mm)$	C_u	$\rho_{s\,(g/cm^3)}$	$e_{\min}$	$e_{\max}$
0.206	1.49	2.65	0.510	0.882

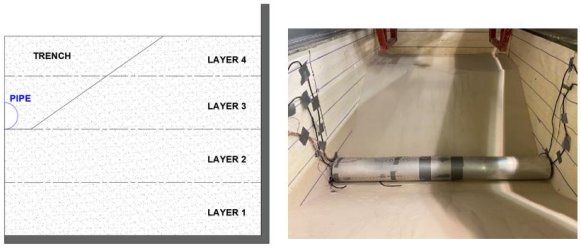

Figure 2. Scheme of the trench in half geometry (left), and pipe installed in the tank (right).

The scaling has been carried out using dimensional analysis, coming from the Vashy-Buckingham Theorem that describes the relationship between the properties of the model and the properties of the prototype, which takes the form of a scale factor λ (Garnier et al., 2007) such as:

$$\lambda = \frac{\text{model property}}{\text{prototype property}} \quad (1)$$

The scale factor on geometry is set to 1/3, meaning that all lengths of the prototype will be divided by 3 in the model scale. The reference prototype pipe, from GRTgaz catalogue, has a diameter of 300 mm. Therefore, a model pipe of 100 mm outside diameter and three different thicknesses (2 ± 0.05 mm, 1.75 ± 0.1 mm, and 1.35 ± 0.1 mm, respectively), have been considered, to investigate a wide range of annular rigidity of the pipe.

Dimensionnal analysis gives the scale factor on other metrics of the model, such as the stresses, that should also be 1/3 of the one of prototype pipes. This also runs for the Young‘s modulus. Thus, because prototype pipe are made of steel TUE360, with a Young‘s modulus of 210 MPa: the model pipes will then be made of aluminium 6060, with a Young‘s modulus of 69.5 MPa.

The resulting annular rigidity is presented in Figure 3, in which the error bar corresponds to the uncertainty resulting from the measured thickness deviation.

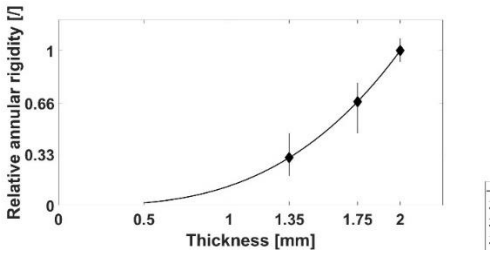

Figure 3. Pipe relative annular rigidity as a function of pipe thickness.

2.3 Loading

An EXLAR IX-40 electric jack ensures a vertical force, which is measured using a 20 kN S-shaped load cell. The load is distributed to the soil through a a 0.1 ×0.1 m² rigid aluminum plate, with four LVDT sensors, measuring the settlement and the tilting of the plate. Loading was applied with a constant velocity of the jack (0.05 mm/s) until the average stress under the loading plate reaches 100 kPa in model configuration (300 kPa in the prototype configuration), with unloading/reloading loops for everytime the loading exeed the previous maximum by 25 kPa. Preliminary tests showed that the bearing capacity of the soil with this surface plate geometry was reached for an average stress of around 110 kPa.

2.4 Instrumentation

This study uses a wide range of instrumentation, for both the pipe and the soil.

Bi-directional 350 Ω strain gauges are placed on the external surface of the pipe, with 45° of spacing between each, see Figure 4, in order to retrieve deformations in both longitudinal and ortho-radial directions at different pipe orientations.

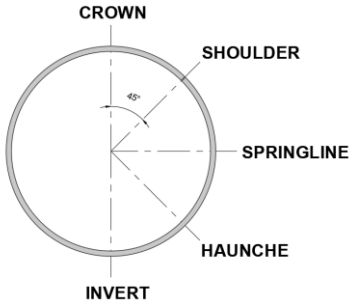

Figure 4. Placement of strain gauges.

Two flexure gauges AU/1 inside the pipe and miniaturized stress sensors placed 20 mm away from the pipe in the soil were also used, for measuring the pipe ovalisation and evolution of stresses in the sand respectively. However, these results will not be presented hereafter.

3 RESULTS AND DISCUSSION

3.1 Pipe stresses and evolution during cycles

The deformations on the pipe given by the strain gauges allow to calculate the acting stresses, in both directions (ortho-radial and longitudinal), assuming that the pipe behaves elastically. For a surface loading of 100 kPa, Figure 5 shows a maximum stress around 5 MPa (far below the yield stress of 60 MPa) for the ortho-radial stress at the springline of the 1.35 mm pipe (relative annular rigidity of 0.33).

Ortho-radial stress plot shows that the pipe is under compression at crown and invert, while experiencing tension at springline, compatible with an ovalisation of the pipe. Shoulders are in tension as well, indicating that the change from tension to compression is happening between shoulders and crown.

It can be seen that decreasing the pipe annular stiffness led to a significant increase in stress in the upper part (crown, shoulders), while variations are small to non-existent at haunches and invert. Longitudinal stresses indicate that the pipe experiences flexion, with compression at crown and tension at invert, as expected by the loading configuration (load concentrated on a small 0.1× 0.1 m² plate). Reducing the pipe thickness does not impose strong variation of the longitudinal stress, due to the fact that the longitudinal flexure rigidity is depending strongly on the diameter, but only marginally on the thickness.

The evolution of stresses during the application 100 cycles of loading between 1 and 100 kPa is presented in Table 2.

Table 2. Stress changes during cyclic loading.

Pipe thickness [mm]	***Max stress [MPa]***		***Stress change for 1000 cycles [%]***	
	Tension	*Compression*	*Tension*	*Compression*
2	0.91	-2.3	+11.7	+2.2
1.35	2.5	-4.5	+18.9	-28.2

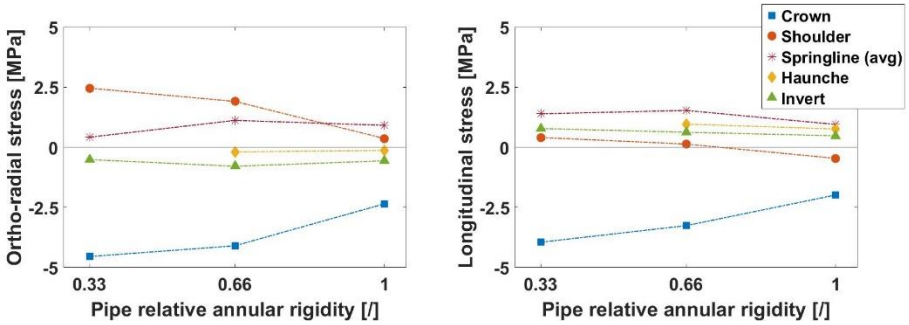

Figure 5. Measured ortho-radial (left) and longitudinal (right) pipe stress, for a surface loading of 100kPa (compression is negative).

Data from the 1.75 mm pipe are excluded due to a malfunction of the strain gauges during cyclic loading. The 2 mm pipe exhibits smaller changes in stresses when compared to the 1.35 mm one, which indicates that the relative stiffness between the soil and the pipe affects the cyclic behaviour.

3.2 Comparison with design models

Results were compared to the predictions made according to the RAMCES software. However, since this software is working at prototype scale, experimental data were upscaled, according to equation 1. This scaling also includes a corrective coefficient for the soil non-linear behaviour, based on numerical simulations, (see details in Mertz, 2023). The prototype situation thus corresponds to 4.25/5.25/6 mm thick steel pipes, with a diameter of 300 mm, loaded with 300 kPa on a 0.30 × 0.30 m² surface.

The metric used for the comparison is the safety factor F_s, defined as the ratio of the calculated stress to the experimental stress. A safety factor above 1 indicates that the model overestimates the actual stress of the pipe, leading to an opportunity of optimisation on the calculation method. The detailed analysis (Mertz, 2023) showed that RAMCES software captured the pipe behaviour quite well, but with F_s around 1.4.

4 CONCLUSIONS

Small-scale pipes with different annular rigidities have been tested in laboratory conditions, in which they were buried and subjected to a controlled surface loading. It appears that reducing annular rigidity increases recorded stresses in the pipe on some locations (crown and shoulder mainly), but also changes the observed behaviour during cyclic loading.

Comparisons with the RAMCES code show that there is an opportunity for optimisation, by improving the physical model used, which can lead to higher safety (by better representation of the pipe behaviour), as well as a more efficient design.

This work will be enriched with additional data, such as the pipe displacement and recorded soil stresses near the pipe, both radially and in the horizontal plane above it, and assessment of the soil-structural interaction will be done.

Bervie Braes at 10 years: critical review of the effectiveness of slope stabilisation measures

Bervie Braes à 10 ans: bilan critique de l'efficacité des mesures de stabilisation des pentes

S.B. Mickovski*
Glasgow Caledonian University, Glasgow, Scotland, UK
**Slobodan.Mickovski@gcu.ac.uk*

ABSTRACT: Bervie Braes is a 750 m long, and up to 55 m high coastal slope above a residential area and harbour in Stonenaven, Scotland, with a history of instability mostly associated with the road traversing the slope. Slope stabilisation works in terms of soil nailing, contour drains and seeding/planting were carried out in 2012 to minimise the risks posed to the former trunk road bisecting the Braes. In this paper, I critically review the effectiveness of the stabilisation measures using an established sustainability assessment tool. Through interviews with the local authority representatives, I am also detailing the timeline of monitoring and maintenance actions in the past ten years and mapping them against the global best practice in terms of sustainability and resilience. Based on the results of our investigation, I am concluding this paper with recommendations for future actions and research that will lead towards more efficient slope stabilisation and use of vegetation for civil engineering purposes.

RÉSUMÉ: Bervie Braes est une pente côtière de 750 m de long et jusqu'à 55 m de haut au-dessus d'une zone résidentielle et d'un port à Stonenaven, en Écosse, avec une histoire d'instabilité principalement associée à la route traversant la pente. Des travaux de stabilisation des talus en termes de clouage du sol, de drains de contour et d'ensemencement/plantation ont été réalisés en 2012 afin de minimiser les risques posés à l'ancienne route nationale coupant en deux le Braes. Dans cet article, J'examine de manière critique l'efficacité des mesures de stabilisation à l'aide d'un outil d'évaluation de la durabilité établi. Grâce à des entretiens avec les représentants des autorités locales, je détaille également le calendrier des actions de surveillance et de maintenance au cours des dix dernières années et les comparons aux meilleures pratiques mondiales en termes de durabilité et de résilience. Sur la base des résultats de notre enquête, Je conclus cet article par des recommandations pour des actions et des recherches futures qui conduiront à une stabilisation plus efficace des pentes et à l'utilisation de la végétation à des fins de génie civil.

Keywords: Sustainability; resilience; erosion; landslides; eco-engineering; slope stability.

1 INTRODUCTION

Bervie Braes is a 750 m long, and up to 55 m high coastal slope above the old harbour in Stonehaven, north-east Scotland. The slope is bisected by a former trunk road (Bervie Road) which once served as a main access route to Stonehaven. Since being downgraded in the 1980s, this road serves mainly as the tourist route that connects Stonehaven with the nearby War Memorial and Dunnottar Castle to the south.

Bervie Braes has historically suffered from instability, often demonstrated as shallow landslides, debris or mud flows, and erosion (Mickovski et al., 2013). These instabilities, together with the risk they posed to the residential properties at the toe of the slope, were the main reason for procuring and completing slope stabilisation measures in the period 2007-2012. The funding for these measures came from the Scottish Government and Local Authority (LA) with the stabilisation works focussing on the slope sections below Bervie Road which were most at risk of instability and failure (Mickovski et al., 2016).

The works carried out in 2012 comprised soil nailing of different sections of the lower slope, drainage works on the road and lower slope, as well as ground bio-engineering works on the lower slope (Mickovski 2014a,b).

After the completion of the works in 2012 (Figure 1), Bervie Road was reopened subject to restrictions while there was no formal programme of inspection and monitoring of the performance or efficiency of the constructed stabilisation measures.

The aim of this study is to critically review the changes occurring at Bervie Braes in the ten years immediately after the completion of the stabilisation works with a view of assessing the efficiency and

success of the stabilisation measures from sustainability aspect. An objective of this study is to also look at the future of Bervie Braes not only from the stability but also sustainability. It is hoped that this review and assessment can be used as a 'lessons learned' tool for projects with a similar context.

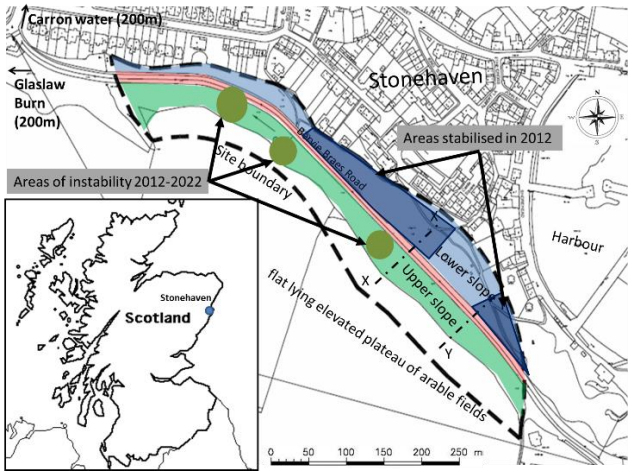

Figure 1. Plan of Bervie braes showing areas of completed works and issues in the last 10 years.

2 MATERIALS AND METHODS

Several methodological approaches were used for this study. Firstly, periodic site visits were carried out of the Bervie Braes site and it surroundings with a focus on the functioning of the constructed measures. These, mostly visual, surveys took place at different seasons. Secondly, three interviews with the LA representative were carried out in the period 2012-2023 in order to collect information on any reported issues on the site but also to query the strategic and tactical planning considerations concerning the site (Mickovski and Thomson 2016). Finally, the information from the site visits and interviews with the LA was used to assess the sustainability of the post-construction stages of the Bervie Braes slope stabilisation project. This assessment was carried out using an established sustainability assessment framework (Mickovski and Thomson, 2017) with a view of providing more objective view of the post-construction activities/works as well as a guideline of what can be done to make the operation and maintenance stage more sustainable.

3 RESULTS

3.1 Site visits

The site visits were focussed on visual assessment and identification of any issues with the installed soil nails, drainage network, and planted/seeded vegetation. Due to the nature of the measure, it was not possible to visually inspect the actual soil nails which were buried so only selected number of soil nail heads, erosion protection cover and protective mesh were inspected on 16 occasions in the period 2012-2024 (Figure 2). There were no major structural defects in either the concrete heads or protective mesh detected, suggesting the nails were functioning as per the design. During the first 3 years after construction it was easier to locate and inspect the soil nail heads because of the size and extent of vegetation (Figure 3). After this period, the erosion protection cover (coir blanket) started to degrade and can now only be seen in few smaller areas which is also in accordance with the design.

Figure 2. South end of Bervie Road in 2012 (left),2014 (centre), and 2022 (right).

The drainage network visually surveyed included the drains on Bervie Road, the raking drains within the slope and the contour drain along the footpaths on the lower slope. During all site visits, all of the inspected appeared to be functioning with no standing water or visible contamination in the network. Although the contour drain covers appeared to collect gravel from the footpaths (Figure 4) on several occasions, the water within them appeared to flow without problems. Similarly, the road drains appeared to be functioning during all site visits despite the fine material deposited within them (noted on few occasions). Not all of the raking drains were seen to drain water through the pipes - only the ones in the zones where high ground water table was recorded during construction.

Figure 3. Results of hydroseeding and tree planting in 2012 (left),2014 (centre), and 2022 (right).

As designed, the vegetation cover on the stabilised slope increased from 0% after construction to around 50% in the two growing seasons after the completion of the works, around 90% after five seasons, to almost 100% in 2022 (Figure 3). The area with slower ground cover recovery was the southernmost part, which is higher than the crowns of the trees on the lower slope and most exposed to the elements. The trees and

shrubs planted in the more exposed areas grew slower than the ones planted in more protected zones. The planting success rate was around 80% with several trees being windthrown and quite a few vandalised over the past 10 years. It is worth noting that the windthrown/broken trees were reported to the LA after inspection and were replaced by the contractor during the defect rectification period.

3.2 Interviews

The interviews with the LA were used to clarify the timeline of actions/events post construction. In summer 2013 Bervie Road was re-opened (April to October only) with installation of orange/white barriers, a 2 tonne weight limit and 1.8 m width restriction for all vehicles. In autumn 2014 a cyclepath was constructed on the seaward side of the road to make the vehicle width reduction permanent. A gate at the southernmost end of the road was also constructed to allow for winter and/or emergency closure. The existing footway construction was left in place to minimise works close to the crest of the lower slope and plastic kerbs were used to minimise the load on the lower slope. In 2022 concrete surfacing and handrails were constructed to footpath on the lower slope leading from the harbour. The contour and raking drains were kept as constructed in 2012.

Figure 4. Controur drain along the stabilised exposed section in 2012 (left),2015 (centre), and 2023 (right).

There was no maintenance carried out in the nailed areas (Figure 5). Slope drains were inspected sporadically but there was no need for maintenance. The road drainage was jetted regularly and specifically after slips on the upper slope in order to keep it functioning. In 2022, the filter drain on the landward side of Bervie Braes was inspected with CCTV – it was found that the pipework was clear and functioning over the whole length although there has been weed growth in the filter material which will have to be cleared.

The interviews also revealed issues associated with the history of instability at Bervie Braes: a landslip on the upper slope in 2014 blocked the inlet to the drain pipe in a storm which resulted in water flowing down the road into Stonehaven. After this, inlet headwall was moved further up the gully on the upper slope, with the extension of the pipe constructed as a large filter drain, to drain the area of the upper slope and prevent any similar blockages to the inlet. The upper slope area slope was cleared up and regraded. There have been some further minor slips in the gully during heavy rainfall events but the drain has not been blocked again.

Figure 5. Nailed section in 2012 (left) and 2022 (right).

There were no further slips on the upper slope until winter 2022 when there was a surface slip (Figure 6). The barriers contained the slip as intended however the road has remained closed to traffic since the slip pending investigation and implementation of a remedial stabilisation scheme. Ground investigation has established that the cause is buildup of groundwater in the slope causing surface failures, exacerbated by a potential failure of a historic drainage system on the slope. Since there was no evidence of deeper failure risk, a remedial scheme to construct filter drains in the affected area is being prepared and should be completed by Summer 2023. When that is complete the road is planned to re-open to traffic.

Cracking in carriageway in the northern, unnailed section of Bervie Road, was noted in 2021 and has been monitored since. This was a section that showed movement prior to the main works and was excavated and reinstated at that time. Investigation was carried out by installing boreholes and inclinometers but no movement was detected during the three month monitoring period. The boreholes are being left in place and further long-term monitoring both visually and with inclinometer will be carried out to determine if any remedial works are required.

Figure 6. Upper slope instability (left) and cracks in the road indicative of deeper-seated instability (right).

Finally, the interviews revealed that in the last ten years the LA worked on Bervie Braes (and other

similar projects in their portfolio) under a significant resource restraint. All the actions/works at Bervie Braes were carried out with LA funding, usually as a reactive mechanism after a significant issue has been reported.

3.3 Sustainability assessment

The two post-construction stages (Monitoring and Long-term considerations) were re-assessed in terms of sustainability key performance indicators of an existing framework (Mickovski and Thomson, 2017). The average score for the monitoring stage was 2.0 (cf. 2.9 in 2012), while the average score for the Long-term stage was 2.8 (cf. 3.0 in 2012) – both of which indicate detriment to the baseline sustainability value (3.0; where 1.0 is very detrimental and 5.0 is very beneficial to sustainability). This is mainly due to the lack of monitoring plan (which, in itself is partly due to the lack of funding and partly due to the traditional reactive approach by the LAs) and lack of focus on future sustainability, ecosystem/biodiversity, and resilience (Mickovski et al., 2022).

4 CONCLUSIONS

The slope stabilisation measures installed in 2012 appear to be functioning as designed. While no major structural damage or deterioration has been noted with the soil nails, the drainage network and the vegetation cover were subject to minor maintenance works in the last 10 years, which helped in keeping them functional and effective. These findings are in line with similar projects in Europe (Mickovski et al., 2022).

No landslips or erosion events occurred on the lower slope (especially not in the stabilised sections) in the past 10 years. However, several landslips occurred on the upper slope and there is an indication that a bigger mass movement may have been reactivated under the Bervie Road in 2022, at a section which has not been stabilised in 2012. The interview with the LA representative revealed that resourcing issues both in terms of physical and financial resources were the major obstacle to extending the stabilisation works and pro-active management of the risks on the braes.

While the above occurrences highlight the stability brought to the braes by the works in 2012, they also confirm that instability may still occur in the areas which have not been stabilised (Mickovski, 2018). In order to mitigate these risks, there is a need for more formal monitoring plan, especially for the upper slope and the sections which have not been stabilised, targeting the links between the climate, precipitation, ground water, slope stability and the vegetation as the basis for increasing ecosystem services provision, sustainability and resilience (Mickovski, 2021).

ACKNOWLEDGEMENTS

I am grateful for the help of Mr James Black (Aberdeenshire Council, retired) for access to information, Dr Alejandro Gonzalez-Ollauri during the site visits, and the financial support provided by the Civil Engineering and Environmental Management Department at Glasgow Caledonian University.

Experimental tests to evaluate skirt penetration resistance in scour protection for offshore foundations

Essais expérimentaux pour évaluer la résistance à la pénétration de la jupe dans la protection contre affouillements pour les fondations offshore

ABSTRACT: Full scale experimental tests were performed to evaluate the penetration resistance of steel plates (skirts), which are present in different types of offshore foundations, like mud-mat foundations. This research is motivated by the design of the jacket foundation for the DolWin kappa offshore substation, within the framework of DolWin6 project Penetration resistance is well-studied in clays and sands, but there is limited information on penetration in coarse granular materials, which are typically used as scour protection. Direct extrapolation of penetration resistance in sands is not possible because of the grain-size effect. Several plate thicknesses and gravel sizes were used to study the influence of the grain-size effect on the penetration resistance. The results of the experimental tests showed a strong dependence of penetration resistance on penetration depth as expected, but also a significant dependence on skirt thickness and gravel grain size. A good agreement with experimental results has been found when analytically interpreting the penetration resistance using traditional bearing capacity formulas, but with an equivalent skirt thickness related to the real skirt thickness and to the grain size, to account for the grain-size effect.

RÉSUMÉ: Des essais expérimentaux à grande échelle, ont été réalisés pour évaluer la résistance à la pénétration des jupes, qui sont présentes dans différents types de fondations offshore, telles que les fondations de type mud-mat. La résistance à la pénétration est bien étudiée dans les argiles et les sables, mais il y a peu d'informations sur la pénétration dans les matériaux granulaires grossiers, qui sont généralement utilisés comme protection contre l'affouillement. L'extrapolation directe de la résistance à la pénétration dans les sables n'est pas possible en raison de l'effet de la taille des grains. Plusieurs épaisseurs de plaques et tailles de graves ont été utilisées pour étudier l'influence de l'effet de la taille des grains sur la résistance à la pénétration. Les résultats des essais expérimentaux ont montré une forte dépendance de la résistance à la pénétration par rapport à la profondeur de pénétration, comme prévu, mais aussi une dépendance significative par rapport à l'épaisseur de la jupe et à la taille des grains de graves. Un bon accord avec les résultats expérimentaux a été trouvé lors de l'interprétation analytique de la résistance à la pénétration en utilisant les formules traditionnelles de capacité portante, mais avec une épaisseur de jupe équivalente liée à l'épaisseur réelle de la jupe et à la taille des grains, pour tenir compte de l'effet de la taille des grains.

1 INTRODUCTION

Offshore wind has a key role in the path towards a net-zero energy mix, it has a large potential for further development and for supplying cheap, clean and safe energy. In fact, offshore wind offers the opportunity to exploit 80% of Europe's offshore wind resource by unlocking shallow to deep water sites. Besides, in the coming years, the power from offshore wind is expected to become cheaper than that from onshore wind because of the larger turbine sizes and the fact that the consistent winds out on the sea allows higher load factors (UK Department for Business, Energy and Industrial Strategy, 2020).

The foundation of offshore wind structures, and in particular critical structures like offshore substations, poses new challenges to a wide range of engineering disciplines like offshore geotechnics. In some cases, such as in skirted or mud-mat foundations, penetration of steel elements into the sea bottom is required to ensure structure stability (e.g., Lu and Maclaren, 2016).

The foundation of offshore structures sometimes requires a scour protection system, which traditionally

is composed of a combination of an armour layer and a filter layer (e.g., Sonneville et al., 2014; Escribano and Brennan, 2017). They are commonly installed in advance and then penetration of foundation steel elements (skirts, shear keys...) must be ensured into the scour protection.

Some existing standards and recommended best practices, namely API RP 2GEO (2011) and DNVGL (2017), provide guidance in evaluating the penetration resistance, by means of bearing capacity formulae (Figure 1) or correlations with cone penetration resistances, respectively. Also, some authors (e.g., Andersen et al., 2008; Houlsby and Byrne, 2005) have further studied the penetration resistance of skirted elements. However, all these studies are focused either on cohesive soils or on sandy soils (fine-grained, non-cohesive soils). Hence, there is limited experience or information in the literature about penetration resistance in gravels, which are the base of scour protection systems.

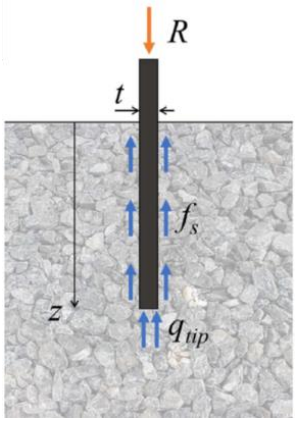

Figure 1. Plate penetration problem and calculation based on bearing capacity.

As presented in the following, extrapolation of formulations for sandy soils to gravels by adjusting the friction angle is not possible due to the influence of the gravel grain size. When the mean grain size (d_{50}) starts to be comparable to the steel plate thickness (t), the grain size increases the penetration resistance. Bolton et al. (1999) studied this particle size effect for cone penetration testing (CPT) in sands and found that the effect appears when the t/d_{50} ratio falls below about 20. More recently, Miyai et al. (2019) presented a notable contribution on the influence of the particle size on plate penetration.

This paper is aimed to study this plate penetration problem accounting for the influence of the gravel grain size and the proposed methodology is based on several full-scale tests. In this manner, this paper further analyses the data presented in Varela et al. (2022) and adds new relevant information, namely the results of direct shear tests on the gravel using a large box (300x300 mm).

2 TEST SET-UP

A 5x5x2.5 m^3 container was designed for the field tests in order to minimize the required volume of gravel and to facilitate the allocation of a 1,000-kN jack. The container was buried in the ground, so that its top part was approximately at the ground surface level. A loading frame was rigidly connected to the container and an auxiliary crane was installed in order to ease the manoeuvring of loads (Figure 2).

Figure 2. Testing container, loading frame and auxiliary crane.

The scour protection required a high-density gravel in this case, and thus an eclogite gravel from Norway was chosen. Two grain size distributions were used, a 0.5-1.5 in. gravel, with a mean grain size (d_{50}) of around 1 in. (25 mm), and 1-3 in. gravel, with a d_{50} of 2 in. (50 mm). Details of some gravel physical properties, grain size distribution and the controlled pouring process to reach the in situ density may found in Varela et al. (2022).

Two steel skirt thicknesses were tested, namely 15 and 80 mm. An additional case with a beveled tip may be found in Varela et al. (2022).

A total of 13 tests were carried out with both gravels and both skirts. The repetitiveness of the tests was ensured through four per test. A summary of the tests performed is given in Table 1. The test procedure was identical for all the configurations. Once the gravel was in place, each skirt was pushed (jacked) into the gravel by means of a hydraulic jack (Figure 3). Both, vertical displacement and vertical load, were measured during each test. The displacement of the skirt was recorded using two ultrasonic displacement sensors (Point 3 in Figure 3).

The hydraulic jack had a maximum capacity of 1,000 kN and a maximum stroke of 500 mm. Thus, for tests with the 80-mm-thick skirt, which had a target maximum penetration depth of 950 mm, the test

procedure was a step-based one, combining the available stroke with coupling steel extensions to the hydraulic jack. Therefore, an unloading-loading cycle is visible in the results.

Table 1. Summary of field tests. Test repetitions and penetration depth for the different test configurations.

Particle size	t=15 mm	t=80 mm
d_{50}=25 mm	4 (z<350 mm)	0
d_{50}=50 mm	4 (z<300 mm)	4 (z<950 mm)
	1 (z<500 mm)	

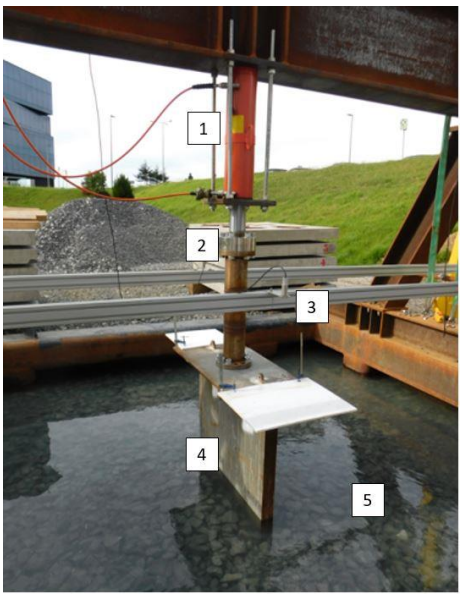

Figure 3. Test set-up. 1-hydraulic jack; 2-load cell; 3-displacement sensor; 4-steel plate; 5-eclogite gravel.

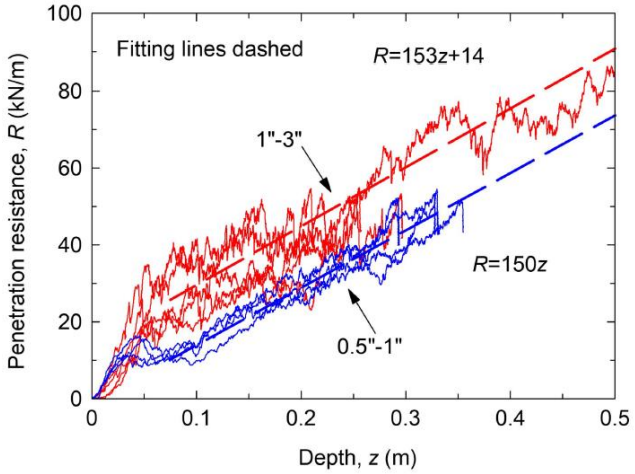

Figure 4. Penetration resistance of 15-mm-thick skirt in both gravels.

3 EXPERIMENTAL RESULTS

Figure 4 presents the penetration resistance versus penetration depth and their linear fittings for the 15-mm-thick skirt in both gravels. As expected, the load required to jack the skirt through the gravel with the larger grain size was higher and it increases with the penetration depth. Besides, the penetration resistance notably oscillated (noise), which was mainly a consequence of the grain-size effect (larger oscillations in the 1-3 in. gravel).

Figure 5 shows the results of the penetration of the 80-mm thick plate in the 1-3 in. gravel. As already explained, there is an unloading-reloading loop at 0.5 m of penetration. Obviously, the penetration resistance is larger for the 80 mm-thick plate than for the 15-mm thick one, but the penetration resistance is increased by a factor of around 2-2.5 times, while the ratio between plate thicknesses is larger.

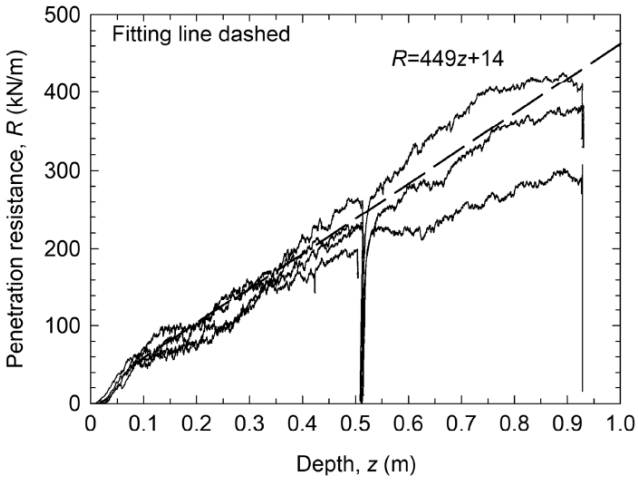

Figure 5. Penetration resistance of 80-mm-thick skirt in 1-3 in. gravel.

The theoretical background for the linear fittings is that the tip resistance is clearly the major component of the penetration resistance (around 98% for these cases, see Varela et al., 2022), while the contribution of the shaft resistance, which increases with the square of the penetration depth, is limited in comparison. From these linear fittings, the back-calculated values of the friction angle for each case using the real and equivalent thicknesses are summarized in Table 2.

It is also worth highlighting that there is a penetration depth beyond which the penetration resistance reduces its increase, e.g., around 0.4 m for the 15-mm-thick skirt and 0.8 m for the 80-mm-thick skirt. This agrees with the limit usually considered for the pile tip resistance of a depth around 20 times the pile diameter (e.g., Tomlinson and Woodward, 2008).

Table 2. Friction angles obtained from back analysis for real and equivalent skirt thicknesses (lengths in mm).

Particle size	t=15	t=80	t=15 + d_{50}	t=80 + d_{50}	t=15 + d_{99}	t=80 + d_{99}
d_{50}=25	54°	--	49°	--	47°	--
d_{50}=50	56°	51°	48°	48°	46°	46°

4 DIRECT SHEAR TESTS

Direct shear tests in a large equipment (300x300 mm box) were performed at different normal pressures, in samples of the smallest gravel (d_{50} =25mm). As expected, peak friction angles obtained decrease with normal stress (Table 3). The high values found, especially for low pressures, might be influenced by the scale factor, as the size of the particles is bigger than 1/6 of the box height. In addition, for loose gravel, the direct shear test results give also higher friction angles than the ones obtained under triaxial conditions, as shown in Varela et al. (2022). Comparing the values of friction angles estimated using the theoretical approaches and those obtained from the direct shear tests, most of them are in the same range, but the friction angles estimated using the equivalent plate thickness are more consistent.

Table 3. Friction angles obtained from direct shear tests at each normal stress for the gravel with d_{50}=25 mm.

σ'=	***25 kPa***	***50 kPa***	***100 kPa***	***200 kPa***	***300 kPa***	***450 kPa***
ϕ	67°	65°	55°	53°	49°	44°

5 CONCLUSIONS

The results of the experimental tests confirm that the penetration resistance increases with the penetration depth, the skirt thickness and the gravel grain size. Tip resistance component is the highest, being the frictional part just around 2% of the total. A good agreement is found between experimental data and semi-empirical approaches when using the equivalent skirt thickness hypothesis proposed by Miyai et al. (2019), in traditional approximations like Andersen et al. (2008). Therefore, this equivalent skirt thickness is the suggested calculation method. In future studies, a wider range of gravel sizes and skirt thicknesses should be tested, in order to increase the reliability of this approach.

ABSTRACT: A prevailing methodology to evaluate the environmental impact and subsequent sustainability assessment of structures is the life cycle assessment (LCA). In civil engineering, LCA methodologies allow for the quantification and evaluation of environmental impacts of comparable structures, considering different materials, processes, and manufacturing. For a valid comparison, structures must satisfy the same function or need. Regarding geotechnical engineering field, particularly for retaining structures, previous studies have shown the reduced environmental impact of reinforced soil walls (RSW) over solutions such as gravity or cantilever walls. RSWs are constructed with polymeric or steel soil reinforcement materials with different geometries (e.g., straps, grids, or sheets). Aside from a structural point of view, the selection of reinforcement can be of lasting impact, as geosynthetic materials can play an important role in meeting the United Nations sustainability goals regarding counting carbon mitigation and adapting to the impacts of climate change. The present work details the LCA of geosynthetic RSWs with concrete panel facings. Environmental impact assessments consider various wall heights, with special emphasis on the sensitivity to transport distances on the overall scoring, considering local and worldwide scenarios. Results show transport activities can be the second to third most impactful factor for RSW LCA

RÉSUMÉ: L'évaluation du cycle de vie (ACV) est une méthodologie courante pour évaluer l'impact environnemental et la durabilité des structures. En génie civil, les méthodologies d'ACV permettent de quantifier et d'évaluer les impacts environnementaux de structures comparables, en tenant compte des différents matériaux, processus et procédés de fabrication. Pour que la comparaison soit valable, les structures doivent répondre à la même fonction ou au même besoin. Dans le domaine de l'ingénierie géotechnique, en particulier pour les structures de soutènement, des études antérieures ont montré la réduction de l'impact environnemental des murs en sol renforcé (RSW) par rapport à des solutions telles que les murs gravitaires ou les murs en porte-à-faux. Les murs de soutènement sont construits avec des matériaux de renforcement du sol en polymère ou en acier de différentes géométries (par exemple, des sangles, des grilles ou des feuilles). Outre le point de vue structurel, le choix du renforcement peut avoir un impact durable, car les matériaux géosynthétiques peuvent jouer un rôle important dans la réalisation des objectifs de durabilité des Nations Unies concernant l'atténuation des émissions de carbone et l'adaptation aux impacts du changement climatique. Le présent travail détaille l'ACV des murs de soutènement géosynthétiques avec parements en panneaux de béton. Les évaluations de l'impact sur l'environnement prennent en compte différentes hauteurs de murs, en mettant l'accent sur la sensibilité des distances de transport à la note globale. Sur la sensibilité des distances de transport sur la note globale, en considérant des scénarios locaux des scénarios locaux et mondiaux.

Keywords: Geosynthetics; reinforced soil wall; life cycle analysis; environmental impact; sensitivity analysis.

1 INTRODUCTION

Reinforced soil walls (RSWs) (also known as mechanically stabilized earth (MSE) walls) are a proven technology which compete with gravity and concrete cantilever walls to perform the same soil retaining wall function. RSWs are characterized by compacted soil layers with embedded longitudinal

reinforcing elements attached to the wall facing elements. The reinforcement can be of the extensible geosynthetic (polymeric) type with different geometries (e.g., straps, grids, or sheets) or relatively inextensible steel type (e.g., strips, grids, and ladders). Life cycle analysis (LCA) has shown that geosynthetic RSWs have significant advantages over gravity and cantilever walls with respect to environmental impact, particularly as structure height increases (Damians et al. 2017, Heerten 2012, Rafalko et al. 2010, Stucki et al. 2011, Zhu et al. 2022). This is largely due to the use of soil as the main structural component, rather than reinforced concrete.

In this study, LCAs were carried out to evaluate the environmental impact of transportation distances of the structural components employed in geosynthetic RSWs. Analyses used a detailed environmental inventory composed of construction materials, transportation to the project site, and construction activities (e.g., excavation, placement and compaction of soil materials) obtained from an environmental database.

2 LIFE CYCLE ANALSIS AND STUDY CASE DESCRIPTION

There are several commercially available software packages to perform LCA. This study used SimaPro v9.4.0.2 (PRé sustainability, 2022), together with ecoinvent v3.8 (Wernet et al. 2016) database (allocation, cut-off classification). There are many environmental impact calculation methods. The ReCiPe 2016 v1.1 (Huijbregts et al. 2017) and CED v1.11 (Frischknecht et al. 2003) methods were selected. The ReCiPe method allows for the evaluation of midpoint and endpoint indicators. For midpoint environmental indicators, 18 categories are calculated in parallel, including global warming potential (GWP), stratospheric ozone depletion, and mineral resource scarcity, among others. Endpoint indicators are the aggregate result of the 18 midpoint categories. The cumulative energy demand (CED) method calculates the consumption of energy throughout the proposed life cycle. As a first approach, the present study uses GWP (measured in equivalent emissions – CO_2 eq.) and CED (measured of consumed energy - J) to compare the effect of transportation distances in a life cycle analysis.

The functional unit was defined as a 1- m of running length of wall with a design life of 100 years. Problem boundaries include cradle-to-gate considerations and three height scenarios (3- m, 6- m, and 9- m tall). Table 1 shows the environmental inventory. Backfill material consisted of a quarried (not washed), high quality granular soil with $\phi = 36^o$, c = 0 kPa, and γ = 1800 kg/m^3. Reinforcements were assumed as polymeric (polyester) straps with 3.6 straps/m in the running wall face direction. Construction activities were included based on diesel or other energy consumptions. Spreading and compaction of the backfill material assumed an energy consumption of 1.97 MJ/m^3 (Stucki et al. 2011). Precast facing panels assumed an installation rate of 0.04 h/m^2 of wall face (Damians et al. 2017)

The main focus of this study is the effect of transportation distances on LCA results. Table 2 shows the modal, minimum, and maximum distance values. Fresh concrete for the levelling pad considered a maximum distance of 60 km, which takes into consideration that, usually, concrete mix-trucks must discharge their load within two hours. Transport distances for geosynthetic reinforcements reflect local and global supplier warehouse locations. Maximum distances were chosen to reflect viable options regarding construction logistics (e.g., maximum distance of 20 km for the backfill material).

Table 1. Structural components inventory for three wall heights.

Item	Wall height		
	3 m	6 m	9 m
Precast panels [a] [m^2]	3	6	9
Concrete [b] [m^3]	0.05	0.05	0.05
Polymeric straps [m]	29.87	119.47	268.8
Granular soil [c] [m^3]	11.5	45.2	101.3

Notes: [a]: includes concrete and steel; [b]: material for levelling pad for the vertical facing; [c]: includes material for drain layers.

Table 2. Proposed modal, minimum, and maximum values for transport distances.

Item	Transport distance [km]		
	Modal	Min.	Max.
Precast panels	50[a]	5[a]	60[a]
Concrete	50[b]	5[b]	100[b]
Polymeric straps	100[a] & 200[c]	50[a]	200[a] & 10000[d]
Granular soil	10[a]	5[a]	20[a]

Notes: [a]: transported by truck; [b]: transported by mix-truck; [c]: transported by train; [d]: transported by sea freight.

3 ENVIRONMENTAL IMPACT RESULTS

Figure 1a and 1b show the relative impact of each component (backfill material, construction activities, concrete and steel, geosynthetics, and transportation activities) and the total values with respect to wall

height from a LCA using modal transport distances (see Table 2). Concrete, steel and backfill materials are the highest contributors to CO_2 eq. and cumulative energy demand, followed by transportation activities. For a height of 3 m, transport activities constitute 13.8% of total CO_2 eq. (Figure 1a) and 19.3% of the total required energy (Figure 1b). For wall heights of 6 m and 9 m, the relative impact of transport-related emissions increases to 17.3% and 19.3%, respectively, for GWP, while CED values increase to 21.7% and 22.8%, respectively. Overall, as wall height increases, the relative impact of concrete and steel is reduced, while the impact of the remaining categories increases. Transport-related impacts are more noticeable for CED than for GWP.

Figure 1c shows the relative GWP impact of each inventory component with respect to transport-related emissions considering modal distances. The input for transportation-related emissions is based on mass and distance (units of metric tonnes×km), meaning that the larger the distance and/or the mass, the higher the impact. Most of the transport related emissions are, as expected, due to the backfill material transportation, since most of the mass of the inventory is soil. As wall height increases, the relative mass of the soil increases more than that of the other materials (e.g., concrete and steel). Polymeric straps are a small fraction of the total mass in the environmental inventory, which results in a negligible contribution to GWP emissions, as seen in Figure 2c.

Figure 2 shows total GWP emissions and CED requirements for all weight hights considering modal, minimum, and maximum transportation distances (see Table 2). At 3 m of height, impact scores vary from -8.2% to +13.4% for GWP, and from -11.4% to +10% for CED, between the mean and minimum or maximum distance scenarios. For 9 m of height, impact scores variations are of -10.4% and +19.3% for GWP, and -12.3% and 10% for CED. Transport-related emissions also depend on mass quantities, thus, for lower height walls (which require less material), the overall impact of distance of transport related activities is slightly lower than in higher walls. Regardless, results show a significant effect on calculated transport-related GWP and CED values due to transportation distance. Clearly, the selection of material suppliers, must take shipping distances into consideration and not only technical considerations and material costs at point of sale. With this in mind, differences between the local and global suppliers for polymeric strap reinforcement had a 4% or less impact on GPW and CED, which is attributed to the low mass of required polymeric straps.

Figure 1. Relative impact [%] of inventory components and total values for (a) GWP [kg CO_2 eq.], (b) CED [GJ], and (c) with respect to transport-related emissions

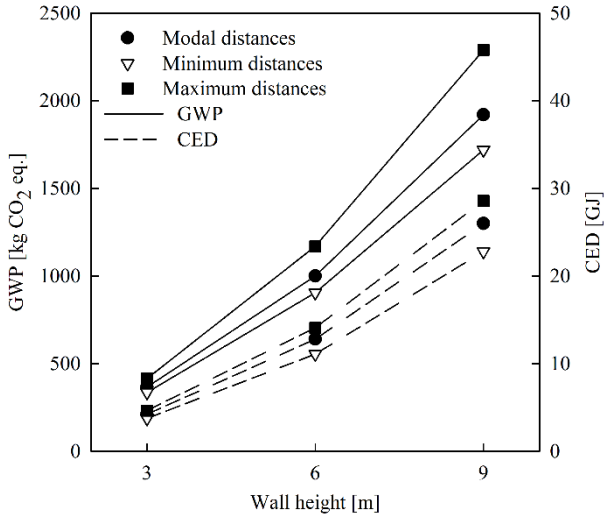

Figure 2. GWP and CED values considering modal, minimum and maximum transport distance values.

4 CONCLUSIONS

Life cycle analyses (LCA) were carried out to quantify the environmental impact of reinforced soil walls with polymeric straps. Analyses were focused on the impact of transport distances in the environmental inventory, using CO_2 eq. and cumulative energy demand as environmental indices. The main findings are:

- transport activities can be the third to second most impactful factor for RSW LCA, depending on the structure height.
- the environmental impact of transport activities will depend on distance and transported mass (or weight).
- backfill material transportation is the most significant contributor. Reducing soil transport distance or using an on-site soil could greatly reduce the environmental footprint.

The present work should be expanded by considering different backfill materials and reinforcement solutions, as well as probabilistic (Monte Carlo) simulations to widen the number of different scenarios. However, it is important to recall that a LCA is only one of several pillars of a proper sustainability assessment, which should also include economic, and social components (e.g., Damians et al. 2018).

An introduction to shared anchor in weak rock for floating systems

Une introduction à l' ancrage en partage de charges dans les roches faibles pour les systèmes flottants

L. Montalti, F. Moreno, V. Terente*
Cathie, Newcastle, UK

**victor.terente@cathiegroup.com*

ABSTRACT: Floating offshore wind is currently going through a significant expansion. However, there are existing gaps between naval architects and geotechnical experts that need to be bridged to achieve cost effective solutions. In this paper, Cathie presents a holistic methodology to cover some of these gaps. This paper investigates the opportunity of novel shared anchor concepts with specific reference to anchoring in rock. This solution not only offers a potential significant reduction on overall number of anchor points but also could allow a substantial reduction of the CAPEX/OPEX and the associated risk mitigation strategies. The study focuses on multiple lines anchor system simulations of anchor forces generated with example semisubmersible structure and a 15 MW wind turbine. The anchors in rock are assessed via state-of-the-art design methods for drilling and grout foundation and driven pile solutions with particular attention to the global capacity based on multi load cases.

RÉSUMÉ: L'éolien offshore flottant connaît actuellement une expansion significative. Cependant, il existe des écarts entre les architectes navals et les experts géotechniques qui doivent être comblés pour parvenir à des solutions rentables. Dans cet article, Cathie présente une méthodologie holistique pour combler certaines de ces lacunes. Cet article étudie l'opportunité de nouveaux concepts d'ancrage partagés avec une référence spécifique à l'ancrage dans la roche. Cette solution offre non seulement une réduction potentielle significative du nombre total de points d'ancrage, mais pourrait également permettre une réduction substantielle des CAPEX/OPEX et des stratégies d'atténuation des risques associées.
L'étude se concentre sur des simulations de systèmes d'ancrage à lignes multiples des forces d'ancrage générées avec un exemple de structure semi-submersible et une éolienne de 15 MW. Les ancrages dans la roche sont évalués via des méthodes de conception de pointe pour les solutions de forage et de coulis de fondations et de pieux battus, avec une attention particulière à la capacité globale basée sur des cas de charges multiples.

Keywords: Offshore floating; shared anchor; weak rock; multiple line anchor.

1 INTRODUCTION

Mooring systems are designed to ensure station keeping capabilities. Motions, both platform translation and rotation responses, must remain within operational boundaries and allow permissible peak anchor loads distributions, separated into horizontal, vertical and torsional components.

Shared anchors solutions for floating system will be a key driver to reduce the overall costs of floating wind farms. However, because of the novelty of shared mooring solutions, no applicable design approaches already exist to guide their application in floating offshore wind turbines (FOWT).

Sloan (2022) and Fontana (2019), evaluated novel multiline anchoring concepts for potential implementation in a real floating offshore wind farm; they assessed the limits on the number of lines per anchor determining the unique load characteristics of a multiline anchor and the cost benefit of the multiline system. However, both authors, did not include specific information on which type of anchors for particular soil condition could be used in a mooring shared anchors system.

With particular attention to foundations, based on the latest offshore leasing areas, and with specific interest for floating wind, it is expected that many of these development areas will be located in regions where rock at or near seabed is present. Therefore, for this paper, a solution for anchors in shallow rock geology is selected.

2 DESIGN MODEL METHODOLOGY

2.1 Case study model

The present study utilizes reference technology that is regularly used for multiple roles within the offshore wind community. The model chosen employs the most commonly studied platform type (semisubmersible) and mooring system type (catenary) in current FOWT technological stages.

The University of Maine (UMaine) Volturn US-S reference floating model designed to support the IEA Wind 15 MW WTG was modelled in OrcaFlex software (see IEA Wind, 2020).

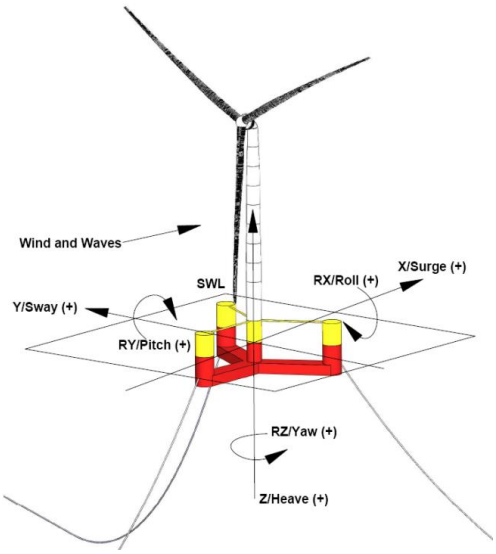

Figure 1. View of the floating system.

2.1.1 Simulation framework

It is important to evaluate the dynamics of the net force over a significant range of environmental and operational conditions. Through an engineering assessment and according to floating wind turbine structure standard - DNV-ST-0119, the most relevant design load cases (DLCs), combined with wind, waves and currents, includes DLC 1.6 and DLC 6.1.

2.1.2 Site characterization

The water depth in the present study associated with the lowest astronomical tide (LAT) is 200.0 m. The tidal water levels for this generic location have been considered.

2.1.2.1 Seabed conditions

The soil stratigraphy at the location predominantly comprises of dense to very dense sands overlying a band of extremely weak to very weak rock strength of mudstone and sandstone, UCS ranges from 2.6 MPa to 4.5MPa with selected values for the rock mass modulus from 44.8 MPa to 72.9 MPa.

2.1.3 Turbine and floating platform

The turbine chosen for this study is the IEA Wind 15 MW is a Class IB. It is composed of a direct drive generator in an upwind configuration. This WTG is coupled with the reference floater UMaine Volturn-U US. The coordinate systems used is shown in Figure 1, courtesy of University of Maine.

2.1.4 Mooring system definition

The use of 3 mooring lines per floater was selected as it is considered as a basic configuration for an initial study, see Figure 2.

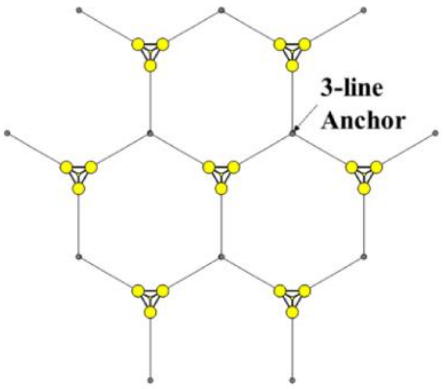

Figure 2. 3-Line anchor layout scheme, Fontana (2019).

2.2 Results

Multiline anchor loading is subjected to loading from any direction over the course of its design life, as the average direction of multiline anchor net force is aligned with the direction of the environmental load. Spatial layout of the multiline anchor for 3-line anchors with colour codes for each of the mooring tensions (Figure 3).

The maximum plan view misalignment angle assumed is ±10°. This is a typical inaccuracy value in the industry. The resolved mooring line load distribution is the characteristic for a catenary mooring system, separated into horizontal, vertical and torsional components. The multiline anchor net force is found using vector summation in each of the mooring line directions.

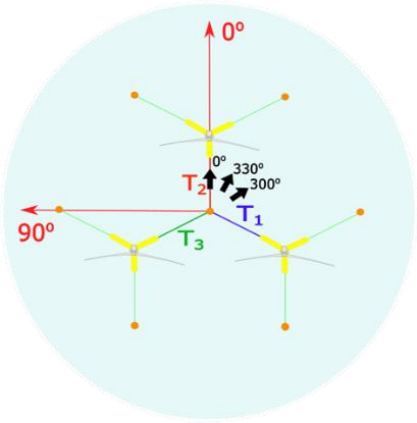

Figure 3. Line anchors.

2.2.1 Design load envelope

The design tension and moment are the sum of two factored characteristic components, the mean and the dynamic. The maximum loads (factored) calculated were a horizontal load of 4.89 MN and a vertical load of 1.05 MN for DLC 1.6 Rated-005, and a torsion load of 2.88 MN·m for DLC 1.6 Rated-011.

3 ANCHORS FOUNDATION CHECK

Based on the mooring system defined in the previous sections, for the shared anchors solution, a single pile foundation was selected which will be connected to 3 mooring lines. Due to the rocky geology condition and rock strength, the foundation was assumed to be installed via drill and grouted (D&G) solution.

3.1 Anchor geometry and assumptions

The anchor pile was selected having a diameter of 2.3 m and thickness of 45 mm with a total length of the pile of 16.5 m. The stick up from the seabed level is assumed approximately of 1.5 m high.

Figure 4 also shows some key considerations and assumptions for the concept design check discussed in this paper.

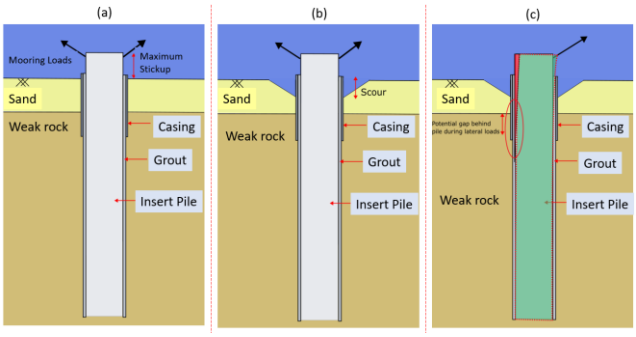

Figure 4. (a) anchor information (b) scour (c) potential presence of a gap behind the lateral loaded pile.

3.2 Axial Capacity check for D&G piles

The axial anchor capacity was estimated based on the methodology proposed by Seidel and Collingwood (2001). Such approach has a theoretical background and accounts for key effects that affect the shaft capacity of D&G piles in rock, i.e. - rock strength (intact drained and residual strength parameter), socket roughness and the general geometry of the interface resulting from the drilling process (rock mass modulus with its Poissons ratio, socket diameter, construction practice). Although the method considers key effects which influence the piles shaft capacity, the ultimate shaft resistance, f_s, remains expressed through the traditional simple relationship as expressed in the following equations:

$$f_s = \alpha \cdot UCS \quad (1)$$

$$SRC = \eta_c \cdot \frac{E_m}{UCS \cdot (1+v)} \cdot \frac{\Delta r}{d_s} \quad (2)$$

Where:
UCS = is the Unconfined Compressive Strength.
α = derived from plots provided by Seidel and Collingwood (2001) based on UCS and SRC values.
Δr = is the mean roughness height defined using Monash model; see Seidel and Collingwood (2001).
d_s = is the socket diameter.
η_c = is the construction method reduction factor, see Seidel and Collingwood (2001).
E_m = rock mass stiffness.
v = rock Poissons ratio.

Figure 5 shows the results for axial factored capacity against the design load for the worst case under DLC 1.6.

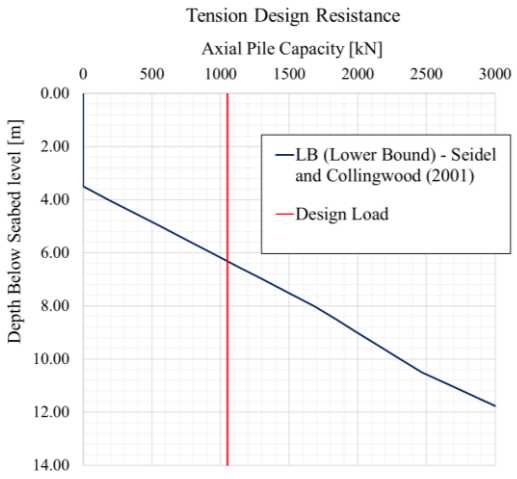

Figure 5. Tension axial capacity check based on Seidel and Collingwood (2001), factored load.

3.3 Lateral design check

3.3.1 PY curves based on Reese, Fragio and Abbs

Three different PY methodologies were used to evaluate the lateral response of the anchor, Fragio et al. (1985), Abbs (1983) and Reese (1997).

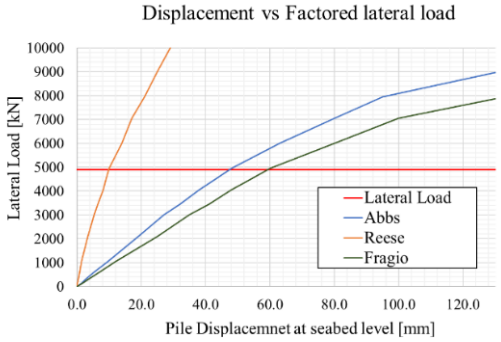

Figure 6. Horizontal displacements at mudline vs lateral load.

The PY curves were included in a 1D model and the Figure 6 show the results for this initial analysis. As expected, and as discussed from various authors, it can be observed how the PY curves from Reese give a stiff response compared to the other methods. Therefore, for a more detailed design is suggested to couple the method from Reese (1997) with the initial stiffness formulation proposed by Liang (2009) where a parametrical study based on 3D FE models was used to study various factors influencing the initial stiffness including the shaft diameter, the stiffness properties of the drilled shaft, the Poisson's ratio and the rock mass modulus.

3.3.2 Torsion check

The torsional response of a pile or anchor embedded in soil (or rock) is a subject which has received little attentions in the past. However, any pile foundation which is loaded laterally is liable to undergo some degree of torsion due to eccentricity of the applied load. Inadequate design against torsion may seriously affect the serviceability and safety of the foundation with catastrophic consequences.

As discussed in the previous sections, the proposed anchors solution with 3 mooring lines converging in a single pile foundation could lead in torsional forces applied to the pile. Structural misalignments, imperfections and anchor position are some of the main sources which will create a torsion force at the anchor. This was also discussed by Fontana et al. (2019), and Pillai et al. (2022), who stated that shared moorings or mooring misalignment during installation can lead to torsion loading.

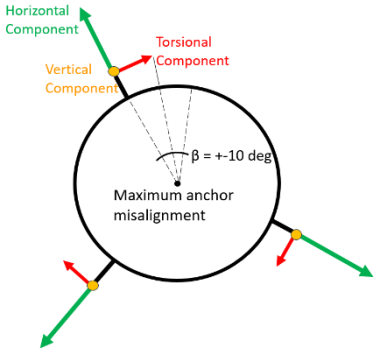

Figure 7. Torsional force from assumed mooring/structure misalignments.

Torsional failure is expected to begin from the surface and then progress down. For a rigid shaft the failure mode for torsion will be rapid where the peak torsion shear resistance is mobilised almost simultaneously everywhere along the shaft. However, for more flexible shafts the progress of slip down the shaft will occur more slowly and the situation may arise where the interface near the top of the shaft has reached a residual condition before the bottom of the shaft has reached a peak. In practical situations, the flexibility of the pile will lead to a gradual reduction in the angle of twist down the length of the pile (Carter & Kulhawy 1988).

Many design methods for check against torsion are available but in general they lack in critical details and justifications regarding the assumptions involved.

In general, the development of the maximum torsional resistance of the foundation involves a complicated interaction between the concrete-rock bonding at the sidewalls and at the tip, the roughness of the interface, and the relative stiffness and strength and surrounding rock mass Carter & Kulhawy (1988). At the moment there are no available full-size tests in weak rock where anchors are loaded under torsion.

There is also a key discussion which needs to be considered for future projects, in relation to the inadequate design of piles against the cyclic torsional loading which may affect the safety and serviceability of the foundation, leading to potential severe consequences (Vickery, 1979; Barker and Puckett, 1997). This discussion will not be part of this paper (which is mainly focused on ULS loads).

The cyclic load initiates the reversal of soil-pile interface shear stress, thus producing a progressive deterioration in strength and stiffness of the surrounding soil and consequently, pile soil interactive performance undergoes significant degradation (Basack, 2015).

There are some available analytical methods which can be used to assess the torsional response of piles, O'Neill (1964-a), Randolph (1981), Chow (1985),

Hache & Valsangkar (1988), Guo & Randolph (1996), Lin (1996), Carter & Kulhawy (1988). However, the majority of these methods were mainly focused on soils, sand/clay strata with some of them with clear limitations as discussed by Nasairat et at (2004). In this initial check the methodology proposed by Stuedlein et al. (2016), which is based on pile torsional response for cohesionless soil was used.

For anchors in weak rock, when the pile is under both axial, lateral and torsion loading there are no specific design methodologies. Further research is needed, also to confirm if the same assumption used for axial capacity, which is based on the working principle for lateral rigidity to prevent dilatancy (Seidel and Collingwood, 2001) could be also used for torsion and how the rock mass condition could affect the torsional response. The figure below clearly illustrates how small variations in assumptions (or methods) can influence the torsional response.

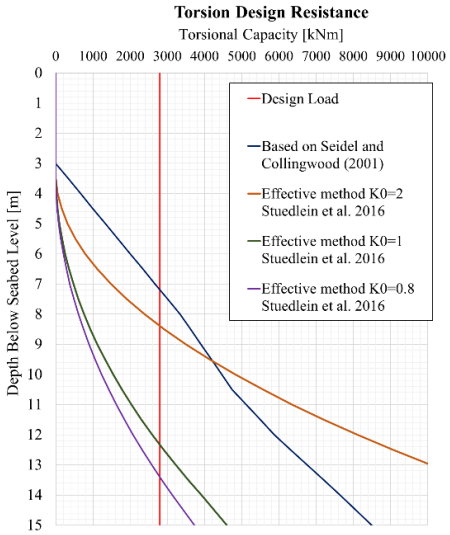

Figure 8. Torsional capacity (factored) vs anchor depth.

4 CONCLUSIONS

The majority of global offshore wind resource lies in water depths exceeding 60 meters, which are not suited to conventional bottom-fixed turbines (WFO, 2022). For example the 2022 ScotWind seabed leasing round has 60% floating capacity i.e. 15 GW of 25 GW total (Crown Estate Scotland, 2022), compared to zero farm-scale floating in previous UK leasing rounds. Floating foundations are therefore necessary to maximize this potential. However, the high capital cost of the support systems remains a primary obstacle. As discussed by Cerfontaine et al. (2023), to meet the expected target installation capacity for floating, the quantities of requited anchors are far beyond the current supply chain capacity, and create motivation for anchor optimization, or anchor sharing (Fontana et al., 2019), to reduce the overall demand. Therefore, the costs could be contained by minimazing the number of required anchors in the system via sharing anchors.

There are many new OWF leases in the East of Scotland and in many other areas for floating where it is expected rocky geology conditions. For these conditions, drilling and grouting could be one of the main option available for anchor solutions. Therefore, in this paper we have covered a conceptual level assessment, including the estimation of loads and the discussion on the effects of such loads on the dimensioning of a drilled and grouted anchor for lateral, torsion and tension capacity purposes.

The paper gives an initial understanding on the importance to provide and integrated approach based on naval architect inputs and geotechnical design in order to optimize wind farm layouts and achieve cost effective solutions via multiple mooring lines attached to a single anchor.

As also stated by Nuerberg et al. (2023), anchor sharing can also reduce the overall net forces acting on the anchors, as the forces from different turbines are "counteracting in direction, therefore the effect partially cancels each other".

With regards to the selected anchor foundation, a future study to be included as part of this line of research will be to investigate the effect of cyclic degradation present during multilateral loading, for instance. Mooring misalignment could also result in two-way cyclic loading (Fontana et al., 2019, and Pillai et al., 2022) which will be a key input to assess final anchor resistance degradation.

Ballast degradation under different cycles and rotational speeds in micro-Deval equipment

Dégradation du ballast sous différents cycles et vitesses de rotation dans un équipement micro-Deval

N.S. Montero-Cubillo*, J. Estaire, E. Marull
LG-CEDEX, Madrid, Spain

**natalia.montero@cedex.es*

ABSTRACT: The ballast layer plays a crucial part in transmitting and distributing the wheel load from sleepers to the underlying sub-ballast and subgrade at a reduced and acceptable level. Upon repeated train loading, ballast becomes degraded. The amount of degraded ballast is directly connected with the load and velocity of the train, and the type of rock. This paper shows the results of 14 Ballast Degradation in micro-Deval equipment (BDMD) tests carried out at different rotation velocities (13, 25, 50, 63, 75, 100 y 120 rpm) and at different number of cycles (0, 1000, 3000, 6000, 9000, 15000, 21000, 69000 y 105000) with samples of two types of railway ballast. The first is gneiss ballast, one of the most common in the High-speed Spanish railways, and the second one is a limestone ballast, forbidden in Spain. For each one of the mentioned cycles, a grain size distribution test is performed. The main objective of this paper is to analyse the influence of the rotational speed and the number of applied cycles on the degradation of the ballast.

RÉSUMÉ: La couche de ballast joue un rôle crucial dans la transmission et la distribution de la charge des roues des traverses au sous-ballast et à la plate-forme sous-jacente à un niveau réduit et acceptable. Le ballast se dégrade sous l'effet de la charge répétée des trains. La quantité de ballast dégradé est directement liée à la charge et à la vitesse du train, ainsi qu'au type de roche. Cet article présente les résultats de presque 11+3 tests de dégradation du ballast dans un équipement de micro-dégradation (BDMD) effectués à différentes vitesses de rotation (13, 25, 50, 63, 75, 100 et 120 tr/min) et à différents nombres de cycles (0, 1000, 3000, 6000, 9000, 15000, 21000, 69000 et 105000) avec des échantillons de deux types de ballast de chemin de fer. Le premier est un ballast de gneiss, l'un des plus courants dans les chemins de fer espagnols à grande vitesse, et le second est un ballast de calcaire, interdit en Espagne. Pour chacun des cycles mentionnés, un test de distribution de la taille des grains est effectué. L'objectif principal de cet article est d'analyser l'influence de la vitesse de rotation et du nombre de cycles appliqués sur la dégradation du ballast.

Keywords: Railway ballast degradation; micro-Deval test; number of cycles; rotational speed.

1 INTRODUCTION

One of the tests used to estimate the degradation resistance of ballast particles is the micro-Deval test. The standard (EN-103450 standard "Aggregates for Railway Ballast) dedicates a specific annex to the testing of railway ballast.

In addition, there are numerous references in which the micro-Deval test is used to quantify the degradation of railway ballast as a function of intrinsic parameters of the ballast particles. The following should be highlighted:

- Bach (2013) investigates the influence of pattern rock type on degradation resistance.
- Nålsund (2014) studies the influence of certain rock textural parameters (such as roughness, mineral grain size, quartz content, and soft mineral content) on the value of the micro-Deval coefficient.
- Moaveni et al. (2014) use a particle image analyser to visualize the changes in particle morphology after micro-Deval testing.

During the micro-Deval test, the ballast particles collide with each other and with the drum walls, producing an accelerated degradation, especially through the mechanisms of abrasion and chipping, which implies the breakage of vertices and edges (Estaire and Montero-Cubillo, 2022), of greater magnitude and homogeneity, than occurred in real tracks. For example, Deiros et al. (2016) estimate that, in some areas of the drum, friction work reached, a maximum value of 10,000 J/mm^2 during a micro-Deval cycle, while at the passage of a train axle in real track a maximum friction work of only 0.1 J/mm^2 under sleeper is produced.

However, although the energy magnitude and the degradation mechanism are not identical between the test and the real track, the energy-degradation relationship in the test has allowed us to obtain certain qualitative and quantitative conclusions applicable to the real track, as can be seen in Estaire et al. (2023). Also, according to several authors (Deiros et al., 2016) and Gupta et al., 2022), the appearance of the particles at the end of the micro-Deval test is very similar to that observed in ballast particles collected from high-speed tracks after a long period in operation. This fact is also corroborated in the tests performed for this paper.

A new procedure was developed in this study when compared with the conventional micro-Deval test. The new test is named Ballast Degradation in micro-Deval equipment (BDMD test). The test was designed to study the relationship between degradation and: a) rotational speed and number of cycles, and b) power and energy supplied by the equipment to the specimen. Also, the variation of particle size distribution of the ballast specimens, along the test, can be analysed.

2 MATERIALS AND METHOD

2.1 Ballast samples

Two types of railway ballast were tested: a) a gneiss (Figure 1a), of metamorphic origin and one of the most common in the high-speed Spanish railways, and b) a limestone, of sedimentary origin (Figure 1b), forbidden in Spain but allowed in other countries, like UK or USA. Both materials were tested to demonstrate the difference in terms of degradation and to establish certain parameters dependent on the rock strength and the degradation.

Figure 1. a) Gneiss ballast particle, b)Limestone ballast particle.

2.2 Test equipment

The equipment used for the BDMD test is an adaptation of the equipment used for the micro-Deval test (EN 1097-1), as shown in Figure 2, in such a way that its standard rotation system is used, but the standard drums are modified. A 304 mm high drum was used, joining two drums of the standard equipment (Figure 2). Also, a variable-frequency drive was connected to the rotation system to vary the rotational speeds and to quantify the applied energy.

Additionally, sieves to perform complete particle size distribution tests were used: 100; 63; 50; 40; 40; 31.5; 22.4; 12.5; 10; 6.3; 5 and 1.25 mm.

Figure 2. BDMD test equipment of LG-CEDEX and joined drums.

2.3 Test procedure

The application of micro-Deval test for ballast is regulated by Annex E of EN-103450 "Aggregates for Railway Ballast". For this study, BDMD tests were performed under different conditions than the standard usual, as can be seen in Table 1.

Table 1. Differences between micro-Deval and BDMD tests.

Test magnitude	Test	
	micro-Deval[a]	BDMD
Initial load (kg)	10	3.8
Cycles	14,000	1,000 to 105,000
Rotational speed (rpm)	100	13 to 120
Water	Yes	No
Degradation (Passing sieve)	1.6 mm (micro-Deval coefficient)	22.4 mm
Complete PSD[b]	No	Yes

[a] According to Annex E/EN-103450
[b] PSD: Particle Size Distribution test

The accumulation of fine material in ballast layers is known as ballast fouling. For assessing the need for ballast treatment, the European Rail Research Institute (ERRI D182/RP3) proposed a ballast fouling level upper or equal to 30%, at which the mechanical properties of railway ballast begin to be altered dramatically. In this study, degradation (Table 1) is considered as ballast fouling (or soiling in ERRI), defined as the percentage by weight of the specimen material that falls through a 22.4 mm sieve.

The procedure followed in BDMD tests was as follows:

a) Specimen preparation. Selection of 10 kg of new ballast particles between 50 and 31.5 mm in size and subsequent drying in an oven at 110 ºC, until constant mass.

b) Selection of 3800 ± 200 g of the specimen prepared in the previous stage, creating the following approximate initial particle size: 20% of 31.5 mm size and 80% of 40 mm size.

c) Selection of the test frequency in variable-frequency drive (which is related to the rotational speed).

d) Reset the energy consumption counter.

e) Place the ballast specimen inside one of the drums.

f) Close the open end using the other hollow drum and tighten the nuts. Additionally, a resin had to be added to the joint area of both drums to avoid dust loss during the test.

g) Place the drums in the equipment

h) Selection, in the control device of the equipment, of the required test time (calculated from the desired number of cycles according to the test rotational speed).

i) Start-up.

j) When the selected time is reached the test stops.

k) Read and note the energy consumed after the number of cycles applied.

l) Separation of the drums and overturning of the specimen in one of them.

m) Weigh the drum with the contained specimen to asses possible dust losses and note.

n) Extraction of the specimen from the drums taking care not to release too much dust when the specimen is poured.

o) Weigh the resulting specimen without the drum and note.

p) Sift, weigh, and take readings for the different fractions mentioned above.

q) Repetition of steps e) to p) until the final number of cycles required is reached, with the same specimen.

2.4 Performed tests

Unlike the test established in the standard, in this study, the cycles were applied in steps: 1,000, 3,000, 6,000, 9,000, 15,000, 21,000, 69,000, and 105,000 cycles. In each of these steps, the specimen was extracted from the drum, and its complete particle size distribution was determined, to evaluate the modification of the original sizes of the particles and the generation of new particles.

Additionally, to analyse the influence of the rotational speed on the degradation mechanisms of the ballast particles, tests were carried out with different rotational speeds of the drums by installing a variable-frequency drive in the original equipment. Almost 11 tests were performed with the gneiss ballast, with 7 different velocities (13, 25, 50, 63, 75, 100, and 120 rpm) and 8 different consecutive applied cycles for each velocity. Also, 3 tests were carried out with the limestone ballast, with 3 different velocities (13, 50, and 100 rpm) and 8 different consecutive applied cycles for each speed.

3 RESULTS AND DISCUSSION

3.1 Degradation, number of cycles, and rotational velocity

The results obtained from these BDMD tests are shown in Figure 3, where the values of the degradation of the ballast particles in the tests performed with different rotational speeds of the equipment are plotted as a function of the number of cycles applied in each test step. The degradation is measured as the percentage by weight of the material passing through the 22.4 mm sieve with respect to the weight of the total specimen.

It should be noted that some of the tests were repeated, using the same rotational speed, to corroborate or disprove some anomalous trends. These anomalous variations, in terms of degradation for the same test speed, may be related to the variability of the shape of the ballast particles of each specimen, randomly chosen.

The curves considered as the most representative of all the tests performed are shown in Figure 3a, for gneiss ballast and Figure 3b for limestone ballast.

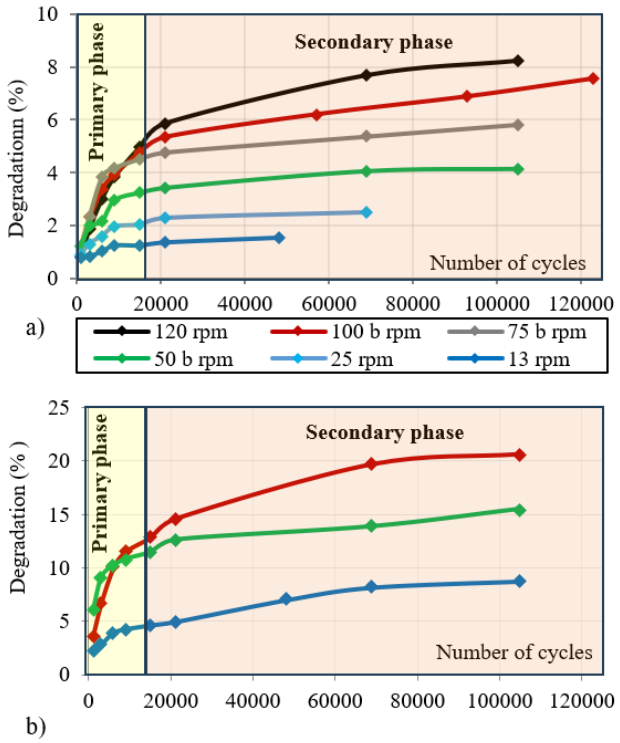

Figure 3. Degradation of ballast particles as a function of the number of cycles at different speeds: a) gneiss ballast and b) limestone ballast.

In Figures 3a and b, two phases of degradation can be seen:

- Primary phase: the initial degradation increases rapidly with the number of cycles. Depending on the rotational speed of each test, the primary phase ends between 10,000 and 20,000 cycles, with an approximate average value of 15,000 cycles. Although it is difficult to specify, it seems intuitive that the primary phase ends earlier the lower the rotational speed used in the test. During this phase, the particles still have a high roughness and angularity due to the presence of sharp vertices and edges, so degradation by abrasion and breakage of vertices and edges is much higher.
- Secondary phase: a second and more linear step is observed (from between 10,000 and 20,000 cycles, depending on the speed), with a constant slope in each test, in which degradation continues to increase with the applied cycles, but more slowly than during the primary phase. In this phase, the ballast particles have less roughness and angularity to break and it is increasingly difficult to generate degradation, since the particles are already more rounded and polished, so the degradation rate decreases.

In any case, the cumulative degradation increases with the rotational speed used in the test and with the number of cycles. It was also possible to verify that degradation accelerates with increasing speed, both in the primary and secondary phases, increasing the slope of the degradation-number of cycles curve.

Also, comparing Figure 3a and Figure 3b, the following differences between gneiss and limestone ballasts can be highlighted.:

- At a velocity of 100 rpm and an accumulated cycles of 1,000 BDMD degradation was: 1.2% in the case of gneiss and 3.5% in the case of limestone.
- At a velocity of 100 rpm and an accumulated cycles of 100,000 BDMD degradation was: 7% in the case of gneiss and 20% in the case of limestone.

Both cases reveal a degradation difference in the order of 3 times more for limestone than for gneiss ballast particles. For this study, some Point Load Tests (PLT) with these two types of ballast were performed. The results showed that the PLT strength is also in the order of 3 times more for limestone (Is_{50} = 3 MPa) than for gneiss (Is_{50} = 7.8 MPa). So the BDMD degradation parameter could be inversely proportional to the PLT strength of the pattern rock which constitutes the ballast particles.

Additionally, an approximate micro-Deval coefficient can be estimated from the BDMD test. Micro-Deval coefficiente was: 4% in the case of gneiss ballast and 11% in the case of limestone ballast. Should be noted that this value was calculated from tests at 100 rpm and 15,000 cycles with the differences between both tests (micro-Deval and BDMD) shown in Table 1.

On the other hand, considering the curves in Figure 3a, the degradation for certain numbers of cycles has been plotted as a function of rotational speed, in Figure 4.

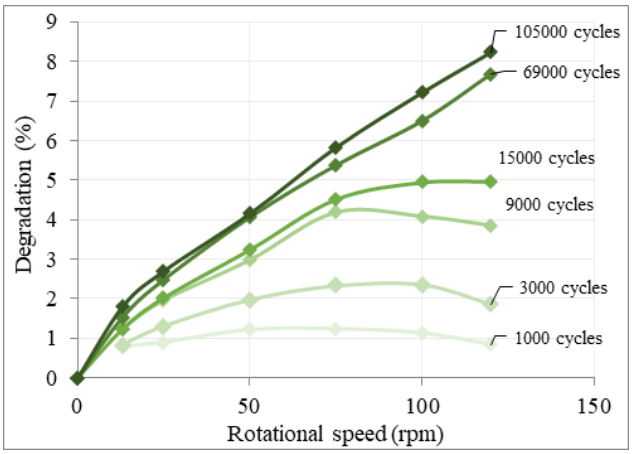

Figure 4. Degradation of ballast particles as a function of rotational speed at a given number of cycles.

The following conclusions can be drawn from Figure 4:

- For the same rotational speed the degradation increases with the number of cycles (also appreciable in Figure 3). The higher the speed, the greater the difference in degradation between 1,000 and 105,000 cycles.
- The degradation does not increase significantly with speed until the number of cycles applied exceeds approximately 1,000. As can be seen, when the number of cycles is low (1,000) the degradation is almost the same regardless of the rotational speed of the test.
- This fact can also be observed in Figure 3, in which at cycles close to 1,000 all the curves overlap, starting at approximately the same degradation value.
- This can be interpreted as if there is an initial degradation energy threshold of about 1,000 cycles. The first degradations that occur in the particles do not seem to require high energy and/or power, so even the test with the lowest energy and power (associated with 13 rpm and 1,000 cycles) manages to produce this degradation and it does not cause more breakage by rotating faster.
- From 1,000 cycles onwards, the effect of rotational speed on degradation starts to be

noticed, and degradation starts to increase linearly with speed for high cycles, from 15,000 onwards.

3.2 Energy - degradation relationship

Another way to appreciate the relationship between degradation, rotational speed and number of cycles is to graph a plot degradation - energy. The energy was estimated as the rotational speed (v) squared multiplied by the number of cycles applied (N) of each test step.

Figure 5 shows that the regression coefficient of this potential expression is very high, proximate to 1 and equal to 0.92. This fact reveals the clear relationship between these three parameters for measuring degradation with the micro-Deval or the BDMD tests and probably when the degradation is measured at the real railways. For more details about the extrapolation of the BDMD results to the railways, see Estaire et al. (2023).

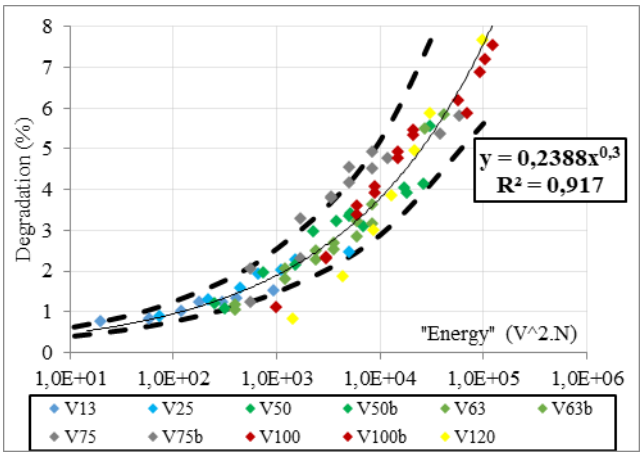

Figure 5. Degradation as a function of applied cycles and rotational speed.

3.3 Particle size distribution and visual analysis

The particle size distributions of all samples before and after BDMD tests were performed. As can be seen in Figure 6, the main generated sizes in this type of test were fine particles under 1.25 mm of diameter, related to abrasion mechanism, and, in a minor proportion, particles of 22.4 or 10 mm, related to chipping mechanism.

Comparing Figure 6a and Figure 6b, the following differences between gneiss and limestone ballasts can be highlighted:

- The percentage of particles with a diameter of 1.25 mm or lower increases, from 0 to 105,000 applied cycles: from 0 to 6% in the case of gneiss ballast and from 0 to 16% in the case of limestone ballast.
- The percentage of particles with a diameter between 22.4 and 12.5 mm increases, from 0 to 105,000 applied cycles: from 0 to 1% in the case of gneiss ballast and from 0 to 3% in the case of limestone ballast.

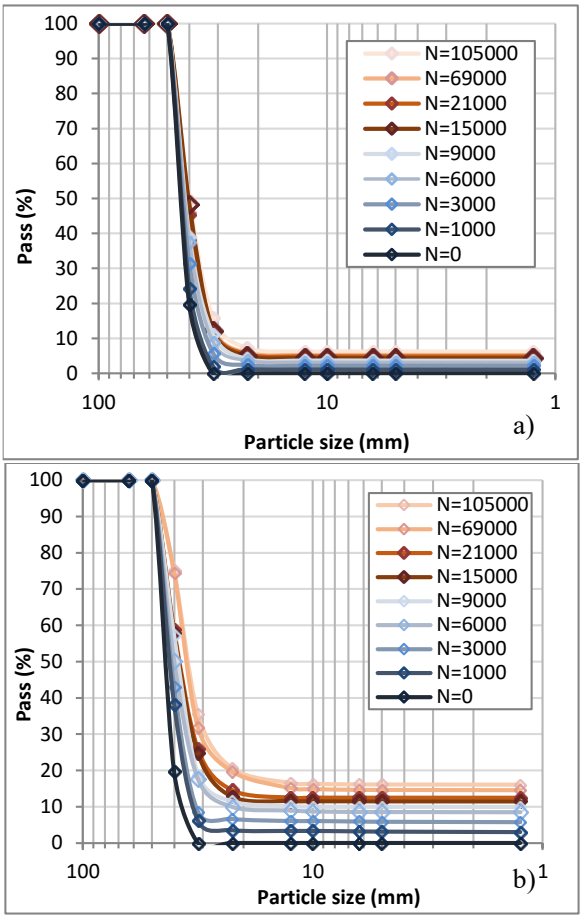

Figure 6. Particle size distribution after tests: a) ballast from gneiss, and b) ballast from limestone.

In Figure 7, the appearance of ballast particles after the application of 15,000 cycles in BDMD test is compared to the aspect of particles collected at real railways. As it can be seen, and other authors indicate (Deiros et al., 2016 and Gupta et al., 2022), the aspect of the ballast particles of the two samples (coming from real track and from BDMD test) are similar, in qualitative terms of roughness and angularity.

Figure 7. Appearance of ballast particles: degraded ballast in track (left) and degraded ballast in BDMD test (15,000 cycles)(right).

4 CONCLUSIONS

The main conclusions of this paper drafts the following highlighted aspects:

- During the primary phase of the BDMD test, the particles still have a high roughness and angularity due to the presence of sharp vertices and edges, so degradation by abrasion and breakage of vertices and edges is much higher and rapidly increases with the number of cycles. In the secondary phase of the BDMD test, the ballast particles have less roughness and angularity to break and it is increasingly difficult to generate degradation, since the particles are already more rounded and polished, so the degradation rate decreases, remaining approximately constant.
- The cumulative degradation increases with the rotational speed used in the test and with the number of cycles. It was also possible to verify that degradation accelerates with increasing speed, both in the primary and secondary phases, increasing the slope of the degradation-number of cycles curve.
- The degradation does not increase significantly with speed until it exceeds approximately 1000 cycles applied. At cycles close to 1000, all the curves overlap, starting at approximately the same degradation value. This can be interpreted as if there is an initial degradation energy threshold of about 1,000 cycles. The first degradations that occur in the particles do not seem to require high energy and/or power, so even the test with the lowest energy and power (associated with 13 rpm and 1,000 cycles) manages to produce this degradation and it does not produce more breakage by rotating faster.
- The BDMD degradation parameter could be inversely proportional to the Point Load Test strength of the pattern rock which constitutes the ballast particles. However, more types of rocks should be studied to set a clear trend.
- In this type of test, particles with 1.25 mm of diameter or lower are mainly generated related to abrasion as the most important performer mechanism.
- The aspect of ballast particles after 15000 applied cycles in DBMD tets is similar to the aspect of particles collected at real railways, as other authors indicate in the case of the micro-Deval test.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the collaboration of the following persons: Felipe García and Elías Roces. The authors are grateful for the ballast samples provided by Rosa Casquero and Franciso Cabrera, from ADIF.

ABSTRACT: Ground thermal regime in cold regions is influenced by seasonal snow cover, which acts as an insulating layer influencing the heat transfer between the atmosphere and the underlying soil. The thermal properties of the snow change with different environmental conditions, playing a crucial role to determine the thermal state of the sub-surface soil. Previous research in this field have faced challenges to accurately characterize thermal properties of seasonal snowpacks under varying spatial and meteorological conditions. To address this issue, two experimental field setups were constructed in Luleå, Sweden, to observe the temperature distribution of the snowpack and the ground sub-surface soil. The first experiment studied a naturally accumulated, undisturbed snowpack. The second experiment was conducted on a roadside ditch where the snowpack consists of a combination of natural accumulated snow and plowed snow from the adjacent road. In this research, heat transfer processes at both field sites were monitored over a winter season each to better understand the complex relationship between snow cover properties and sub-surface thermal regime. Furthermore, thermal conductivity of a basal layer in each snowpack was calculated over a time period, based on the field measurements. The results showed that the history of snow deposition, meteorological conditions, and changes in soil moisture impact the metamorphism process within the snowpack, thereby altering the structure of the layers of snowpack and its influence on the thermal regime of the sub-surface soil. The findings of this research have important applications in various sectors, from mining to road maintenance and agriculture.

RÉSUMÉ: Le régime thermique du sol dans les régions froides avec une couverture neigeuse saisonnière est influencé par la couche isolante de neige, qui agis sur le transfert de chaleur entre l'atmosphère et le sol sous-jacent. Les propriétés thermiques de la neige changent en fonction de différentes conditions environnementales, jouant un rôle crucial dans la détermination de l'état thermique du sous-sol. Des recherches antérieures dans ce domaine ont rencontré des défis pour caractériser de manière précise les propriétés thermiques des manteaux neigeux saisonniers dans différentes configurations spatiales et des conditions météorologiques variables. Pour résoudre ce problème, deux dispositifs expérimentaux ont été construits à Luleå, en Suède, afin d'observer la distribution de la température dans le manteau neigeux et le sol. La première expérience a étudié un manteau neigeux accumulé naturellement et non perturbé. La deuxième expérience a été menée dans un fossé en bordure de route où le manteau neigeux est constitué d'une combinaison de neige accumulée naturellement et de neige déblayée de la route adjacente. Dans cette recherche, les processus de transfert de chaleur sur chacun des sites ont été surveillés pendant une saison hivernale pour mieux comprendre la relation complexe entre les propriétés de la couverture neigeuse et le régime thermique en sous-sol. De plus, la conductivité thermique d'une couche de base dans chaque manteau neigeux a été calculée sur une période donnée, en fonction des mesures sur le terrain. Les résultats ont montré que l'historique du dépôt de neige, les conditions météorologiques et les variations de l'humidité dans le sol affectent le processus de métamorphose au sein du manteau neigeux, modifiant ainsi la structure des couches du manteau neigeux et son influence sur le régime thermique du sous-sol. Les conclusions de cette recherche sont applicables dans divers secteurs, de l'exploitation minière à l'entretien des routes et à l'agriculture.

Keywords: Ground thermal regime; thermal properties; seasonal snow cover.

1 INTRODUCTION

The ground thermal regime in cold regions is strongly influenced by the presence of seasonal snow cover, which acts as an insulating layer during the cold season. Alterations in snow cover conditions have a significant influence on the correlation between meteorological conditions and the thermal state of the soil beneath the snow. Scientific research conducted in the Arctic and sub-Arctic regions has revealed that the seasonal snow cover is composed of distinct layers with varying physical and thermal characteristics (Benson & Sturm, 1993). Of particular interest in recent years is the formation of a basal layer of snowpack known as the depth hoar, which has important implications for the properties of the snowpack and interacts closely with the soil beneath the snow. Depth hoar crystals are characterized by their large size, hollow facets, and poor interconnectivity, resulting in layers of low density and low thermal conductivity. These crystals play a significant role in the thermal insulation of the snowpack.

Domine et al. (2018) emphasized that the formation of depth hoar is primarily influenced by soil moisture and wind conditions. Understanding this relationship is crucial to simulate snow properties accurately, particularly thermal conductivity, in order to effectively model the ground thermal regime.

To explore this matter, two experimental test sites were established in Luleå, located in the northern part of Sweden. The objective of the experimental configurations at the sites was to investigate and analyze how two types of seasonal snowpack, each characterized by a unique thermal conductivity in their basal layer, affect the thermal regime of the ground.

2 FIELD MEASUREMENT

Measurements were conducted at two distinct experimental field sites: Experimental Site 1 (ES1) during the winter of 2021-2022, and Experimental Site 2 (ES2) during the subsequent winter of 2022-2023, as illustrated in Figure 1 and Figure 2.

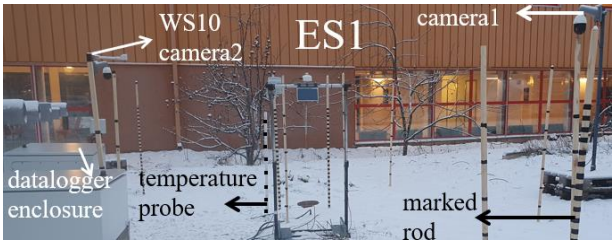

Figure 1. ES1 during the winter 2021-2022.

ES1, was situated within the premises of Luleå University of Technology. The site was specifically selected for studying a naturally accumulated and undisturbed snowpack. ES2 was located near the Luleå airport on a roadside ditch, where the snowpack consisted of a mixture of naturally accumulated snow and plowed snow from the adjacent road. At both field sites, meteorological data was collected using a WS10 weather station (Lufft Mess und Regeltechnik GmbH, 2019). To quantify snow depth, a system was implemented where two cameras were stationed at each site. The cameras captured images of rods, marked at 5 (cm) intervals, providing clear reference points for measurement. Images were taken at 4-hour intervals. Additionally, a temperature measurement probe equipped with thermocouples type T produced by Pentronic were utilized to measure the temperature of the soil sub-surface at a depth of 40 (cm), the temperature at the soil-snow interface and the temperature of 15 (cm) above the interface within the snowpack. Furthermore, thermal conductivity of the

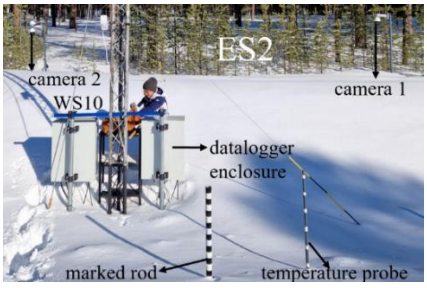

Figure 2. ES2 during the winter 2022-2023.

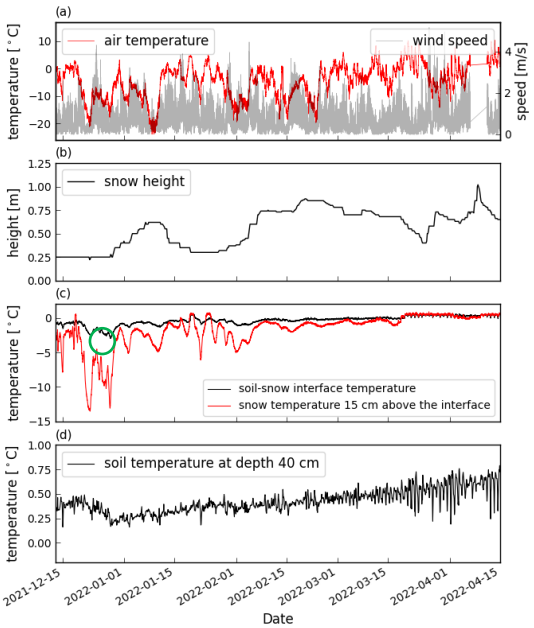

Figure 3. Recorded measurements at ES1 a) air temperature and wind speed, b) snow depth, c) temperature at the soil-snow interface and within the snowpack at a height of 15 cm above the interface, and d) soil sub-surface temperature at a depth of 40 cm.

sub-surface soil at a depth of 40 (cm) was measured using a TP01 thermal sensor. The sensors were connected to a CR1000X datalogger, manufactured by Campbell Scientific. The datalogger was housed in an enclosure equipped with additional insulation to ensure that the measured junction temperature was representative of the entire terminal block.

Figure 3 and Figure 4 present the recorded measurements at ES1 and ES2, respectively. These figures show the measurement results spanning two winter seasons, from December 13 to April 18. During the measurement period at ES1, the air temperature fluctuates between -23.7 (ºC) and 14.8 (ºC), with an average temperature of -4.5 (ºC). Similarly, at ES2, the air temperature ranges from -23.6 (ºC) to 9.9 (ºC), with an average temperature of -6.9 (ºC). However, the wind speed at ES2 is higher than at ES1.

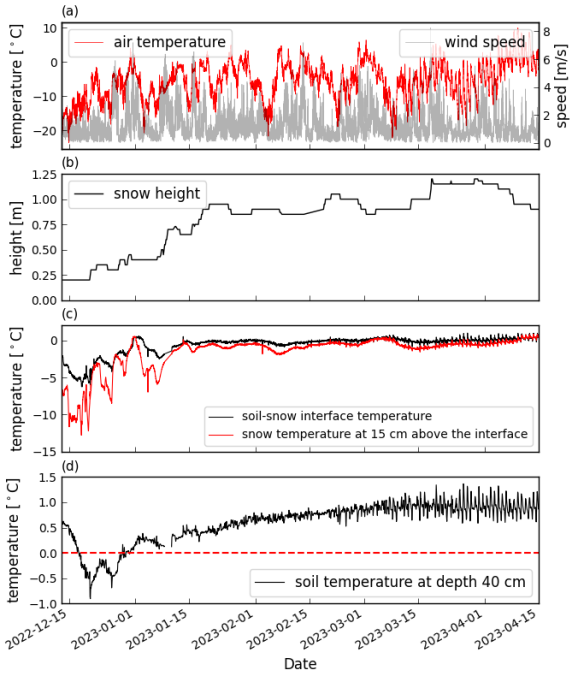

Figure 4. Recorded measurements at ES2 a) air temperature and wind speed, b) snow depth, c) temperature at the soil-snow interface and within the snowpack at a height of 15 cm above the interface, and d) soil sub-surface temperature at a depth of 40 cm.

2.1 Seasonal freeze/thaw development

The air temperature at ES1 exhibits fluctuations around the freezing point during the initial phase of the measurement period, Figure 3(a), contrasting with ES2 that initially just experiences negative air temperature, Figure 4(a). Nevertheless, within a few days, the air temperature at ES1 converges to a comparable range as that recorded at ES2. Furthermore, the data presented in Table 1, along with Figure 3(b) and Figure 4(b), highlights that the snow cover height at ES1 surpasses that at ES2 by a margin of 5 (cm) at the onset of the measurement.

Figure 3(c) and Table 1 highlight a distinct trend at the ES1 soil-snow interface in the beginning of the winter. Here, the interface temperature maintains stable just below 0 (ºC) for an extended period, characterized as the "zero-curtain" and illustrated in the figure by a green circle, before gradually dropping to -3 (ºC). This stability coincides with a phase transition from water to ice in the soil moisture, leading to the release of latent heat. Meanwhile, Figure 4(c) and Table 1 indicate a -6 (ºC) temperature decrease at the ES2 interface.

ES1 is characterized by sandy loam soil, whereas ES2 consists of poorly graded sand. Thermal conductivity measurements conducted at the sites revealed that ES1 demonstrated an average thermal conductivity of 0.57 ($Wm^{-1}K^{-1}$), while ES2 exhibited a slightly higher value of 0.8 ($Wm^{-1}K^{-1}$). The water table beneath ES1 is situated 2 (m) below the soil surface, while the water table beneath ES2 is found at a depth of 10 (m) below the soil surface. Thus, it is expected that the soil moisture content at ES1 will be higher than that at ES2, owing to both the proximity of the water table to the soil surface and the differing soil compositions.

As shown in Table 1, the initial temperature of the sub-surface soil at ES2 is 0.4 (ºC) higher than that of ES1 at the start of the measurement period. Nevertheless, unlike ES2, the sub-surface soil at ES1 remained unfrozen throughout the entire season, as shown in Figure 3(d). Conversely, the corresponding sub-surface soil at ES2 experienced approximately 10 days of freezing after one full day of the zero-curtain phenomenon at that depth. While thawing at ES2, the sub-surface soil experienced a full-day period of zero-curtain before it fully thawed. This sequence is outlined in Table 1 and visually represented in Figure 4(d).

The air temperature at both experimental sites typically remains within a similar range, with only a brief variation noted at the onset of the measurements. Furthermore, the difference in snow depth covering the sites is merely 5 (cm) at the commencement of the study. Despite a marginal difference of 0.23 ($Wm^{-1}K^{-1}$) in the thermal conductivity of the soil between ES2 and ES1, the higher moisture content in the soil at ES1 prevents the subsurface from freezing throughout the measurement period. This can be attributed to the significant latent heat energy released during the transition of water to ice. However, the subsurface soil at ES2 experienced a short period of "zero curtain" before undergoing freezing and subsequent thawing. This phenomenon can be attributed to the low moisture content of the soil at ES2.

2.2 Snow depth

Based on the analysis by Sokratov and Barry (2002), snow depth affects the soil surface energy balance, from beginning of the active layer freezing until the snow depth reaches its maximum level. Sturm and Holmgren (Zhang, 2005) conducted field measurements on November 17, 1998 in Ivotuk, Alaska. It was observed that the influence of snow depth on soil-snow interface temperature becomes less significant when the snow depth exceeds 40 (cm).

Table 1. Variation of critical temperature with snow height during the winter season at soil-snow interface and sub-surface soil at a depth of 40 cm at ES1 and ES2.

	Temperatue (ºC)	Snow height (cm)	Date
Soil-snow interface			
ES1	-0.7	25	2021-12-13
	-2.9	25	2021-12-28
	almost stable at 0	60	2022-02-06
ES2	-1.9	20	2022-12-13
	-6.3	20	2022-12-18
	almost stable at 0	65	2023-01-13
Sub-surface soil at a depth of 40 cm			
ES1	0.3	25	2021-12-13
	0.1	25	2021-12-28
ES2	0.7	20	2022-12-13
	zero-curtain	20	2022 -12-17 2022-12-18
	-1	25	2022-12-20
	zero-curtain	40	2022-12-28- 2022-12-29

Zhang (2005) underscores the significant impact of snow thickness variations on soil-snow interface temperatures, particularly when the snow depth is below approximately 50 (cm). Nevertheless, the data from the sites ES1 and ES2 demonstrate that when the snow depth reaches 60 (cm), the soil-snow interface temperature remains consistently at 0 (ºC), as depicted in Table 1 and Figure 1(b) and (c), as well as Figure 2 (b) and (c).

3 HEAT TRANSFER

3.1 Depth hoar formation

Seasonal snow cover usually consists of a coarse depth hoar layer at the base of the snowpack. This layer is characterized by its low-density and low-thermal conductivity < 0.2 ($Wm^{-1}K^{-1}$) (Sturm, et. al, 2002, Domine, et.al, 2016). Depth hoar typically forms through the metamorphism of snow exposed to a temperature gradient > 20 (Km^{-1}) (Marbouty, 1980).

A study conducted by Domine et al. (2018) has demonstrated the significance of wind as the primary factor influencing depth hoar formation in the polar desert. Investigations on subarctic snowpack, where wind is weak and uncompacted snow accumulates, have revealed that such snow exhibits high permeability, facilitating convection through the pore spaces (Sturm & Benson, 1997) leading to water vapor movement that encourages the growth of depth hoar crystals.

Davesne et al. (2022) have shown that snow pits in humid sites exhibit lower thermal conductivity values and less variability in the basal layer compared to dry sites. In regions characterized by higher humidity, the depth hoar crystals typically exhibit a coarser texture compared to drier locations. A lower soil moisture level leads to less latent heat released during the freezing process, speeding up the freezing of the active soil layer and consequently soil cooling. This, in turn, reduces the temperature gradient within the snowpack, resulting in decreased water vapor flux and slower snow metamorphism.

3.2 Heat transfer at soil-snow interface

As the snow accumulates and reaches a specific height, the soil-snow interface temperature stabilizes at 0 (ºC), as shown in Figure 3(c) and Figure 4(c). Therefore, the energy balance at the soil-snow interface can be expressed as

$$Q_s + Q_{sn} + I_0 = 0 \quad (1)$$

where Q_s(Wm^{-2}) represent the heat flux coming from sub-surface soil layer, Q_{sn}(Wm^{-2}) denote the heat flux within the basal layer of snowpack, and, I_0(Wm^{-2}) indicate the amount of solar radiation absorbed at the interface.

Due to the relatively small pore sizes compared to the overall volume of the soil structure, heat conduction is considered to be the dominant heat transfer mechanism within the soil.

As a result of sufficient height for the accumulated snow, the snowpack basal layer and a layer above are no longer exposed to a significant temperature gradient. Consequently, the rate of metamorphism becomes relatively slow, and the local impact of released latent heat can be disregarded. This is due to the presence of a highly conductive ice network that connects the ice volume enabling rapid heat conduction away from the layer. Furthermore, under a

sufficient depth of snow cover, solar radiation at the soil-snow interface becomes insignificant.

The energy balance at the soil-snow interface when the snow reaches a sufficient height, can be depicted as follows:

$$k_s \frac{T_{1S}-T_0}{h_s} = k_{sn} \frac{T_{1Sn}-T_0}{h_{sn}} \quad (2)$$

where $k_{s/sn}$ (Wm^{-1}K^{-1}) denotes the thermal conductivity of soil/snow, $h_{s/sn}$ (m) represents the thickness of the respective soil/snow layer, T_{1S} (ºC) signifies the soil sub-surface temperature at the depth of h_s, T_0(ºC) indicates the soil-snow interface temperature, and T_{1Sn} (ºC) represents the temperature of the snow layer above the interface at the height of h_{sn}. Figure 5 provides a comprehensive view of the heat transfer mechanisms within the soil/snow layer.

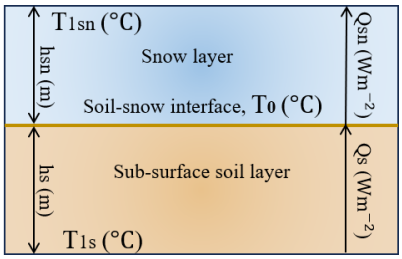

Figure 5. Heat transfer within the soil/snow layer.

3.3 Thermal conductivity of basal depth hoar layer

During the final eight days of February for the two consecutive winter seasons in ES1 and ES2, the measured temperature close to the soil-snow interface does not change very much, as shown in Figure 6(b) and (d), as well as Figure 7(b) and (d).

The heat flow from the soil to the snowpack at the interface was evaluated at both research sites by analyzing the temperature measurements and the thermal conductivity of the soil. Using Eq.(2), the thermal conductivity of the snowpack basal layer situated above the soil-snow interface was estimated, relying on the recorded temperature data. The computed thermal conductivity illustrated in Figure 6(a) and Figure 7(a) indicating that the snowpack basal layer at ES2 exhibits higher thermal conductivity.

In Section 2.1, it is evident that the soil moisture at ES2 is lower than that at ES1. This lower moisture content has led to a faster freezing of the active soil layer, resulting in a reduced temperature gradient with the atmosphere. Consequently, the rate of metamorphism in the snowpack basal layer has been affected. Figure 3(c) and Figure 4(c) illustrate this phenomenon, showing that, at the beginning of the measurement period, the temperature difference between the measured temperatures is more pronounced at ES1 than at ES2.

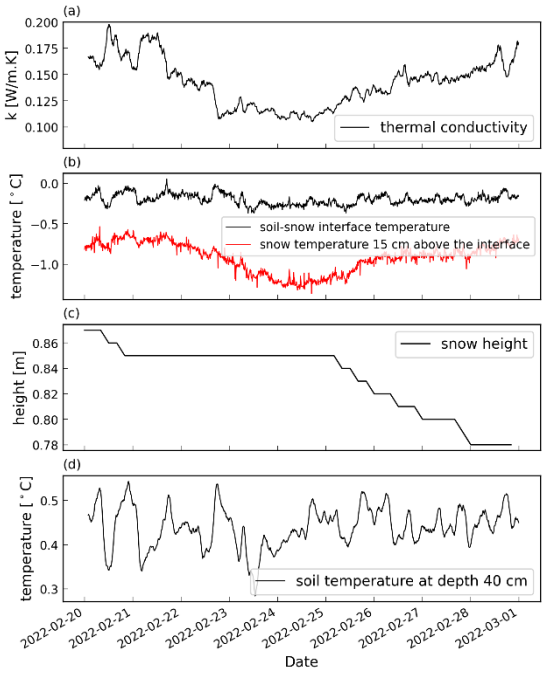

Figure 6. ES1, a) calculated thermal conductivity of snow layer above the soil-snow interface b) soil-snow interface temperature and snow temperature at 15 cm above the interface c) snow height d) soil sub-surface temperature at a depth of 40 cm.

In the ES1 area, the wind speed mostly remained below 4 (ms^{-1}), see Figure 3(a). In contrast, ES2 experiences higher wind speed up to 6 (ms^{-1}), as illustrated in Figure 4(a). The lower wind speed at ES1 compared to ES2 is expected to result in increased porosity and decreased density in the basal layer. Additionally, at ES2 the snowpack consists of a combination of naturally accumulated snow and plowed snow from the adjacent road, leading to a more compacted snowpack with reduced porosity and increased density in the basal layer.

The examination of the estimated thermal conductivity within the basal layer of the ES2 snowpack indicates that a depth hoar layer has not formed at the base of the snowpack. This is attributed to the fact that the thermal conductivity of this layer falls outside the typical range associated with depth hoar formation. This absence significantly affects the thermal regime of the ground, resulting in a diminished insulating effect, as summarized in Table 1.

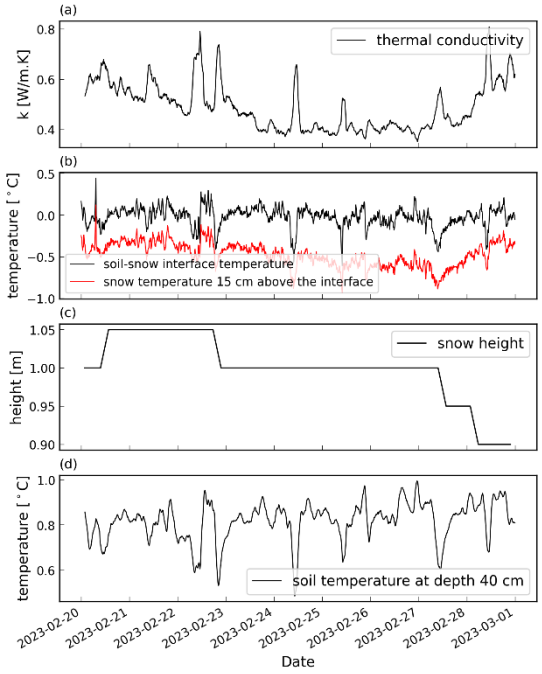

Figure 7. ES2, a) calculated thermal conductivity of snow layer above the soil-snow interface b) soil-snow interface temperature and snow temperature at 15 cm above the interface c) snow height d) soil sub-surface temperature at a depth of 40 cm.

4 CONCLUDING REMARKS

The present study underscores the vital role of snow metamorphism in shaping the structure of the layers of the snow cover. This metamorphic process, influenced by factors such as snow deposition history, meteorological conditions, and soil moisture content, results in alterations of the thermal properties of snow, particularly its thermal conductivity. Consequently, the varying thermal conductivity of different types of snow cover leads to diverse heat transfer effects on the thermal regime of the ground. However, accurately measuring snow thermal conductivity poses challenges due to the variability in snow properties across different spatial and environmental conditions. Consequently, physical models of snow struggle to adequately simulate snow properties and in particular thermal conductivity.

These findings hold implications for various maintenance sectors, for instance road maintenance, in planning both cost-effective and environmentally friendly operations. Nevertheless, it is essential to recognize that the existing body of research on the influence of different types of seasonal snow cover on seasonally frozen ground remains limited.

ABSTRACT: The growing energy needs of urban areas and the environmental context are leading to the development of new geothermal technologies. In this context, energy geostructures, such as thermo-active (or energy) piles, were developed in the early 1980s and consist of heat exchanger tubes fixed to the reinforcement cages of foundation piles to extract/inject heat from/into the ground to meet the heating and cooling needs of buildings. Their specificity lies in their dual function: structural support and energy exchanger. Therefore, two aspects can be critical and should be considered in their design. The first is the nature of the cyclic thermal load acting along the energy pile, which can affect its mechanical response. Consequently, the cyclic thermal loading can cause a variation in the shear stresses at the soil-pile interface, thereby affecting the pile's load-bearing capacity. The second aspect concerns the adaptation of the design under combined lateral and axial loading, i.e. the interaction between lateral (or axial) loading and the axial (or lateral) behaviour of the energy piles, coupled with volumetric thermal loading acting on the surrounding soil and along the pile. These configurations are the most favourable for the installation of heat exchange tubes, as they mechanically require reinforcement cages along the entire lenght of the pile. The objective of the COOP project, funded by the French National Research Agency (ANR), is to improve the knowledge of the behaviour of energy piles under these complex load configurations by proposing different research topics, from real experimental case studies to physical centrifuge modelling and numerical modelling, with the final aim of providing engineers with a relevant tool for the design of energy piles under combined loading.

RÉSUMÉ: Les besoins énergétiques croissants des zones urbaines et le contexte environnemental conduisent au développement de nouvelles technologies de géothermie. Dans ce contexte, les géostructures énergétiques, telles que les pieux thermoactifs (ou énergétiques), ont été développées au début des années 1980 et consistent en des tubes échangeurs de chaleur fixés aux cages de renforcement des pieux de fondation pour extraire/injecter de la chaleur du/dans le sol afin de répondre aux besoins de chauffage et de refroidissement des bâtiments. Leur particularité réside dans leur double fonction : rôle structural et échangeur d'énergie thermique. Par conséquent, deux aspects peuvent être critiques et doivent être pris en compte dans leur dimnesionnement. Le premier est la nature de la charge thermique cyclique, qui agit sur toute la longueur du pieu et qui peut affecter sa réponse mécanique. Par conséquent, une charge thermique cyclique peut entraîner une modification des contraintes de cisaillement à l'interface sol-pieu et donc impacter la capacité portante du pieu. Le deuxième aspect concerne l'adéquation de la méthode de calcul à une charge transversale et axiale combinée, c'est-à-dire l'interaction entre la charge transversale (ou axiale) et le comportement axial (ou latéral) des pieux énergétiques, associée à une charge thermique volumétrique agissant sur le sol environnant et le long du pieu. Ces configurations sont les plus favorables à l'installation de tubes d'échange de chaleur, car elles nécessitent mécaniquement des cages de renforcement sur toute la hauteur du pieu. L'objectif du projet COOP, financé par l'Agence Nationale de la Recherche (ANR), est d'améliorer la connaissance du comportement des pieux énergétiques sous ces configurations de charge complexes en proposant différents thèmes de recherche, allant d'études de cas expérimentaux réels à la modélisation physique en centrifugeuse et à la modélisation numérique, dans le but final de fournir aux ingénieurs un outil pertinent pour le dimnesionnement de pieux énergétiques sous chargements combinés.

Keywords: Energy piles; combined loading; in situ experiment; centrifuge modelling.

1 INTRODUCTION

The growing energy needs of urban areas and the environmental context lead to the development of new energy technologies. In particular, since the 1980s, a new geothermal method has been developed: energy geostructures, consisting in fixing heat exchanger pipes to the reinforcement cages of geotechnical structures like foundations to extract/inject the heat from/into the ground with the purpose of meeting the building heating and cooling demands. Among them, Energy Piles (EP) have been widely studied because their thermal behaviour is quite similar to the one of usual Ground Source Heat Pumps installations, with the specificity of a dual function: structural support and energy exchanger (Loveridge et al. 2020). These studies provide knowledge about mechanical behaviour upon mainly the axial direction and about the assessment of the energy performance of the system. Despite all economic and ecological advantages of this technology, EP installation in France is still held back by some uncertainties, which among them one concerns the thermo-mechanical behaviour under complex loading.

Indeed, based on the application, EP may be mechanically subjected to predominantly vertical loading due to a supported superstructure, and lateral loading if used in a bridge abutment or embankment stabilization, or combined vertical-horizontal loading (and potentially moment too) in buildings subjected to pile eccentricity (figure 1). Moreover, although wind and earthquakes induce dynamic loads, in common engineering practice their effects are considered as horizontal static loads applied to the pile head (NF EN NF P 94-262, 2017).

All these configurations, where combined vertical-horizontal loading is encountered, are the most favourable for installing heat exchanger pipes since, from a purely mechanical point of view, they require reinforcement cages all along the pile height. It is then crucial to offer to engineers a relevant knowledge to design energy piles under combined loading and this project aims at characterizing the effect of combined loading on energy piles and at the development of open-source and easy-to-use design tools for energy piles, capable of **constructing an overall failure envelope including thermal cycling loading effects**.

2 STATE OF THE ART

In the current design practice, the response of conventional pile under combined axial and horizontal loading is separately analysed and then superposed. This approach neglects the coupling effect of the combined loads while the optimum design of pile foundations requires consideration of the influence of axial loads on their horizontal response. Most previous studies have investigated the behaviour of conventional piles under pure horizontal loads and only a limited number have considered combined axial and horizontal loading (Heidari et al., 2022). Moreover, these studies gave contrasted results and the coupling effects of combined axial and lateral loads still raise complexities and uncertainties, even regarding conventional piles. This might be intensified in the case of energy piles because the thermal variations could affect the pile properties, the behaviour of the surrounding soil, lead to creep effects, or cause ratcheting phenomena in heavily-loaded piles subjected to cyclic thermal loads. Accordingly, it is necessary to identify the influence mechanism of combined axial and compression loads on the global behaviour of energy piles.

Descriptive diagram of combined loads in geothermal piles supporting a building.

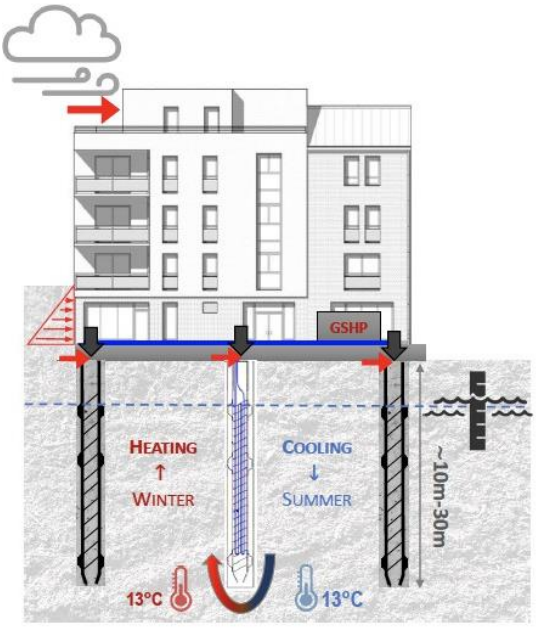

Figure 1. Combined loads acting on energy piles.

Many researchers have put a lot of effort into better understanding the thermo-mechanical behaviour of energy piles during monotonic heating or cooling and one or multiple thermal cycles. The work of Vitali et al. (2021) could be considered as the only available study using centrifuge model tests to investigate the influence of monotonic heating on the flexural behaviour of horizontally-loaded energy piles. Several studies have been performed to assess the behaviour of axially-loaded energy piles during multiple thermal cycles through field scale tests (Sutman et al. 2019), 1-g small-scale physical model tests (Nguyen et al., 2020) and centrifuge model tests (Ng et al. 2015).

A recent critical review of knowledge upon energy piles (Cunha and Bourne-Webb, 2022) draws an accurate picture of the experiments realised until now. It appears that very few experiments have been carried out on real scale energy piles considering combined mechanical loadings. This lack of experiments should be fulfilled even if centrifuge modelling offers alternative results.

The centrifuge modelling approach to characterize the transient thermo-mechanical response of energy foundations during heating-cooling cycles has been first used by Stewart and McCartney (2014). During successive cycles, slight decreases in upward thermal head displacement were observed. Later, Ng et al. (2020) have assessed rigorously scaling effects on the centrifuge modelling of floating energy piles by the so-called 'modelling of models' technique (two centrifuge models tested at two different *g* levels simulating the same prototype). Recently, Zhao et al. (2022) have presented the study on the thermally-induced ratcheting under a constant horizontal load. Yet, this first study has been performed in a dry sample without measurement of the pile strain to compare with numerical modelling.

Complementary to experimental results, numerous numerical studies have been performed to investigate the Thermo-Hydro-Mechanical THM behaviour of energy piles. The key findings are: (i) Heating/cooling of the pile induces stress changes in the pile and at the pile-soil interface; (ii) Heating/cooling cycles can degrade the side friction at the pile-soil interface; (iii) Thermal loads can induce irrecoverable displacement if the mechanical load is high; (iv) Irreversible and accumulating settlement over yearly thermal cycles, with a ratcheting phenomenon, also seems to take place in the long term during cyclic continuous loading. It should be noted that these findings were obtained exclusively from studies investigating piles subjected to axial mechanical load. The unique numerical study investigating the behaviour of energy pile subjected to sustained lateral load, from our knowledge, is Zhao et al. (2022). This study, based on finite-element simulations showed that ratcheting was evident in laterally-loaded piles in sand and its extent was more significant when the working horizontal load was higher. The ratcheting phenomenon was attributed to the accumulation of soil plastic strain due to the cyclic mechanical loading induced by pile thermal horizontal expansion and contraction, soil dilation upon soil-pile interface shearing, and creep. Beside these studies, we can't find any numerical study investigating the mechanical behaviour of energy piles, subjected to thermal cycles, under sustained combined lateral-axial loads. It should be noted that investigating the mechanical behaviour of pile subjected to combined lateral-axial loads itself already requires advanced numerical methods including 3D mesh and soil-pile interface models (Achmus & Thieken, 2010; Suryatriyastuti et al., 2013a-b, 2016; Hazzar et al., 2017).

The experimental and numerical studies mentioned above are focused on the behaviour of energy piles. To transfer this knowledge to the practice, it is crucial to develop engineering tools allowing the design of energy piles. Numerous works have been driven (Knellwolf et al., 2011; Mimouni and Laloui, 2013), but none of them have integrated the effect of lateral component of load in the axial response of pile. Mroueh and Shahrour (2009) have shown that combined load acting on pile may have great effect on its axial response and therefore on its design.

3 OVERALL METHODOLOGY

3.1 Organisation of the project

To investigate the questions raised hereby, the French National Research Agency (ANR) funded a project, called *Combined lOading Of energy Piles* (COOP), driven by Université de Lille and involving Université Gustave Eiffel, Ecole des Ponts ParisTech and the Pinto company. It aims to offer to engineers a relevant tool to design energy piles under combined loading. To achieve this objective, a specific organisation has been designed including a multiscale study of the thermo-mechanical behaviour of energy piles relying on three Work Packages (WP1, 2 and 3) and a Work Package dedicated to the transfer of knowledge to engineering practice (WP4). In addition, the WP0 is dedicated to project management.

The WP1 will allow to study the behaviour of energy piles under lateral loading through testing two experimental energy piles (0.42 m in diameter and 12.0 m in length), which have been installed in the campus of Ecole des Ponts ParisTech (Vasilescu, 2019). They are equipped with PE tubes for the circulation of the heat transfer fluid, PT 100 temperature sensors and optical fibre sensors. Temperature sensors are also installed in the soil, around the piles. The piles will be initially subjected to axial static compressive load (10, 20, or 40% of the ultimate axial load) and then in the subsequent stage, horizontal static load will be incrementally applied (30, 50, or 70% of the ultimate horizontal load), while the axial load is kept constant. The horizontal load will be applied by an actuator between two piles to ensure they are submitted to the same loading. At each level of horizontal load, to simulate the actual operating condition of energy piles, ten thermal cycles with

temperature variation of -/+ 10 °C will be repeatedly applied to one of the piles while the mechanical loads are maintained constant. The unheated pile will be used as a control experiment. The principle of this testing is represented on Figure 2.

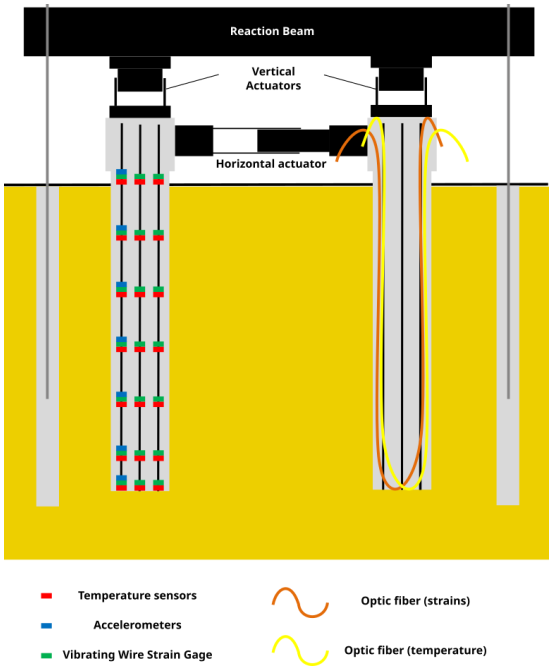

Figure 2. Principle of the real-scale testing.

In WP2, the behaviour of energy piles subjected to lateral loading will be studied through smallscale model tests performed in centrifuge. The advantage of placing these small-scale models in a macro-gravity field is to generate on this model the same stress state that is applied to the prototype in real size. In the perspective of energy piles, the second advantage of the physical modelling in centrifuge is to also reduce the time scale. Thus, the time scale (for diffusion) of a 1/N model subjected to N×g is reduced by N^2 (at 100×g), 1 hour of centrifuge test represents 14 months in the prototype scale ("real scale"). In this way, centrifuge tests can model several years of cyclic thermal loading. Moreover, in the framework of this project, the tests performed in centrifuge are particularly well suited to calibrating the numerical model developed in the WP3. Indeed, in centrifuge, the boundary conditions, the soil homogeneity and the different loadings are very well established and controlled which gives valuable data up to failure.

For this study, the centrifuge test principle consists in applying a thermal cyclic loading inside the pile while the mechanical loads (horizontal and vertical) remain constant. The accumulation of lateral displacement (the ratcheting effect) will be monitored. Several couples of thermal and mechanical loadings will be studied. A parametric study will be conducted on key aspects governing the energy pile response subjected to lateral loading will be studied: i) the pile slenderness ratio, ii) the soil saturation and iii) the soil density. Using a system adapted from (Ouzzine et al., 2023) for the thermal loading, initial tests have been carried out including only horizontal mechanical loading (Figure 3).

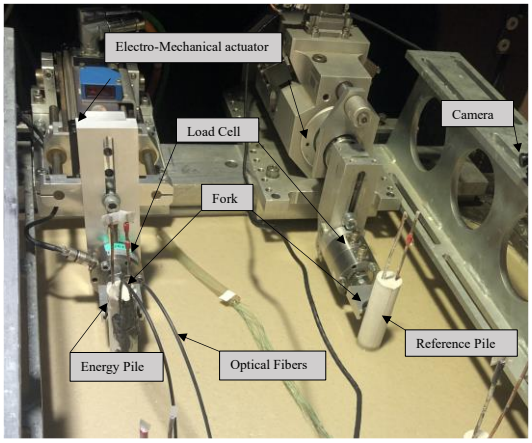

Figure 3. Initial centrifuge tests.

WP3 aims to investigate the thermo-mechanical behaviour of energy pile subjected to thermal cycles under sustained combined lateral-axial loads. This goal will be achieved by using complex 3D modelling on CESAR-LCPC software (Humbert et al, 2005). It is a Finite Element software dedicated to the modelling and analysis of civil engineering projects, particularly well-suited to geotechnical problems and continuously developed by Université Gustave Eiffel. It integrates a wide range of calculation capabilities for extending the analyses to heat transfers and THM couplings.

WP4 will focus on the development of a simplified design tool, accounting for combined loading, which is of paramount importance in the industry uptake and large-scale deployment of energy piles. Drawing from the results obtained from the real scale (WP1) and centrifuge tests (WP2) as well as the results of the parametric study performed in the WP3, an open-source simplified design tool will be developed to bridge the gap between research and engineering practice. The principal goal of this application will be to determine the stresses and displacements resulting from a set of combined thermomechanical loads and a 3D failure envelope corresponding to the energy pile combined axial and lateral response and accounting for thermal cyclic loading.

4 CONCLUSIONS

The first steps towards characterization of the effect of combined loading on energy piles have been hereby

presented as well as the organisation of the project COOP whose final goal is the development of an open-source user-friendly design tool.

The development and dissemination of such tool is essential to maximize the development and deployment of energy pile technology in the construction sector. Providing access to such tools to building contractors, design engineers, and control offices will allow to easily design and control energy pile solutions without resorting to complex 3D modelling and experimented engineers. We believe that the easy access to design tools will promote a virtuous cycle of energy geostructures' development, multiplying the examples and proving the performance and necessity of such solution.

ABSTRACT: Advanced models for soft organic layers encountered in the shallow subsoils in the Netherlands have been developed recently at TU Delft. The models are based on high-quality laboratory data on peats and soft organic clays. The constitutive effort mostly focussed on some partially unexplored features, such as the role of fibres, extension stress conditions, and the dependence of hardening on deviatoric plastic strains, besides anisotropy. Although the models have proven to be able to reproduce and predict the behaviour over a variety of triaxial probe tests, validation at the field scale is lagging behind. On the one hand, field soil response encompasses diverse stress paths and histories not replicable in the laboratory. On the other hand, the role of the advanced features introduced in the models on the engineering structure response needs to be quantified. We back-analyse a well-documented full-scale test performed in the Netherlands, the Leendert de Boerspolder stress test, where the role of different soft soil layers both on the pre-failure and failure response has been investigated. Comparison between numerical simulations and available monitoring data is used to demonstrate the contribution of advanced models to the understanding of the engineering response of soft soils.

RÉSUMÉ: Des modèles avancés pour les couches organiques molles trouvées dans les sous-sols superficiels aux Pays-Bas ont été développés récemment à TU Delft. Les modèles sont basés sur des données de laboratoire de haute qualité sur les tourbes et les argiles organiques molles. L'effort constitutif s'est principalement concentré sur certaines caractéristiques partiellement inexplorées, telles que le rôle des fibres, les conditions de contrainte d'extension et la dépendance de l'écrouissage aux déformations plastiques déviatoriques, en plus de l'anisotropie. Bien que les modèles se soient avérés capables de reproduire et de prédire le comportement lors d'une variété d'essais à la sonde triaxiale, la validation à l'échelle du terrain est à la traîne. D'une part, la réponse du sol sur le terrain englobe diverses chemins de contraintes et histoires qui ne peuvent être reproduites en laboratoire. D'autre part, le rôle des caractéristiques avancées introduites dans les modèles sur la réponse de la structure d'ingénierie doit être quantifié. Nous rétro-analysons un essai en échelle réelle bien documenté réalisé aux Pays-Bas, l'essai de contrainte de Leendert de Boerspolder, où le rôle de différentes couches de sol mou a été étudié à la fois sur la réponse avant rupture et sur la réponse à la rupture. La comparaison entre les simulations numériques et les données de surveillance disponibles est utilisée pour démontrer la contribution des modèles avancés à la compréhension de la réponse d'ingénierie des sols mous.

Keywords: Soft soils; advanced constitutive modelling; numerical simulation; case-history.

1 INTRODUCTION

The Netherlands relies on an extensive network of primary and secondary flood defence embankments. Many dykes, especially in the western part of the country, lie on thick deposits of peat and organic clay, prone to settlement and shear deformation. Assessing the serviceability and safety of these dykes is challenging due to the complex behaviour of soft soils under general stress paths.

To better understand the engineering response of these soils, advanced models for the soft organic layers encountered in the shallow subsoils in the Netherlands have been recently developed at TU Delft. These models include non-associated plastic flow rule, anisotropy described by a rotational hardening law, and a generalised hardening rule, which depends on both deviatoric and volumetric plastic strains. While the models have proven to be able to replicate the

response of the soils in a variety of triaxial stress paths, validation at the field scale is lagging behind.

In this study, we back-analyse a well-documented full-scale stress test performed in the Netherlands, the Leendert de Boerspolder stress test (De Gast, 2020; Jommi et al., 2021). Finite element simulations incorporating standard and new advanced models for soft soils are carried out, and the results of the numerical simulations are compared with in-situ monitoring data.

2 OVERVIEW OF THE FIELD TEST

The Leendert de Boerspolder dyke was a regional dyke located north of Leiden (Figure 1). Under service conditions, the water levels in the canal and polder were regulated with little variations: the canal regulating system kept the water level on the canal side at constant h = - 0.6 m NAP, in which the NAP (Normaal Amsterdams Peil) is used as the reference for the vertical coordinate. On the polder side, it was managed by pumping stations at h = - 2.3 m NAP.

Figure 1. Plane view of the test area at the Leendert de Boerspolder before the start of the failure test (https://www.stabialert.nl/nl/projecten/ldeb-polder/).

The stress test consisted of a series of excavation and dewatering stages operated at the toe of the dyke to induce the failure. The schematisation of the cross-sectional view of the dyke, along with the geometry of the excavations and the position of monitoring instrumentation, are presented in Figure 2.

In the first stage, a trench was excavated at the toe of the dyke while maintaining the water level in the trench unchanged. Subsequently, the water level was lowered by one meter in two steps. At the end of the first stage, the water was refilled back to the same water level as at the start. Similar operations were performed in the following second and third excavation stages, with a more extensive portion of soil being removed. The dyke failed during the last dewatering step between Section Centre and Section South (Figure 1).

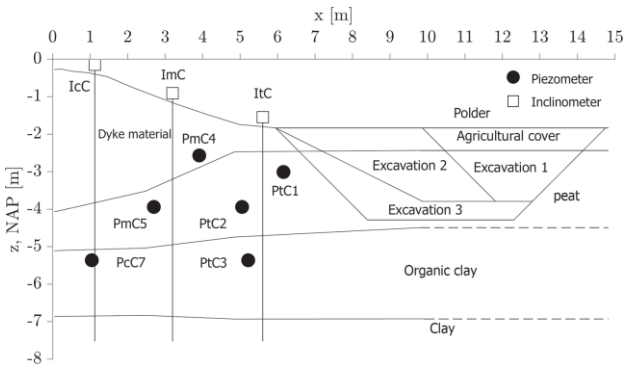

Figure 2. Schematisation of the central cross-sectional profile of the dyke and monitoring instrumentation.

2.1 Subsoil properties

To characterise the soil layers at the test site, an extensive site and laboratory investigation program was carried out including CPTu, triaxial, simple shear and oedometer tests on undisturbed soil samples (Ponzoni, 2017). The reconstructed soil profile consists of: (i) highly heterogeneous dyke material; (ii) peat layer with a varying thickness between 1.5 – 2.5 m; (iii) organic clay deposit with a thickness of about 2.0 m; (iv) deep clay layer above the Pleistocene sand. The dry density, void ratio, hydraulic conductivity, and over-consolidation ratio estimated from oedometer and triaxial tests on undisturbed samples, are summarised in Table 1. For the peat layer, the dependence of the hydraulic conductivity on the void ratio is reported by Zhao and Jommi (2023). For the in-situ void ratio, the hydraulic conductivity is in the range between 10^{-6} m/s to 10^{-7} m/s.

Table 1. Material properties for each layer.

Layer	ρ_d [kg/m^3]	e [-]	k [m/s]	OCR [-]
Dyke	1290	1.3	5×10^{-8}	1.0-1.6
Peat	150	9.0-13.0	$k\,(e)$	1.0-3.0
Organic clay	610	2.8	5×10^{-9}	1.0-3.0
Clay	900	1.0	5×10^{-9}	1.0

2.2 Monitoring instrumentation

The in-situ instrumentation was designed with the two primary purposes of providing sufficient data on the pre-failure response of the system, during excavation, dewatering, refilling, and collecting as much information as possible during the failure. It included: (i) 25 piezometers; (ii) 5 automatic two-axis inclinometers; and (iii) 9 vertical rod-type extensometers allowing to automatically record settlement and heave of the different soil layers. The sensors were installed at three cross-sections along the longitudinal direction, namely Section North, Centre, and South. Figure 2 reports the

position of the instrumentation in the Section Centre which was the most instrumented one.

3 CONSTITUTIVE MODELS

Different constitutive models are chosen for the different soil layers. In all the numerical simulations, the dyke material and the deep clay layer are modelled as linear-elastic perfect plastic material with the Mohr-Coulomb failure criterion. For the peat layer and the organic clay layer, the results of the two analyses are compared. In the first one, the Modified Cam Clay (MCC, Roscoe and Burland, 1968) was used. The second one was run adopting the advanced models developed at TU Delft.

For the peat layer, the model proposed by Muraro and Jommi (2021) is adopted. It includes a non-associated isotropic yield surface and plastic potential and a mixed volumetric and distortional hardening law derived from triaxial probe tests. For the organic clay layer, the recently proposed model by Chao (2024) is adopted. The model extends the generalised expression of yield locus proposed by McDowell and Hau (2003) to account for anisotropy. The evolution of anisotropy in the model is described by an amended version of the rotational hardening rule proposed by Dafalias and Taiebat (2013) to better capture the stress-strain response observed in the extension domain. The proposed expression for the rate of evolution of the rotation hardening variable, α, and the corresponding asymptotic values, α_b, are defined as

$$\delta\alpha = \langle L \rangle c p_{atm} \frac{p'}{p'_c} (\alpha_b - \alpha) \tag{1}$$

$$\alpha_b = \begin{cases} \frac{M_{g,c}}{z_c}\left[1 - \exp\left(-s\frac{|\eta|}{M_{g,c}}\right)\right]^y, \eta \geq 0 \\ -\frac{M_{g,e}}{z_e}\left[1 - \exp\left(-s\frac{|\eta|}{M_{g,e}}\right)\right]^y, \eta < 0 \end{cases} \tag{2}$$

with $M_{g,c}$, $M_{g,e}$ critical stress ratio in compression and extension, η stress ratio, p_{atm} atmospheric pressure, p' mean effective stress, p'_c preconsolidation stress, L plastic multiplier, and z_e, z_c, c, s, y model constants. Both constitutive models are implemented in ABAQUS in UMAT subroutines.

The model parameters adopted in the numerical simulations for each soil layer and summarised in Table 2, Table 3, and Table 4 were calibrated on triaxial stress probe tests (Ponzoni, 2017; Muraro and Jommi, 2021; Chao 2024). The compression parameters for the peat and organic clay in the new models remain as in the MCC.

For the organic clay, the constants of the rotational hardening rule (Equations (1) and (2)) are z_c = 1.6, z_e = 1.2, c = 50, s = 2.2, y = 2. The initial inclination of the yield locus and plastic potential was determined following the procedure described by Dafalias et al. (2006), assuming K_0 conditions for the stress state of the sample in the field. The calculated initial inclination is α_i = 0.50.

Table 2. Input parameters for dyke and deep clay.

Layer	E [kPa]	ν [-]	φ [°]	ψ [°]	c [kPa]
Dyke	5600	0.3	30.0	3.0	5.0
Clay	5200	0.3	31.0	6.0	5.0

Table 3. Input parameters for peat and organic clay modelled with the MCC.

Layer	κ^* [-]	ν [-]	λ^* [-]	M [-]	K [-]
Peat	0.08	0.3	0.36	1.75	0.8
Organic clay	0.009	0.2	0.09	1.42	0.8

Table 4. Input parameters for peat and organic clay modelled with the new advanced models.

Layer	$M_{g,c}$ [-]	$M_{g,e}/M_{g,c}$ [-]	$M_{f,c}$ [-]	χ_f [-]	χ_g [-]
Peat	1.75	0.80	1.5	2.0	0.98
Organic clay	1.42	0.80	1.0	1.25	2.0

4 NUMERICAL MODEL

The field stress test is modelled as a 2D plane-strain, hydro-mechanical coupled problem in the finite element software ABAQUS, and its geometry is presented in Figure 3. The model consists of 10128 type "CPE8RP" elements.

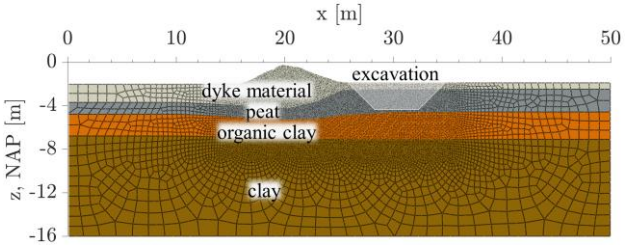

Figure 3. Geometry and mesh of the FE model.

4.1 Boundary and initial conditions

The following boundary constraints are imposed: (i) the two lateral vertical boundaries are fixed in the horizontal direction; (ii) the lower boundary is fixed in the horizontal and vertical directions; (iii) hydrostatic

pore pressure profile is applied to the lateral boundaries corresponding to the water level in the canal and the water table at the polder; (iv) drainage-only flow condition is imposed on the outer slope of the dyke.

To simulate the excavation process underwater the module "Model Change" is used which reduces gradually the forces/fluxes exerted by the region to be removed. In the dewatering step, a drainage-only flow condition is applied to the lateral boundaries of the excavation trench, which enables the reduction of pore pressure to the desired value. The boundary conditions applied during the excavation and dewatering steps are displayed in Figure 4.

To reflect the different stress history and stress levels in the foundation layers, an initial profile of OCR changing in the x-direction is assigned to the peat and the organic clay layer as shown in Figure 5. The chosen OCR profile simplifies the interpolation of oedometer data from undisturbed samples.

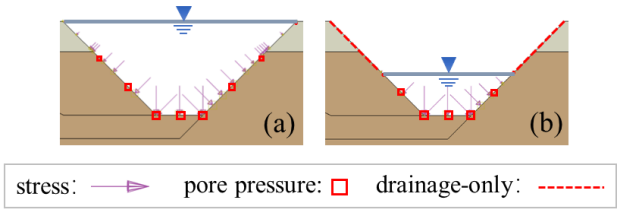

Figure 4. Schematization of the boundary conditions: (a) at the end of excavation; (b) at the end of the dewatering.

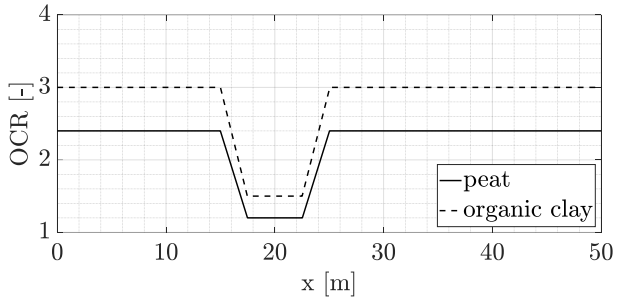

Figure 5. OCR profile in peat and organic clay layer.

4.2 Analysis phases

The analysis steps defined in the numerical simulations are presented in Table 5. The so-called "geostatic step" at the beginning of the analysis is used to establish equilibrium before the loading stage with the applied loads, boundary conditions and initial conditions. Each other step replicates one operation of the stress test. It should be noted that the third dewatering step (on 10-14, Table 5) involved three sub-steps, each pumping 0.5 meters of water with a 30-minutes consolidation period in between.

Table 5. Analysis steps in the simulations.

Operation	Label	Start (mm-dd)	Duration (h)
Initial State	-	-	-
Excavation 1	E1	09-28 09:20	6.9
Dewatering 1	D1	09-30 09:20	2.7
Filling 1	F1	10-01 12:45	1.3
Excavation 2	E2	10-05 08:00	9.5
Dewatering 2	D2	10-07 09:05	4.3
Filling 2	F2	10-08 08:00	2.1
Excavation 3	E3	10-12 07:20	9.4
Dewatering 3	D3	10-14 00:30	5.6

5 NUMERICAL RESULTS

In this section, the numerical results in terms of horizontal displacements and pore pressure response are presented and compared with in-situ measurements. The attention is given to the prediction of different constitutive models, MCC and the new advanced models for peat and organic clay layers.

5.1 Horizontal displacements

Figure 6 shows the resultant displacement predicted at the end of the final dewatering step from both the MCC and the advanced models. Both simulations predict a failure mechanism characterized by the outward bulging of the peat layer at the toe. This pattern, typical for peat (Landva and La Rochelle, 1983) is consistent with the field monitoring data.

Figure 7 presents the numerical predictions and the inclinometer measurements installed at the crest (IcC), mid-slope (ImC) and toe (ItC). The layering is indicated with the letters D, P, and OC which stand for dyke material, peat and organic clay. The data for the first, second, and third dewatering steps are plotted in black, red, and blue, respectively. The comparison in Figure 7 shows better qualitative and quantitative prediction of the horizontal displacement profile by the new advanced models compared to the MCC. Very good agreement is observed for the organic clay layer at the toe and mid-slope of the dyke where the MCC underestimates the magnitude of the displacement. Reconstruction of the failure mechanics from in-situ measurements revealed that the failure originated initially in the organic clay layer at the toe (Jommi et al., 2021). It is worth remarking that the inclinometer ImC was working down to – 5.5 m (NAP) only.

The benefit of the new models is also evident for the peat layer with a bulging profile predicted at the toe very close to the observed one. The simulation with the advanced models yields a maximum displacement of 0.086 m, compared to 0.065 m predicted by the

MCC, thus very close to the observed one, 0.1 m. The difference in predicted and observed displacements increases towards the upper peat layer, likely due to different mechanical properties of the surficial and deep peat layer as indicated by laboratory tests. Good agreement is also observed in the peat layer at the mid-slope of the dyke (ImC). For the inclinometer IcC, the final horizontal displacement is slightly overestimated. Laboratory tests indicated slightly stiffer peat and organic clay samples below the crest of the dyke compared to the polder side.

It is worth noticing that the difference between the MCC and the new models predictions is not evident in the first two dewatering stages but becomes clear in the last dewatering stage (blue lines in Figure 7). In the early dewatering stage, the soil stress state remains mostly inside the elastic domain, given the initial OCR profile. The difference becomes dominant as the stress state enters the plastic domain. The initial yield locus rotation and progressive reorientation during the last stages of dewatering improved the predictions for the organic clay layer, particularly at the toe of the dyke. Additionally, adopting a non-associated flow rule calibrated on experimental data helped to better replicate the plastic deformation mode in the peat layer.

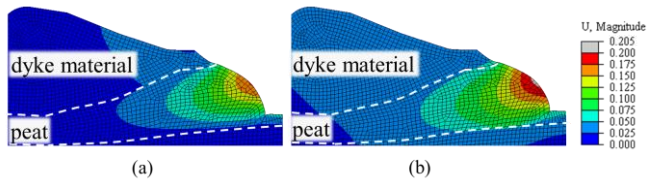

Figure 6. Displacement contour at the end of the third dewatering step: (a) MCC; (b) new models (units in m).

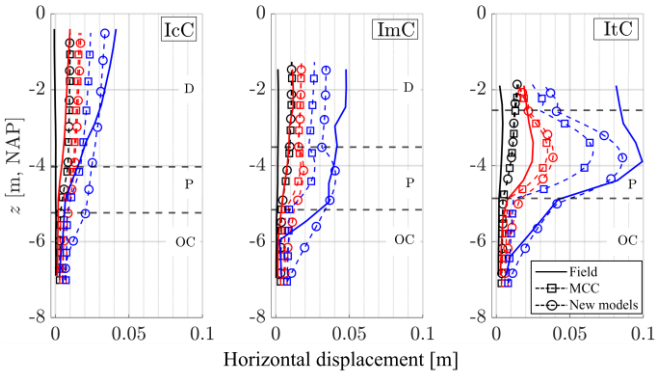

Figure 7. Measured and simulated horizontal displacement along inclinometer IcC, ImC, and ItC at the end of three dewatering stages.

5.2 Hydraulic response

The hydraulic response predicted by the numerical simulations and the comparison with field measurements is presented in Figure 8 in terms of variation of the excess pore pressure at piezometers PtC1, PtC2, PtC3, and PmC4 located at the toe of the dyke and in the dyke material (Figure 1) throughout the different steps. The timing of each operation is indicated by the labels E, D, and F as indicated in Table 5. The excess pore pressure is calculated based on the pore pressure before the first excavation stage.

The changes in pore water pressure during the initial excavation and dewatering step (E1, D1) are minimal due to the limited extent of excavation and the relatively small drawdown during the first operation stage. Small differences are observed in the numerical prediction for PmC4 during refilling after the first excavation and dewatering, with the new models better replicating the measurements.

The reduction in pore water pressure observed during the second and third excavation and dewatering phases (E2, D2, E3, and D3) is well captured.

Despite the difference in the displacement profile previously outlined, the variation of pore water pressure between the simulations, using the MCC and advanced models, is nearly identical. This suggests that the compressibility coefficient dominates the pore pressure response. In addition, it is relevant to mention that the dyke failure took place between Section Centre, here considered as representative cross-section, and Section South. Additional examination of the piezometer measurements at both Section South and Section North will be necessary to fully assess the model predictions in terms of hydraulic response.

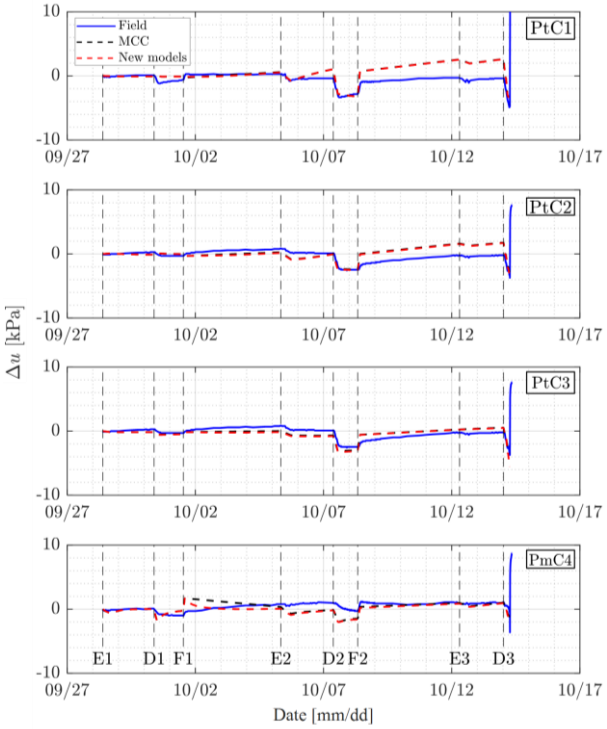

Figure 8. Measured and simulated time history of excess pore pressure at piezometer PtC1, PtC2, PtC3, and PmC4.

6 DISCUSSION AND CONCLUSIONS

This study presents a comparison between finite element simulations and in-situ measurements of a well-documented case study of a full-scale dyke stress test conducted on a regional dyke in the Netherlands. Particular attention is given to analysing the behaviour of the foundation layers consisting of peat and organic clays. Hydro-mechanical coupled finite element simulations are conducted with both traditional and new advanced constitutive models developed at TU Delft to better capture the complex behaviour of organic soft soils.

The numerical simulations show the benefits of the advanced models in better replicating both qualitatively and quantitatively the observed displacement field. In particular, the new models show a more diffusive displacement profile in the organic clay layer, where failure originated and a more pronounced lateral bulging profile very characteristic of peat.

The evolution of pore water pressure at different positions is well captured, with variations nearly identical in simulations using both MCC and advanced models possibly due to the dominant role of the compressibility coefficient in the overall volumetric response.

The comparison between the predicted displacement field along the entire cross-section profile with the in-situ data and laboratory data suggests possible variations of the compression coefficients within the foundation layers along the horizontal direction which should be accounted for a further refinement of the geotechnical model used in the numerical simulations. In addition, given the very small effective stress level which characterises regional dykes on soft soils, a proper initialisation of the in-situ stress state and OCR profile is of paramount importance to assess the engineering response of geo-infrastructure on soft soils.

ACKNOWLEDGEMENTS

The financial support of STOWA and the Dutch organisation for scientific research NWO, under the project “Reliable Dykes 13864“ is acknowledged. Thanks are due to Tom de Gast, who managed the design of the stress test in the field as part of his PhD research.

Type-curves to assess seepage under sheet-piles for dewatering geotechnical works in limited 2D geometries

Courbes types pour évaluer l'infiltration sous palplanche pour les travaux géotechniques de drainage dans des géométries 2D limitées

S. Navarro Carrasco, J.A. Jiménez-Valera*, I. Alhama Manteca
Mining and Civil Engineering Department, Technical University of Cartagena, Spain
jose.jvalera@upct.es

ABSTRACT: Graphical methods based on flownets or numerical modelling are two procedures traditionally used to estimate groundwater flow under different geotechnical structures (dams, sheet-piles, diaphragm walls, among others). In this work, both methods are combined with dimensionless analysis to set out and verify the dimensionless groups that govern the groundwater discharge. The results are a set of type-curves charts easy-to-use to assess seepage per metre transversal length of sheet-pile. The chart is applied to flow under sheet-piles for maritime or fluvial shored scenarios, where permanent dewatering is required in the enclosure. Geometrical parameters like sheet-pile height, depth of sheet-pile embedment, impervious bedrock depth, excavation width, horizontal stretch in the back face and water levels and physical parameters as hydraulic conductivity are input data in the chart, all of them included in the monomials. The physical scenario assumes isotropic medium and cross-section symmetry.

RÉSUMÉ: Les méthodes graphiques basées sur les flownets ou la modélisation numérique sont deux procédures traditionnellement utilisées pour estimer le mouvement des eaux souterraines sous différentes structures géotechniques (barrages, palplanche, paroi moulée, entre autres). Dans ce travail, les deux méthodes sont combinées avec une analyse adimensionnelle pour définir et vérifier les groupes adimensionnels qui régissent le mouvement des eaux souterraines. Les résultats sont un ensemble de courbes types faciles à utiliser pour évaluer l'infiltration par mètre de longueur transversale de palplanche. Les courbes est appliqué au mouvement sous les palplanches pour des scénarios de berges maritimes ou fluviales, où un assèchement permanent est nécessaire dans la tranchée. Les paramètres géométriques tels que la hauteur des palplanches, la profondeur d'encastrement des palplanches, la profondeur du substratum rocheux imperméable, la largeur de l'excavation, l'étirement horizontal et les niveaux d'eau, ainsi que les paramètres physiques tels que la conductivité hydraulique, sont des données d'entrée dans le diagramme, toutes incluses dans les monômes. Le scénario physique suppose un milieu isotrope et une symétrie de la section transversale.

Keywords: Numerical modelling; dimensionless monomial; seepage; dewatering.

1 INTRODUCTION

Most civil engineering construction sites requires working under the ground surface. The stability of the excavation is, in many cases, supported by geotechnical structures like sheet pile walls, steel sheeting, diaphragm walls, cut-off walls, or cofferdams. The design of them relies on soil mechanics properties and on the presence of groundwater. The groundwater flowing under the retaining structure and into the excavation (seepage) is conditioned by the geometry, the specific boundary conditions and the hydraulic conductivity.

In this work, we focus on the calculus of seepage in a 2D isotropic scenario outlined in Figure 1. The 2D geometry of the aquifer is constrained by "*H*" and "*L*", both having finite values. The solution is given as a set of abacuses and the type curves depicted in them relates dimensionless monomials (groups of parameters involved in the solution).

Similar solutions are found in technical or scientific literature. For example, in Puertos del estado and Ministerio de Fomento (2005) and Graham (2006), the solution was given for a non-horizontal limited scenario (length "*L*" was not included). In Preene et al. (2014), the horizontal and vertical extend "*L*" and "*H*", respectively, were not defined. This last case was also studied in Navarro Carrasco et al. (2023), but considering anisotropic media. A problem we found in some of these works is the lack of explanation about the meaning of some parameters required to use the abacuses. Most of them are not even defined in the documents, what make them difficult to understand.

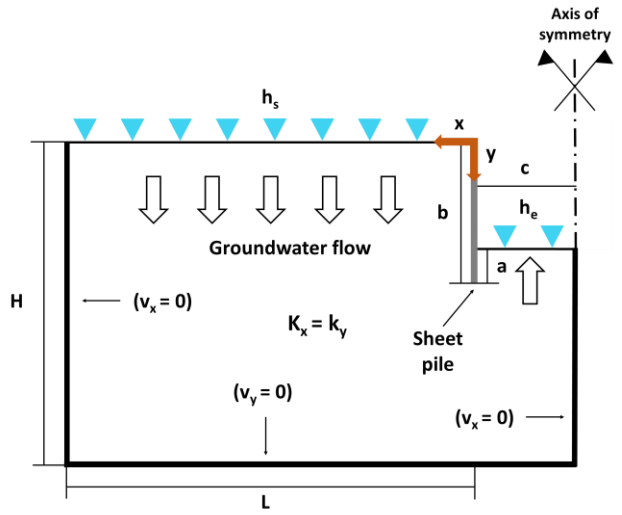

Figure 1. 2D schema of the problem with geometric data and boundary conditions.

This work is a first step before further studies with anisotropic media or heterogeneous layered substratum. A theoretical example of application is given at the end of section 3, to illustrate the use of the abacuses.

2 PHYSICAL MODEL AND GOVERNING GROUPS

The list of parameters that define the problem are shown in Figure 1: piezometric heads at the back of the wall (h_s) and inside (h_e) the excavation, the horizontal (L) and vertical (H) extend, the depth of the retaining structure in contact with groundwater b, the embedment a, half of the horizontal extend of the excavation c, and the isotropic hydraulic conductivity K. The transversal extend of the excavation is large enough to neglect effects at the edge and axis-symmetry is assumed. To ensure that the horizontal and vertical extension are short enough to influence on the solution, the concept of characteristic lenghts previously studied in Navarro Carrasco et al. (2023) and Martínez-Moreno (2022), is applied. This concept relates to specific vertical (T^*) and horizontal (L^*) lengths: if $H > T^*$ and $L > L^*$ the solution is similar to an infinite scenario (not the case here we are dealing with), and if $H < T^*$ and $L < L^*$ the solution is that of a finite scenario. In section 3 it will be clarified with and example.

As shown in Figure 1, water is flowing from the surface to the bottom of the excavation and under the geotechnical structure. The boundary conditions are Dirichlet condition (constant head) at the ground surface and bottom of the excavation and Neumann condition (impervious limits) at the geotechnical structure, vertical limits ($v_x = 0$) and at the bottom ($v_y = 0$). As it can be apreciated, the ground located over the prehatic level is not conditioning the seepage.

Each monomial (group of parameters involved in the solution) is obtained from classical dimensional analysis techniques (Palacios, 1964). The values of the 4 monomials obtained govern the solution. It means that, as long as the values of the monomial remain constant, the solution is the same irrespective of the values of the parameters included in the groups. The monomials are:

$$\pi_1 = a/b \quad (1)$$

$$\pi_2 = b/c \quad (2)$$

$$\pi_3 = b/H \quad (3)$$

$$\pi_4 = c/L \quad (4)$$

$$\pi_Q = \frac{Q}{(h_s - h_e)\cdot k} \quad (5)$$

According to Pi Theorem (Buckingham, 1914), the group π_Q with the unknown Q is a function of the rest of groups (1-4) and its value was previously set by Martinez-Moreno (2021). A total number of 72 simulations with MODFLOW (Harbaugh et al., 2000), each of them taking an average of less than 15 second to compute, were carried out to depict the abacuses and type curves, so the function π_Q was defined. The procedure required keeping three monomials constant and while changing the values of the fourth, so the variation π_Q can be drawn as a function of the fourth. The process is repeated by taking turns with all the monomials.

3 RESULTS: TYPE CURVES

4 abacuses containing 3 type curves each one, are shown in Figure 2.

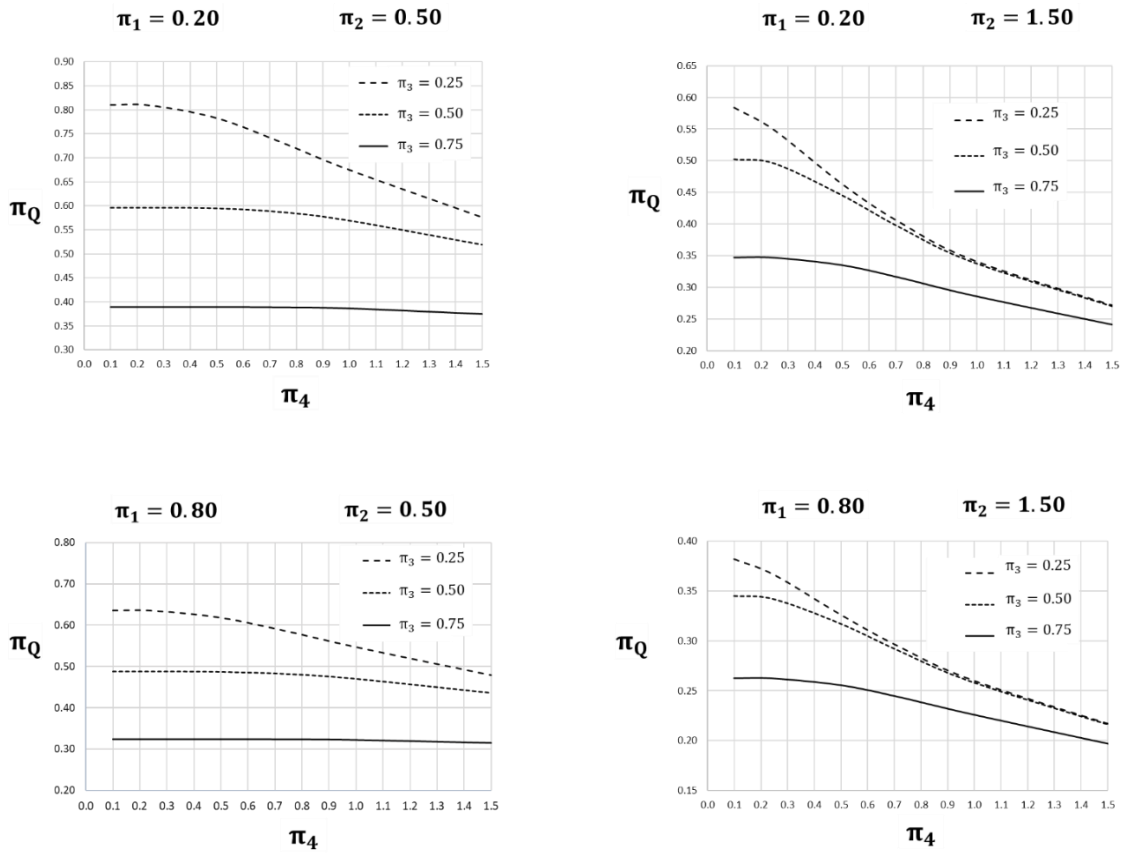

Figure 2. Type curves to calculate seepage under a retaining structure and into the excavation.

The curve parameter is π_3 and the values considered are 0.25, 0.50 and 0.75. The abacus parameters are π_1(0.2-0.8) and π_2 (0.5-1.5). On each graph, π_4 ranges from 0.1 to 1.5. These values were chosen to consider aspect related to stability or heave.

To illustrate the use of the abacuses, a theoretical application based on example 3.3 of Berry and Reid (1993) is solved. The parameter values and the monomials are shown in Table 1.

Table 1. values of the variables in the theoretical example.

Parameter/monomial	Value	Units
a	4.0	m
b	5.0	m
c	3.0	m
L	12.0	m
H	9.0	m
$\boldsymbol{h_s - h_e}$	4.0	m
k	$7 \cdot 10^{-5}$	m/s
$\boldsymbol{\pi_1 = a/b}$	0.80	dimensionless
$\boldsymbol{\pi_2 = b/c}$	1.67	dimensionless
$\boldsymbol{\pi_3 = b/H}$	0.56	dimensionless
$\boldsymbol{\pi_4 = c/L}$	0.25	dimensionless

The steps that must be followed are:

Step 1: Check if the values of L and H are lower than those of the characteristic legths L^* and T^*, so that the type-curves of Figure 3 can be used. Figures 3 and 4 are used in this step.

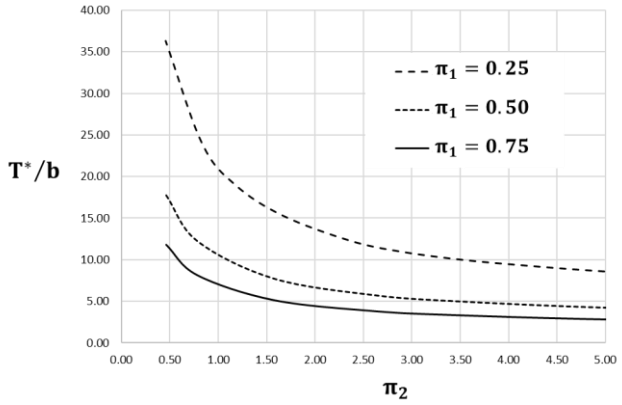

Figure 3. Type curves to calculate the vertical characteristic length T^*. Modified from Navarro Carrasco et al. (2023).

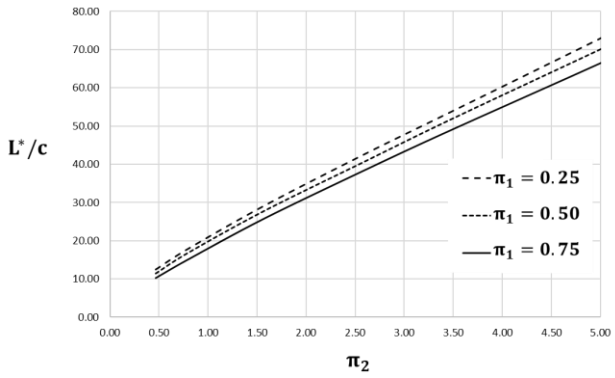

Figure 4. Type curves to calculate the horizontal characteristic length L^*. Modified from Navarro Carrasco et al. (2023).

According to values in Table 1, L^* = 84 m and T^* = 25 m, both greater than L = 12 m and H = 9 m, so the abacuses in Figure 3 can be used.

Step 2. We select the abacus according to the values of the monomials, in this case, the one with π_2 = 1.5 (the closest) and π_1 = 0.8. With the value of π_4 = 0.25 and π_3 = 0.56, the function containing the unknown is π_Q = 0.33.

Step 3. With the values of π_Q = 0.33, we obtain Q from equation 5: $Q = 9.24 \cdot 10^{-5}$ m^3/s/m.

In Berry and Reid (1993), the result for $L = \infty$ (in our variant we have considered L = 12 m) is $Q = 8.96 \cdot 10^{-5}$ m^3/s/m. Simulating the example of Berry and Reid with L = 12 m in MODFLOW, $Q = 9.14 \cdot 10^{-5}$ m^3/s/m.

4 CONCLUSIONS

In this work, we provide 12 type-curves distributed in 4 abacuses to calculate seepage under embedded retaining structures from geometrical and physical data. Each graph depicts the monomial containing the unknown π_Q, as a function of the 4 dimensionless groups. The conditions are isotropic hydraulic conductivity and limited horizontal and vertical extension of the scenario, so that the geometry is conditioning groundwater flow.

To illustrate the use of the type-curves, a modified example has been carried out. The first verification compares by using two charts, the vertical (H) and horizontal (L) length of the scenario with the characteristic lengths T^* and L^*, respectively. It allows to differentiate between limited and infinite scenarios, those where the geometry is not conditioning the seepage.

Producing pore pressure due to heat for bentonite-sand mixture with difference dry densities

Production d'une pression interstitielle due à la chaleur pour un mélange bentonite-sable avec des densités sèches différentes

T. Nishimura*
Ashikaga University, Tochigi, Japan
**nishimura.tomoyoshi@g.ashikaga.ac.jp*

ABSTRACT: Radioactive waste has to be isolated from the human habitat for absolutely so long time period until its radioactivity has decayed to an innocuous situation. Many researchers have reported and demonstrated the interpretation of thermal hydration mechanical chemical couple phenomena (i.e. THMC phenomena) for unsaturated-saturated bentonite. There is lack to measure the pore pressure, and discuss the fluid pressure phenomena. This study represents pore pressure associated to heat, and have used in developed steel mold accomplished crucial pressure sensor within the high resistance to temperature. The materials used in this test program are bentonite and sand, and the bentonite is sodium type and sand are classified into silica. The bentonite sand mixture remains a ratio of 70% and 30% in dry weight. The specimen variety from 0.80 Mg/m^3 to 1.80 Mg/m^3 in dry density. The specimen closed in the steel mold have received heat performance, and the temperature achieve to 80 degrees Celsius. The pore pressures result that all of specimens with the difference dry densities describe more than 10 kPa in the pressure, and the dense specimens verify the high pore pressures.

RÉSUMÉ: Les déchets radioactifs doivent être isolés de l'habitat humain pendant une période de temps absolument longue jusqu'à ce que leur radioactivité soit devenue inoffensive. De nombreux chercheurs ont rapporté et démontré l'interprétation des phénomènes de couple mécanique-chimique d'hydratation thermique (c'est-à-dire les phénomènes THMC) pour la bentonite insaturée-saturée. Il manque de mesurer la pression interstitielle et de discuter des phénomènes de pression des fluides. Cette étude représente la pression interstitielle associée à la température de la chaleur et a utilisé dans le moule en acier développé un capteur de pression crucial dans la haute résistance à la température. Les matériaux utilisés dans ce programme de test sont la bentonite et le sable, et la bentonite est de type sodium et le sable est classé en silice. Le mélange de sable bentonite reste dans une proportion de 70% et 30% en poids sec. La variété spécimen de 0,80 Mg/m3 à 1,80 Mg/m3, en densité sèche. Les échantillons fermés dans le moule en acier ont reçu des performances thermiques et la température atteint 80 degrés Celsius. Les pressions interstitielles font que tous les échantillons avec des densités sèches différentes décrivent une pression supérieure à 10 kPa, et les échantillons denses vérifient les pressions interstitielles élevées.

Keywords: Pore pressure; bentonite-sand mixture; unsaturated soil; shear strength; heating.

1 INTRODUCTION

Many researchers have reported and demonstrated the interpretation of thermal hydration mechanical chemical couple phenomena (i.e. THMC phenomena (Huertas and Santiago, 1997) for unsaturated-saturated bentonite, and the variety in the mechanical of bentonite sand mixture caused by THMC phenomena. Lloret et al., (2004) reported the results of the thermo-hydro-mechanical (THM) in the laboratory test and established the calibration of the models. It is verified the influence of the microstructure changes in bentonite. Sellin et al., (2020) explained the key objective of Beacon, and verified the tools for the assessment of the mechanical evolution of installed bentonite components and the eventual performance of the barrier. There is lack to measure the pore pressure, and discuss the fluid pressure phenomena. It is often understood as gas migration and gas generation in the arterial barrier system.

2 PURPOSE OF THIS STUDY

This study represents pore pressure associated to heat temperature, and have used in developed steel mold accomplished crucial pressure sensor within the high resistance to temperature. The materials used in this test program are bentonite and sand, and the bentonite is sodium type and sand are classified as silica. The bentonite sand mixture remains a ratio of 70% and 30% in dry weight. The specimen variety from 0.80 Mg/m^3 to 1.80 Mg/m^3, in dry density. The specimen closed in the steel mold have received heat

performance, and the temperature achieve to 80 degrees Celsius. The pore pressures result that all of specimens with the difference dry densities describe more than 10 kPa in the pressure, and the dense specimens verify the high pore pressures.

3 TEST PRODUCER

3.1 Soil material

This testing program have the purpose such as deformation, strength and pore fluid pressure under heat produce. Considering, Kunigel V1, a sodium bentonite, is used in a series of three testing programs to confirm the Thermal-Hydro-Mechanical properties in experimental laboratory studies. Majority of chemical components are as following; SiO_2 is 70.2%, Al_2O_3 is 14.2%, Fe_2O_3 is 2.5% and CaO is 2.0%.

3.2 Specimens

The bentonite sand mixture is put into the stiffness steel mold with an inner diameter of 38.0 mm, a thickness of 18.0 mm and a height of 76.0 mm. In term of friction stress at inner surface and soil material, it is assumed to be neglection, because of density distribution is equal in previous experimental works. Then, the pre-consolidation pressure is measured at processing the compaction, as result, approximately 10 MPa is estimated through consolidation test.

3.3 Apparatus

This testing programs consist of five testing programs. These test programs are divided categories into thermal-hydration and thermal-mechanics. The developed steel mold and thermal heating triaxial compression apparatus are used to appear the key futures for unsaturated bentonite-sand mixture specimen.

3.4 Testing program

This testing programs consist of five testing programs. These test programs are divided categories into thermal-hydration and thermal-mechanics.

3.4.1 Measurement of relative humidity

Testing program (A) measure the relative humidity in steel mold under heating that use miniature relative humidity and temperature sensor. Some salt solutions are put into the steel mold, subsequently, the steel mold is completely closed that is undrained conditions. The controlling relative humidity is following the vapor pressure technique that is common in suction measurement method.

Figure 1. Developed steel mold wit sensor.

3.4.2 Heating under free deformation

Testing program (B) conducted out heating for unsaturated specimens in the steel mold. All of specimens produce the deformations (i.e., axial direction and horizontal directions). After heating, all of specimens are measured compressive strength.

3.4.3 Heating under confirmation of lateral deformation

Testing program (C) attempted the heating application and measure unconfining compressive strength. All of specimens in the steel mold prevent the expansion deformations in the horizontal way. Other hand, free deformations allowed in axial way.

3.4.4 Triaxial compression tests with heating for saturated specimen

Testing program (D) produce the triaxial compression test used for saturated specimens., which are prepared due to apply the vacuum in the water bath. Either distilled water or salinity water is supplied in the bath and the concentration is 3.5% for salinity water. Applied temperature is 80 degrees Celsius.

3.4.5 Measurement of pore pressure due to heating

Considering of pore pressure increment is employed in Testing program (E). The steel mold is used as shown in Fig 1, which installed two pressure sensors (PHF-S-3MPS3B manufactured by KYOWA) with high temperature resistance. Calibrations are often investigated through this testing programs. Some specimens with variation dry densities are prepared for measurement of pore pressures under heating.

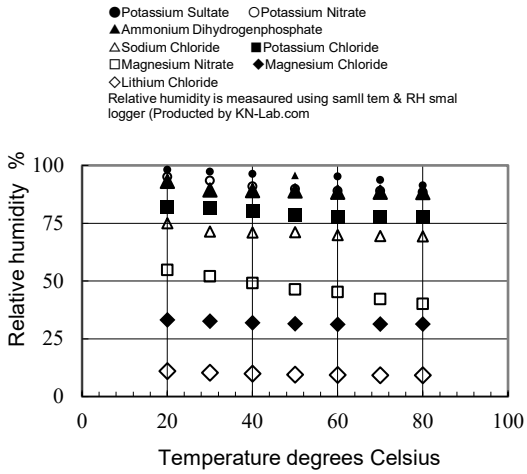

Figure 2. Change of relative humidity.

4 TEST RESULTS

4.1 Changing of relative humidity

The steel mold is prepared that some salt solutions are installed in order to investigate relative humidity changing in Testing program (A). Whole the mold was placed in thermostat oven, in which controlled a range from 20 degrees Celsius to 80 degrees Celsius. Variations of salt solutions are used to create relative humidity ranges, and the results is described as shown in Figure 2. Determined relative humidity has a range from 95% to 9.0%. All of chemical substances have common tendency which is reduction with increment of temperature regardless of relative humidity at 20 degrees Celsius. Much reductions of relative humidity are indicated in such tendency when Magnesium Nitrate is place in the mold, that it is from 54.7% to 40.2% in relative humidity.

4.2 Unconfined compressive strength subjected to deformations

All specimens, are equivalent to given temperature s and relative humidity as above mentioned in Section 4.1 that used for determination of unconfined compressive strength according to unconfined compression test (Figure 3). While compression process in the triaxial compression cell, reproduce the temperature at 20, 40, 60 and 80 degrees Celsius remaining. As mechanical component, removing of unconfined compressive strength for unsaturated bentonite subjected to heating and developed relative humidity is significant factor. The specimens except of 20 and 40 degrees Celsius have some cracks. All specimens derive that the unconfined compressive strength decrease according to heat, are smooth tendency in plotted strength with temperatures. Particularly, the specimens with equivalent to relative humidity of 75% that describe the further reduction by heat, and the different in strength is over 500 kPa between 20 degrees Celsius and 80 degrees Celsius.

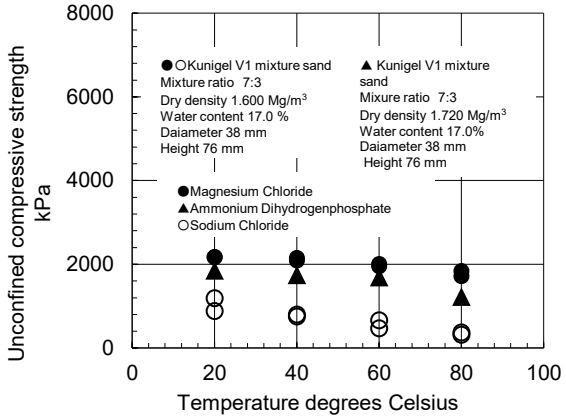

Figure 3. Reduction of shear strength (Test (B)).

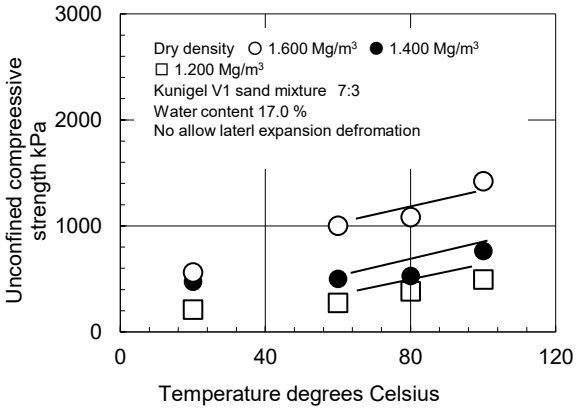

Figure 4. Increment of shear strength (Test (C)).

4.3 Unconfined compressive strength considering axial strains

Three different dry densities are selected that are 1.200 Mg/m^3, 1.400 Mg/m^3 and 600 Mg/m^3, and all of these specimens are common the water content of 17.0% and bentonite-sand ratio is 7:3. All specimens present the shrinkage phenomena at beginning of test air surrounding of 20 degrees Celsius. Contrast, exchange axial strain with increment temperature that are coincident regardless of different of dry density, axial strain stays in remaining expansion deformation.

The relationship between temperature and unconfined compressive strength is produced as shown in Figure 4. Investigation of the unconfined compressive strength used the thermal triaxial compression apparatus. It obviously confirms that measured unconfined compressive strength increase with the dry density regardless of the temperature. Even if increment of temperature is applied to the

specimens, the influence of dry density on strength is remained and the increasing of temperatures. The difference in strength varied from 563 kPa to 1421 kPa through changing of temperature for dry density of 1.600 Mg/m^3, and describe further increment beyond 60 degree Celsius. For both two dry densities (i.e. 1.200 Mg/m^3 and 1.400 Mg/m^3) the strength increases smoothly with heat, and verified the lines are seem to be straight with some slopes. These slopes are closely at range from 60 degrees Celsius and 100 degrees Celsius. Case of dry density of 1.600 Mg/m^3 compare, the large slope is provided that are 10.5 kPa per degree Celsius. Other two lines have a slope of 6.5 and 5.5 kPa per degree Celsius. Figures. 3 and 4 show the contradictory results that the cause is suggested deformation characteristic properties. The results shown in Figure 3 related to all direction deformation and the results for Figure 4 is allowable deformations in limitations.

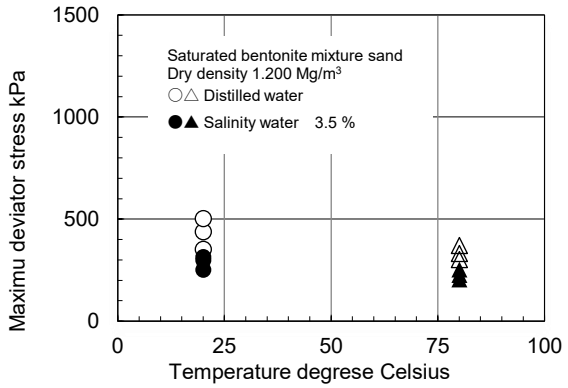

Figure 5. Change of maximum deviator stress.

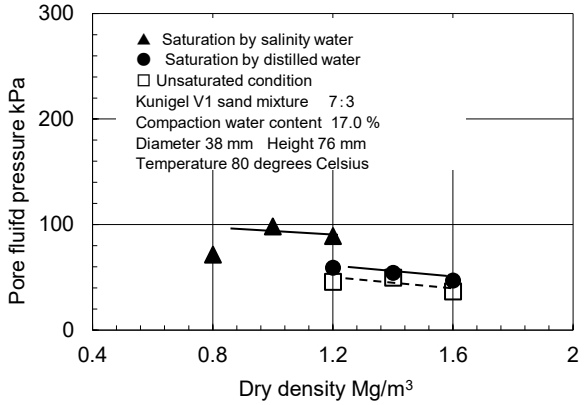

Figure 6. Produced pore pressures.

4.4 Shear strength for saturated specimen under heating

This study appear the shear strength obtained from thermal triaxial compression test that all of specimens are saturated condition, and the applied lateral confining pressures are 100 kPa, 300 kPa and 600 kPa. Also, soaking waters are distilled water and salinity water, the salinity water has the concentration is 3.5%. The saturated shear strength has the influence of temperatures as shown Figure 5 that the increment of temperature causes the reduction shear strength.

4.5 Producing of pore pressure by heating

Above mentioned, it is obviously that the heating actions is significant factors such as THMC phenomena. This study measures the produced pore pressures due to heating that the relationship between temperature and pore pressures is shown in Figure 6. The investigation is conducted out under 80 degrees Celsius s for unsaturated specimen and saturated specimens. According to be increase the dry density, the pore pressure decreases regardless of dry density.

5 CONCLUSIONS

This study represents pore pressure associated to heat temperature, and unconfined compressive strength in other subjection.

1. The relative humidity decreases with associated to be heating. The unconfined compressive strength changes due to application of heating that is close related to deformation characteristic properties due to heat.
2. The pore pressures are induced by increment of temperatures, and the measured pore pressures decrease with dry density.

Database of measured shear wave velocity profiles for Icelandic soil sites

Base de données des profils de vitesse des ondes de cisaillement mesurés pour les sites de sols islandais

E.A. Olafsdottir*, S. Erlingsson, B. Bessason
Faculty of Civil and Environmental Engineering, University of Iceland, Reykjavik, Iceland
**elinasta@hi.is*

ABSTRACT: MASW (Multichannel Analysis of Surface Waves) is an active-source surface wave method that provides information on shear wave velocity (V_S) distribution down to 10–30 m depth. The technique has been found well-suited for profiling of Icelandic soil sites, including gravelly sites and sites with partly cemented materials or mixed soils containing cobbles or boulders. This paper introduces a database where results of MASW measurements conducted in Iceland can be accessed. The database is available in open-access online and provides the user with an interface which allows results from different sites to be viewed simultaneously and compared in terms of dispersion curves, V_S profiles and time-averaged V_S.

RÉSUMÉ: MASW est une méthode d'onde de surface à source active qui fournit des informations sur la distribution de la vitesse des ondes de cisaillement (V_S) jusqu'à 10 à 30 m de profondeur. La technique s'est avérée bien adaptée au profilage des sites de sols islandais, y compris les sites graveleux et les sites avec des matériaux partiellement cimentés ou des sols mixtes contenant des galets ou des rochers. Cet article présente une base de données où les résultats des mesures MASW effectuées en Islande peuvent être consultés. La base de données est disponible en libre accès en ligne et offre à l'utilisateur une interface permettant de visualiser simultanément les résultats de différents sites et de les comparer en termes de courbes de dispersion, de profils V_S et de V_S moyenné dans le temps.

Keywords: Iceland; shear wave velocity; surface wave analysis; MASW; database.

1 INTRODUCTION

Seismic site characterization is a fundamental aspect of engineering design of structures in seismically active areas. The seismic hazard in Iceland is considered moderate to high, with the largest earthquakes occurring within two complex fracture zones: the South Iceland Seismic Zone (SISZ) in the south and the Tjörnes Fracture Zone (TFZ) in the north (Einarsson, 2008). The soil site conditions in Iceland are shaped by a combination of volcanic activity, glacial drift, and sea level variations through the ages. The soil deposits largely consist of coarse-grained granular materials of basaltic origin (i.e., coarse silt, sand, gravel, and coarser grains), although thick peat deposits exist in some locations. Clayey materials are uncommon in Iceland (Erlingsson, 2019).

Surface wave methods have been found well-suited for profiling of Icelandic soil sites, including gravelly sites and sites characterized by conglomerated materials or mixed soils containing cobbles or boulders. From 2013 to 2021, MASW (Multichannel Analysis of Surface Waves) measurements were conducted in 19 areas in Iceland. Together, the tested sites represent the three most commonly encountered types of natural soil deposits in Iceland, in addition to engineered fills. This paper describes the first efforts made to create a database where the measurement results, along with supporting data, can be accessed. The database is accessible in open access at https://serice.hi.is. The user interface allows results from different sites to be viewed simultaneously and compared in terms of dispersion curves and measured shear wave velocity (V_S) profiles. The V_S profiles are further presented as time-averaged shear wave velocity ($V_{S,z}$) in line with the site categorization in the current Eurocode 8 [EC8] (CEN, 2004).

2 ANALYSIS PROCEDURE

The term MASW describes a linear data acquisition layout where a vertical impact source is applied in-line with an array of equally spaced receivers that are placed on the surface. The interval V_S profile of the underlying soil stratum is then obtained by inverting the dispersion characteristics of the recorded Rayleigh waves.

The same data acquisition and analysis approach was used for all the sites that are currently included in the database (Figure 1). The in-situ measurements were generally conducted using 24 vertical 4.5 Hz geophones with a spacing of 0.5 m, 1 m, and/or 2 m, depending on site conditions. In exceptional cases, the number of receivers was 12 or 16. Rayleigh waves were generated with a sledgehammer that was struck at various distances (usually in the range of 3–30 m) from one or both ends of each geophone array. Several shot gathers were recorded for each array length and impact point location. Each multi-channel record was analysed separately to quantify the variability of the dispersion curve estimates prior to the inversion. Comparison of dispersion curves obtained at different impact points (i.e., different source offset lengths and forward/reverse shot gathers) was further used during the data analysis for detection of possible near-field effects at certain source offsets and for validation of the 1D assumption adopted in the inversion process. For each test site, the resulting dataset was merged into a single composite curve by adding up the elementary dispersion curves within log-spaced wavelength bands. The composite experimental dispersion curve is subsequently referred to by the abbreviation EDC. A Monte Carlo global search process was then used to identify a set of V_S profiles that fit the observed data, given the uncertainty of the mean EDC and the assumed ground model. A comprehensive description of the data processing and inversion procedures is provided in Olafsdottir et al. (2023).

3 DATABASE OF MEASURED V_S PROFILES

The soil site database currently stores measured dispersion curves, V_S profiles and $V_{S,z}$ from 19 sites in Iceland. Between one and seven measurements are available for each site with an inter-profile distance below 1.1 km and an investigation depth between 10 m and 30 m (Olafsdottir et al., 2023).

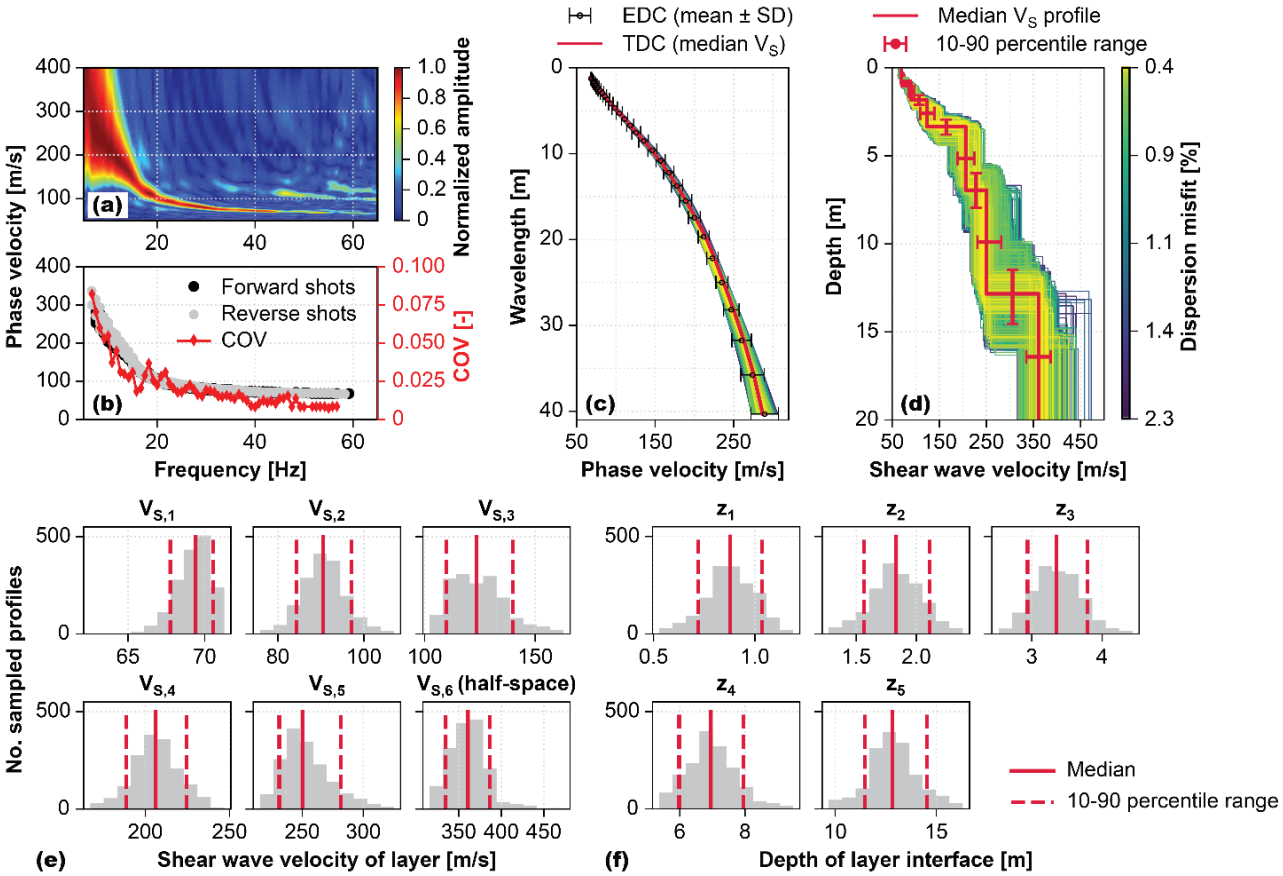

Figure 1. MASW survey by the Ölfus River in South Iceland, illustrating the workflow used for all sites. (a) Spectral image of a single shot gather. (b) Dispersion curves identified from repeated shot gathers (left-hand axis) and variation of the phase velocity values (right-hand axis). (c,d) Sampled V_S profiles (six-layered model) whose theoretical dispersion curves (TDC) fall within the boundary EDCs. The median and 10th to 90th percentile range of the V_S models, and the TDC corresponding to the median V_S profile, are shown in red. (e) Distribution of the shear wave velocity in the i-th layer, $i \in \{1, \dots, 6\}$, and (f) the depth of the i-th layer interface, $i \in \{1, \dots, 5\}$, for the set of velocity models shown in (d).

The user interface is based on an interactive map that shows the surveyed sites (Figure 2). By clicking on a specific map marker, the measurement locations at the given site are displayed (Figure 3a) and the profile(s) of interest can be selected by clicking their unique identifiers (IDs) (Figure 3b). The data are presented in figure form as shown in Figures 3d–f. Results from an unlimited number of measurements (from any survey sites) can be viewed simultaneously. The selected measurements are managed using the check boxes (view/hide) and cross marks (remove) by their profile IDs (Figure 3c).

The interval V_S profile shown for each measurement (Figure 3e) is the median of the subset of sampled V_S profiles whose associated theoretical dispersion curves fall within the boundary EDCs at all wavelengths. The 10th and 90th percentiles of $V_{S,i}$ and z_i are further provided (here $V_{S,i}$ and z_i denote the shear wave velocity in the i-th layer and the depth of the i-th layer interface, respectively).

The mean EDC and its boundary curves are presented as shown in Figure 3d. The boundary EDCs are defined as one standard deviation (SD) above and below the mean curve, except for measurements conducted on top of earth-rockfill dams with a central core, where they are specified as 1.5 SDs from the mean EDC. In those cases, the acquired multi-channel time series likely represent a mixture of the response of the core and shell materials. The theoretical dispersion curve of the median V_S profile is given, thus allowing the user to visually evaluate its fit to the EDC.

The median V_S profile is also given as time-averaged shear wave velocity ($V_{S,z}$, Figure 3f), defined by Eq. (1) where $V_{S,i}$ and h_i are the velocity and thickness of the i-th layer for a total of N layers down to depth z:

$$V_{S,z} = \frac{z}{\sum_{i=1}^{N}\left(\frac{h_i}{V_{S,i}}\right)} \quad (1)$$

Figure 2. The map interface of the soil site database. The current test sites are shown with red markers.

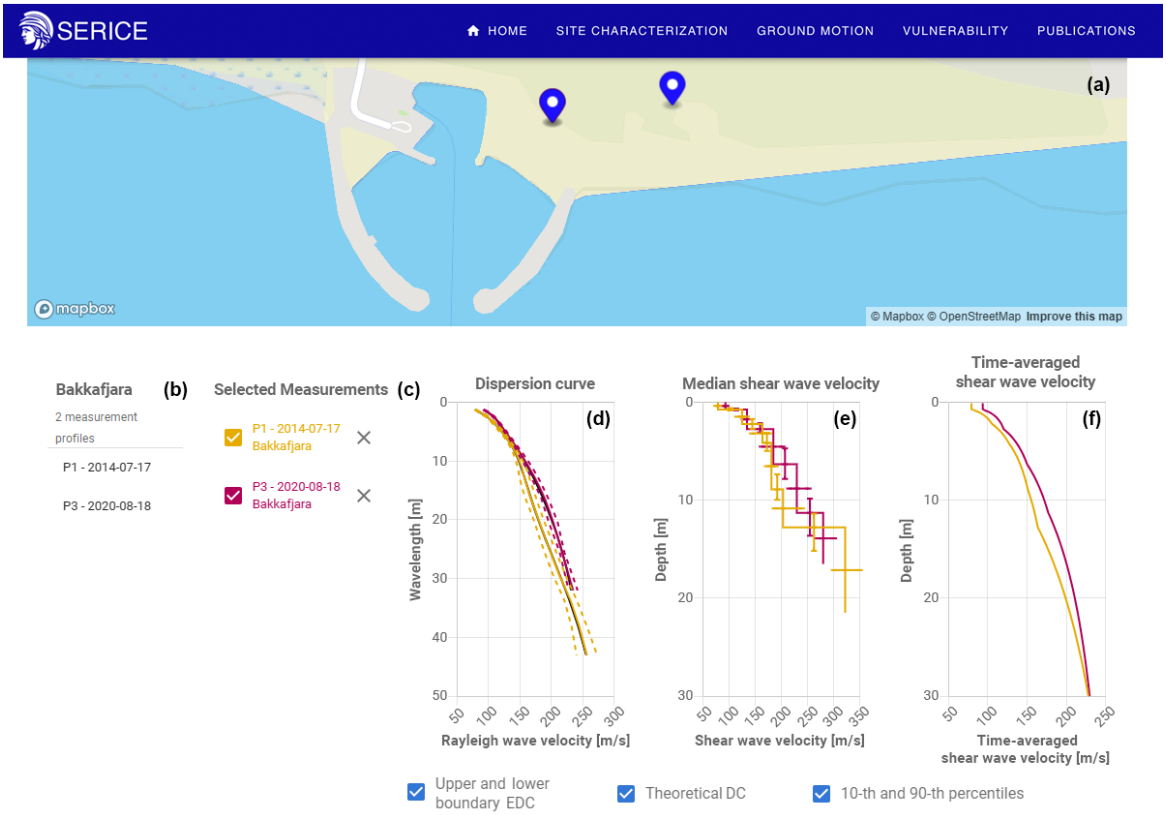

Figure 3. The user interface of the soil site database. (a) Measurement locations and (b) their profile IDs. (c) List of selected measurements. Results presented in terms of (d) dispersion curves, (e) median V_S profiles, and (f) time-averaged V_S.

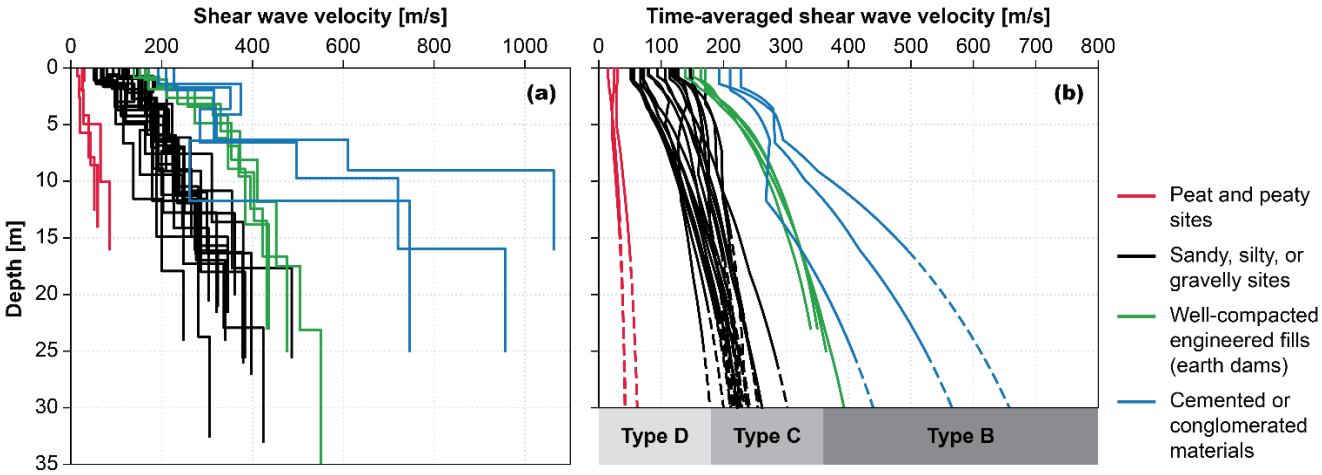

Figure 4. (a) Shear wave velocity (V_S) and (b) time-averaged shear wave velocity ($V_{S,z}$) profiles in the database. The $V_{S,z}$ profiles are shown with dashed lines at depths $z > z_{max}$ for natural sites with a survey depth of $z_{max} < 30$ m. The grey shaded areas in (b) illustrate the $V_{S,30}$ ranges defining ground types B, C, and D in the current EC8 (CEN, 2004).

The $V_{S,z}$ profile of each natural soil site is evaluated down to 30 m. In instances where the survey depth (z_{max}) is less than 30 m, the median V_S is extended to 30 m using the half-space velocity for calculation of $V_{S,z}$ at $z > z_{max}$. When V_S increases with depth, as is expected for all the sites currently included in the database, this approach provides a conservative estimate of $V_{S,30}$.

Figure 4 shows the current collection of median V_S profiles and the corresponding $V_{S,z}$. The tested sites are classified by general soil characteristics as (i) peat and peaty sites, (ii) silty, sandy, or gravelly sites, (iii) well-compacted engineered fills, and (iv) cemented or conglomerated materials. As shown, there is a distinct separation between the four classes. The estimated $V_{S,30}$ values further provide a general indication of the expected EC8 site category of sites within each class. It is though worth mentioning that a $V_{S,30}$ categorization of the peat and peaty sites included in this work is considered uncertain as they might also be categorized as type E or, in some cases, type S_1 or S_2.

4 CONCLUSIONS

Here we present a database (https://serice.hi.is) of surface wave measurements conducted in Iceland. The main purpose is to give researchers and professional engineers access to data and interpreted velocity profiles for design and further analysis.

Future work is aimed at extending the database by adding results from additional sites, as well as adding information on key site effect proxies. Future surveying efforts will also be aimed at assessing the depth of the seismic bedrock formation or the fundamental frequency of the soil deposits, which are required for site categorisation according to the 2nd gen. EC8 (CEN/TC250/SC8, 2021). Further research in this field is believed to be of high value for professional engineers to implement the new site classification scheme and aid simplified identification of site categories in cases where little (or no) site-specific information is available.

Assessment of soil constitutive models to predict the response of offshore wind turbines subjected to lateral cyclic loads

Évaluation des modèles constitutifs des sols pour prédire la réponse des éoliennes offshore soumises à des charges cycliques latérales

ABSTRACT: Monopiles are the frequently used foundation types for offshore wind turbines (OWTs) to withstand the cyclic loads from wind and waves ensuring safe and reliable operation. Under such cyclic loads, strain accumulation occurs while the soil undergoes repeated loading and unloading cycles throughout the OWT's lifespan. Such a mechanism, referred to as "ratcheting", causes changes in soil properties and affects the performance of the OWT. Large accumulative displacements and rotations can cause fatigue damage and serviceability problems which may result in structural failure and operational disruptions. While a wide range of methods is available to predict the monotonic monopile response, limited advanced soil models are available to capture the complex mechanism of cyclic strain accumulation. Such models have different levels of accuracy, complexity, and parameter calibration process. Prior to assessing any boundary value problem, it is important to evaluate the performance of the soil constitutive models at the soil material level. This work presents a comparative numerical study of two state-of-the-art constitutive models for sands i.e., SANISAND-MS and PM4SAND, under triaxial test conditions via OpenSees and PLAXIS. A discussion on the model parameters, analysis settings, and the effect of the number of cycles in the response is presented.

RÉSUMÉ: Les monopieux sont les types de fondations fréquemment utilisés pour les éoliennes offshore afin de résister aux charges cycliques dues au vent et aux vagues, garantissant ainsi un fonctionnement sûr et fiable. Sous de telles charges cycliques, une accumulation de contraintes se produit pendant que le sol subit des cycles répétés de chargement et de déchargement tout au long de la durée de vie de l'éolienne. Un tel mécanisme, appelé "ratcheting", provoque des changements dans les propriétés du sol et affecte les performances de l'éolienne. De grands déplacements et rotations cumulatifs peuvent causer des dommages par fatigue et des problèmes de service qui peuvent entraîner une défaillance structurelle et des interruptions opérationnelles. Bien qu'une large gamme de méthodes soit disponible pour prédire la réponse monotone des monopieux, il existe peu de modèles avancés de sol pour capturer le mécanisme complexe d'accumulation de déformations cycliques. Ces modèles ont différents niveaux de précision, de complexité et de processus d'étalonnage des paramètres. Avant d'évaluer tout problème de valeur limite, il est important d'évaluer les performances des modèles constitutifs du sol au niveau du matériau du sol. Ce travail présente une étude numérique comparative de deux modèles constitutifs de pointe pour les sables, à savoir SANISAND-MS et PM4SAND, dans des conditions d'essai triaxial via OpenSees et PLAXIS. Une discussion sur les paramètres du modèle, les paramètres d'analyse et l'effet du nombre de cycles sur la réponse est présentée.

Keywords: Monopiles; cyclic lateral loads; strain accumulation; constitutive models for sands.

1 INTRODUCTION

Soil constitutive models describe the mechanical behavior of soils by defining the entire incremental stress-strain response under different loading conditions. The description of the soil behavior is particularly important for sands surrounding OWT monopiles. The pore water pressure buildup increases and affects cyclic mobility (Wichtmann et al. 2019). The strain accumulates resulting in tilting of OWTs and affecting structures' fatigue life (Liu et al., 2019).

Single element tests are commonly used to calibrate and verify soil constitutive models. Assessment of these models on their predictive capability of element tests gives an intuition about their use in boundary value problems (Duque et al., 2021). Wichtmann et al. (2019) and Duque et al. (2021) inspected triaxial simulations of different soil models on Karlsruhe fine sand (KFS). Both studies have concluded that there were deficiencies in accurately replicating some important attributes, such as pore pressure reproduction and accumulation of plastic strains. Since the results showed relative density (D_r) dependence, it is inferred that the bounding surface cannot be adequately characterized solely by the mean effective stress and void ratio for all stress-strain paths. Duque et al. (2021) claimed that a comprehensive model capable of addressing all these challenges has yet to be developed.

This paper compares the predictive power of two cutting-edge soil constitutive models: SANISAND-MS (Liu et al., 2019) and PM4SAND (Boulanger and Ziotopoulou, 2015) with SANISAND04 (Dafalias and Manzari, 2004) by numerical simulations of triaxial tests in OpenSees (Zhu et al., 2018) and PLAXIS (Bentley, 2020). The objective of the paper is to obtain insights for practical offshore foundation applications by gaining a deeper understanding of the capabilities and limitations of these models to capture strain accumulation at long-lasting cyclic loading events.

2 TRIAXIAL SIMULATION

An 8-node hexahedral linear isoparametric fully coupled *u-p* element with a single point integration point (SSPbrickUP) is used for effective stress analyses in saturated soils. Rayleigh damping with $\mathbf{C} = 0.05\,\mathbf{M} + 0.00032\,\mathbf{K}$ is defined to damp out the waves. For the shearing, each cycle is comprised of compression (1/4 of a full cycle), extension (2/4 of a full cycle), and compression again (1/4 of a full cycle). Cyclic loading continues until the predefined number of loading cycles is reached.

SANISAND04 is the first member of the SANISAND family. SANISAND-MS includes a memory surface to better control large strains. PM4SAND is formulated under plane strain conditions and features a revised fabric formation requiring three primary model input parameters: G_0, h_{p0}, and D_r, which are most important for model calibration. Secondary parameters are set to default values, which typically align with observed trends.

KFS was extensively tested in monotonic/cyclic, drained/undrained triaxial test conditions by Wichtmann and Triantafyllidis (2016). The soil model parameters calibrated in former studies are held for the comparison study (Wichtmann et al., 2019 for SANISAND04 and Liu et al., 2019 for SANISAND-MS). Although these models share 13 parameters in their model formulation, it is observed in the literature that model parameters for the same sand might be calibrated to arrive at a different set of parameters. For PM4SAND, G_0 is adopted from SANISAND-MS, and h_{p0} is calibrated by the PLAXIS Soil Test parameter optimization tool via SANISAND-MS predictions. The selected parameters are presented in Table 1.

3 RESULTS AND DISCUSSION

OpenSees simulations are compared against the soil tests simulated by the commercial software PLAXIS, which uses a single-point algorithm. In this section, each model will be examined separately.

3.1 SANISAND04

While the model can predict the butterfly-shaped last cycles, it shows inadequate performance in realistically capturing the excess pore pressure development rate and the subsequent pace of effective stress reduction (Figure 1). Although the strain expands to both sides in the triaxial experiment, it accumulates more on the extension side. However, the prediction shows a stronger accumulation on the tension side with a pace different than the actual soil test data (Figure 2).

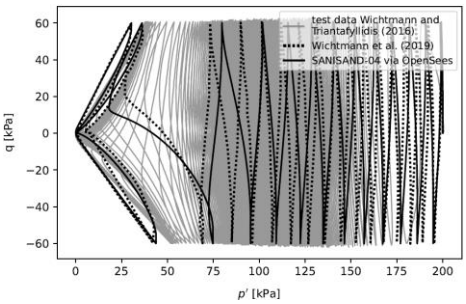

Figure 1. UCT results for q_{amp}=60 kPa, p_0=200 kPa, and D_{r0}=87%: deviatoric stress vs. effective mean pressure.

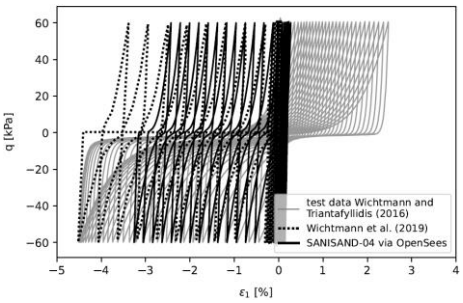

Figure 2. UCT results for q_{amp}=60 kPa, p_0=200 kPa, and D_{r0}=87%: deviatoric stress vs. axial strain.

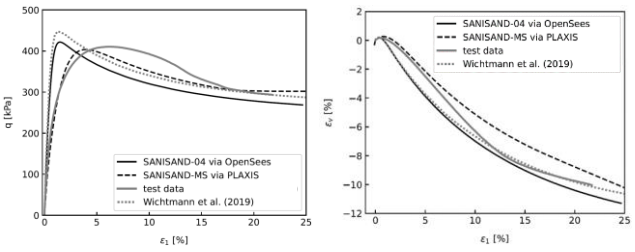
3.2 SANISAND-MS

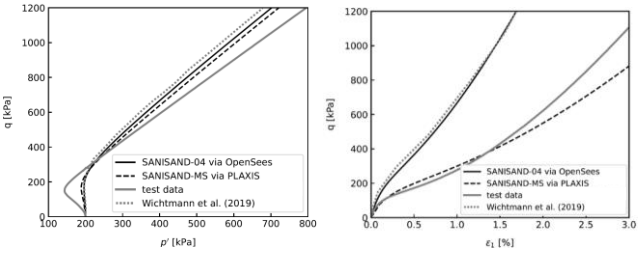
The model has been compared against SANISAND-04 since PM4SAND is formulated in plane strain conditions. For the drained analysis (Figure 3), SANISAND-MS appears to represent the triaxial test data more accurately than SANISAND-04, as it exhibits a trend that aligns more closely with the test results. Since both model parameters are calibrated towards cyclic loading tests, and it is known that one set of parameters for both cyclic and monotonic loading tests are not attainable, such results were anticipated.



(a) (b)

Figure 3. DMT results for p_0=100 kPa and D_{r0}=85%: (a) deviatoric stress vs. axial strain and (b) volumetric strain vs. axial strain.

For the undrained analysis (Figure 4), SANISAND-MS shows slightly better (but still higher in terms of stress ratio q/p) predictions considering the larger displacements it can predict under deviatoric stress. However, in terms of stress paths, none of the models could predict the dense-sand dilatant behavior as we expect from the triaxial tests. This proves the previous findings stating that the bounding surface cannot be adequately characterized solely by the mean effective stress and void ratio for all stress-strain paths.



(a) (b)

Figure 4. UMT results for p_0=200 kPa and D_{r0}=87%: (a) deviatoric stress vs. effective mean pressure and (b) deviatoric stress vs. axial strain.

Since a stress-controlled test was not possible for PLAXIS simulations, comparisons are held for a strain-controlled test. The differences are evident in the cyclic tests shown as can be seen in Figure 5 and Figure 6. The model predictions are similar yet deviate from the triaxial test data.

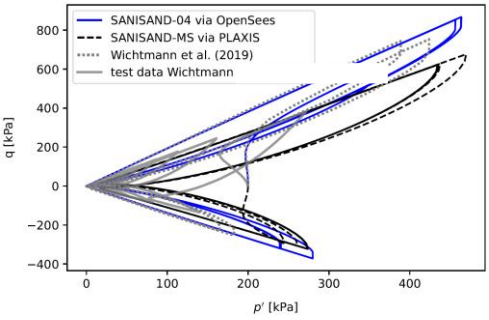


Figure 5. UCT results for ε_{amp}=1%, p0=200 kPa, and D_{r0}=94%: deviatoric stress vs. effective mean pressure.

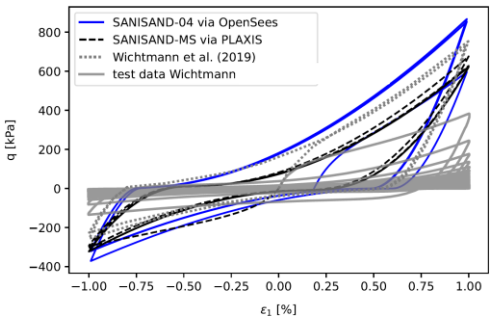

Figure 6. UCT results for ε_{amp}=1%, p_0=200 kPa, and D_{r0}=94%: deviatoric stress vs. axial strain.

3.3 PM4SAND

Figure 7 shows that SANISAND-04 and MS models exhibit similar stiffness degradation and damping with shear strain (with a higher dissipated energy for SANISAND-MS). PM4SAND predicts different behavior than these two models mostly attributed to parameter selection. This underscores the importance of secondary parameter calibration for the model.

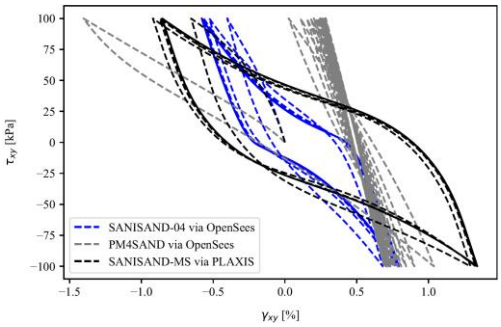

Figure 7. CDSS results for p_0=200 kPa and D_{r0}=94%: shear strain vs. shear stress.

4 CONCLUSIONS

This study aims to conduct a comparative analysis of two state-of-the-art constitutive models for sandy soils: SANISAND-MS and PM4SAND, with their predecessor SANISAND-04. The main findings of this work can be summarized as follows:

Despite the fact that the models can predict the butterfly-shaped loading path, the excess pore pressure development rate is not realistic.

Models are not that accurate in reproducing the strain development pace. This is more pronounced in high cyclic loading.

Since the models are engineered to accommodate certain conditions, when subjected to more complex loading scenarios, the models could yield results that are not in agreement with physical observations. As such, overshooting following immediate reloading or reverse loading can be attributed to the physics imposed within the mathematical formulations of the models.

ABSTRACT: The most important pathologies that occur in civil constructions are a consequence of the foundations. Expansive soils are among the most problematic soils, being the cause of some of these pathologies. It is possible to design foundations that can resist and restrict the action of expansive soils. One of the alternatives that could be applied to some constructions is to mix the soil with an additive. In this paper, the additive used to modify the swelling properties of an expansive Patagonian soil is lignin, a calcium lignosulphonate (CLS). CLS was analysed considering its influence on the behaviour of the soil. A series of tests were carried out to get a better understanding of the impact the addition of lignin produces on the soil. Tests performed were focused on the physicochemical and microstructure characterization (XR diffractometry, mercury intrusion porosimeter and scanning electronic microscope), volumetric behaviour upon wetting (free swelling), hydraulic behaviour (water retention test using dew-point potentiometer and permeability test) and mechanical behaviour (uniaxial compression test). Time of contact clay-CLS was considered as a variable to analyse the stability of the mixture.

RÉSUMÉ: Les pathologies les plus importantes qui surviennent dans les constructions civiles sont la conséquence des fondations. Les sols expansifs sont parmi les sols les plus problématiques, étant la cause de certaines de ces pathologies. Il est possible de concevoir des fondations capables de résister et de limiter l'action des sols expansifs. L'une des alternatives pouvant être appliquée à certaines constructions consiste à mélanger le sol avec un additif. Dans cet article, l'additif utilisé pour modifier les propriétés de gonflement d'un sol expansif de Patagonie est la lignine, un lignosulfonique de calcium (CLS). Le CLS a été analysé en fonction de son influence sur le comportement du sol. Les essais réalisés ont porté sur la caractérisation physico-chimique et de la microstructure (diffractométrie XR, porosimètre à intrusion de mercure et microscope électronique à balayage), le comportement volumétrique lors du mouillage (gonflement libre), le comportement hydraulique (essai de rétention d'eau à l'aide d'un potentiomètre à point de rosée et de la technique du papier filtre, essai de perméabilité) et le comportement mécanique (essai de compression uniaxiale). Le temps de contact argile-CLS a été considéré comme une variable pour analyser la stabilité du mélange.

Keywords: Expansive clay; calcium lignosulfonate; stabilizing additive; biopolymer.

1 INTRODUCTION

For a long time, the additives have been used as stabilizers in expansive soils. Lime is one of the most common additives, but it has a negative impact over the environment, reason why, nowadays, new, and more eco-friendly biopolymers are being studied to replace it. Some examples of alternative stabilizers being studied are waste tire rubber fibre (Bekhiti et al. 2019), burned olive waste (Attom and Al-Sharif, 1998), seeds and starches (Orlandi et al. 2021), ultrafine palm oil fuel ash (Pourakbar et al. 2015), rice hush ash (Brooks, 2009) and gypsum (Yilmaz and Civelekoglu 2009), among others.

All around the world, the paper pulp industry produces lignin in large quantities, and its disposal has become an environmental global problem (Ijaz and Dai, 2020). Some researchers have been studying this waste as an expansive soil stabiliser for the last decade (Alazigha et al., 2018, Orlandi et al., 2019, Fernandez et al., 2021). Significant advancements have been made in analysing the mechanical and hydraulic behavior of CRclay with varying additions of calcium lignosulfonate (CLS) ranging from 3% to 10%, along with the microstructural changes induced (Orlandi et al., 2019, Fernandez et al., 2021).

This article studies the influence of different curing ages (1 day, 1 month, 3 and 6 months and 1 year) of a Patagonian soil (CRclay) mixed with 10%CLS. The efficacy of the 10% CLS added to CRclay was studied considering the changes in microstructure and the hydraulic and mechanical behaviour. Using 10% CLS was shown to be effective in reducing the swelling potential of CRclay (Orlandi et al., 2019).

2 MATERIALS: CRCLAY - CLS

CRclay is Patagonian expansive soil located in Comodoro Rivadavia (Argentina) classified as MH by Unified Soil Classification System (USCS). Table 1 shows the CRclay properties (Manzanal et al., 2019). CRclay is a soil with a high swelling potential (LL=74.5%, PI= 35.3%, Contraction limit = 24.2%), and high surface area (563 m^2/g). The active clay mineral smectite (Sm), known for its swelling behaviour upon hydration was identified within the XRD diffractogram of CRclay (Fernandez et al., 2021). Additionally, impurities such as calcium (Ca^{2+}) and feldspar (F) were also observed.

Table 2. CRclay properties.

Properties	CRclay
% clay	76.64
% silt	21.4
% sand	1.96

CLS was a commercial biopolymer which was provided by Norlig® which has a degradation temperature of 300ºC, a glass transition temperature, Tg = 80ºC, and 10.33% ash content (Orlandi et al., 2021).

3 METHODS

Utilizing their prior expertise in determining optimal CLS content (Orlandi et al., 2019; Fernandez et al., 2020), this study explores the influence of curing time on CRclay samples and CRclay-10%. All samples were uniformly prepared by static compaction at a dry unit weight of 13 kN/m^3. The natural water content of 18% was maintained for samples of various tests, including free swelling, uniaxial compression, mercury intrusion porosimetry (MIP), and scanning electron microscopy (SEM). Variable Charge Permeameter (VCP) tests were conducted on samples compacted at a moisture content of 33%. Samples were sealed with film to prevent moisture fluctuations and stored under controlled temperature and humidity until testing. Different ages of testing were adopted for each type of test: free swelling tests were carried out on samples of 1 day and 9 months and uniaxial compressive tests were performed over samples with ages of 1 day, 1 month, 3 months, 6 months, 9 months, and 1-year. The microstructure (MIP and SEM) was analysed for samples aged at 1 day and 1 year. Water retention (WP4: dew-point potentiometer), and permeability tests were conducted on samples aged 1 day.

4 RESULTS AND DISCUSSION

The water retention capacity of the unsaturated compacted samples of CRclay and CRclay+10%CLS were obtained using dew-point potentiometer (WP4) as is illustrated in Figure 1. When comparing samples with equal degrees of saturation in terms of water content and dry unit weight ($13kN/m^3$), it was observed that the addition of CLS increases suction in the sample. This trend is more pronounced in samples with saturation degrees higher than 50% (similar to the molding moisture content of 18%). Comparable findings were also reported using other techniques (Fernandez et al., 2021, Orlandi, 2021). The evolution of unsaturated compacted samples at the water content of 18% was evaluated with the VCP test and free swelling test.

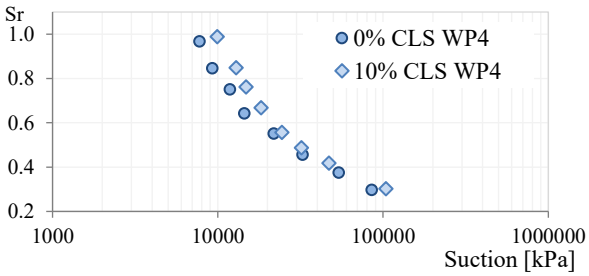

Figure 1. Suction obtained by using WP4 for 0%CLS and 10%CLS.

The VCP test demonstrates that the addition 10% CLS increases the permeability compared to CRclay, as illustrated in Figure 1. This is attributed to the change in inter-aggregate porosity caused by CLS

(Fernandez et al., 2021). Moreover, we note a gradual decrease in VCP permeability over two months of testing due to specimen expansion at constant volume, and the sequential saturation processes of inter-pore, intra-pore, and eventual development of the diffuse double layer (Delage, 2007).

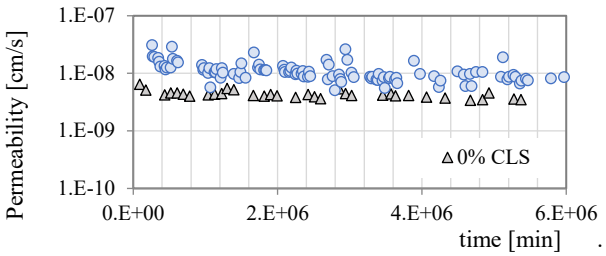

Figure 1. Permeability evolution for 0%CLS and 10%CLS.

The volumetric behaviour of both CRclay and CRclay-10%CLS samples upon wetting is shown in Figure 2. Results reveal a substantial reduction in free swelling for specimens with CLS, with a decrease of 84% observed for samples tested one day after moulding and 83% for those tested after 9 months, compared to the volumetric behaviour of CRclay.

The time evolution of free swelling depicted in Figure 2 displays three clear periods. The initial swelling is attributed to the saturation of interaggregate porosity, followed by primary swelling associated with the ongoing saturation of intra-aggregate porosity, culminating in secondary swelling once the double-layer expansion is fully saturated.

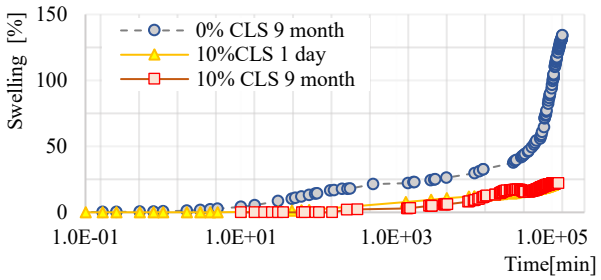

Figure 2. Free swelling for 0% CLS and 10% CLS, at 1 day and 9 months aged samples.

The unconfined compressive stress-strain behaviour of CRclay (Figure 3a) and CRclay-10%CLS (Figure 3b) illustrates the impact of varying sample ages. Overall, the results indicate a slight increase in UCS for samples with the addition of 10% CLS, accompanied by enhanced ductility. The additive does not modify the mechanical behaviour as a function of time but follows the trend shown by the compacted soil.

The variation of stress-strain curves with the age of the sample could be related to gradual water redistribution after the sample compaction stage is finalized. This migration within a sample induces changes in the distribution of interaggregate porosity and porosity with time (Figure 4), which are contingent upon the initial moisture content and dry density of the mixtures. This redistribution may account for the time-dependent fluctuations observed in permeability and simple compressive strength (Delage, 2007, Fernandez et al., 2021).

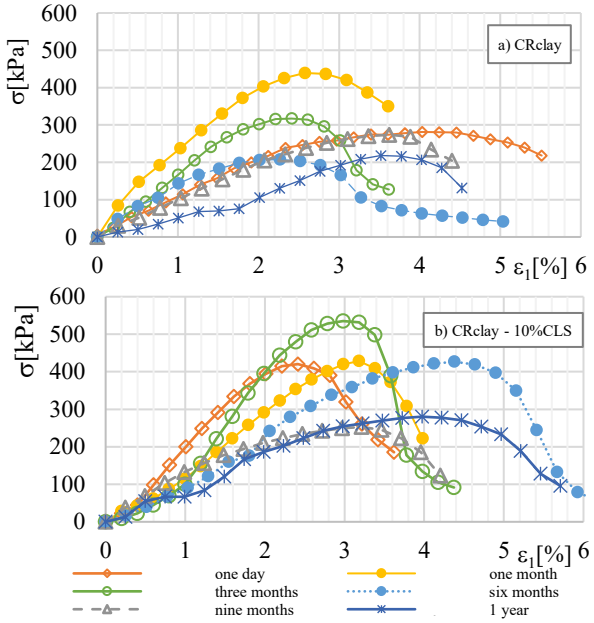

Figure 3. Unconfined Compressive test for nine different curing ages for a) CRclay and b) CRclay-10%CLS samples.

The physicochemical interaction mechanisms between CRclay and CLS are illustrate in Figure 4 (right), revealing the emergence of new lamellar and elongated linear structures within the soil matrix. However, due to the inability to analyse the composition of these structures, assessing their impact on the overall behaviour is not feasible. Furthermore, the presence of spores, known for their natural ability to polymerize lignins, may generate effects which were not evaluated in this study (Orlandi, 2021).

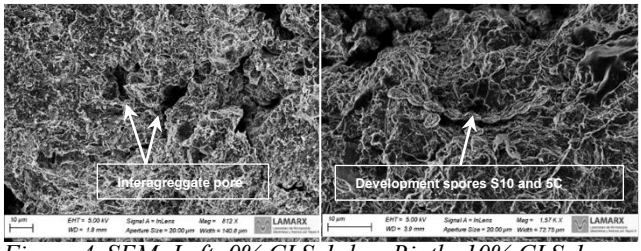

Figure 4. SEM: Left: 0% CLS-1 day. Rigth: 10% CLS-1 year SEM.

Upon further analysis of the influence of sample age on pore distribution using MIP for CRclay-10% CLS samples, we observe significant in the bimodal

distribution between samples aged 1 day and 1 year, with a notable variation in intrapore density increasing with age. Interporosity shows an increase in total pore volume but a decrease in characteristic pore diameter.

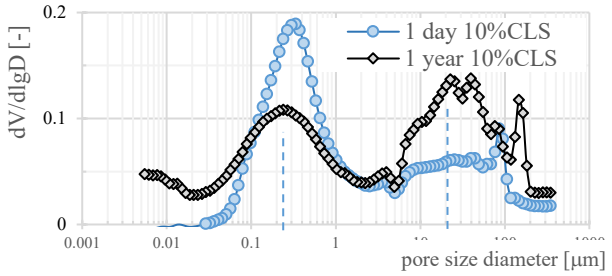

Figure 5. MIP: *Pore size diameter distribution* for CRclay+ *10% CLS* sample.

5 CONCLUSION

The stabilization mechanisms formed between CRclay, and calcium lignosulphonate (CLS) induce mechanical, hydraulic, and microstructural changes in the soil. The incorporation of 10% CLS yields positive effects on soil behaviour, and these changes persist over time. The additive does not alter the mechanical behaviour over time; rather, it mirrors the trend exhibited by the compacted CRclay. This phenomenon could be attributed to the redistribution of water within the soil pores in an unsaturated state.

It can be highlighted:

- The impact on water retention capacity is more pronounced in samples with water content exceeding the natural moisture for the dry unit weights studied.
- The saturation process of the samples in constant volume tests (VCP) and volume change upon wetting confirms the three stages studied by other authors: The initial swelling is attributed to the saturation of interaggregate porosity, followed by primary swelling associated with the ongoing saturation of intra-aggregate porosity, culminating in secondary swelling once the double-layer expansion is fully saturated.
- The effect of time on both CRclay and CRclay+10% CLS samples follows a similar trend in the unconfined compression tests. Variations in porosity observed in SEM and MIP analyses confirm a time-dependent effect in both the CRclay and CLS mixture, signifying an increase in interporosity in the CLS samples, indicating a tendency to disrupt clay aggregation.

The mechanical results should be validated through triaxial tests to verify the contraction-dilatant behaviour of the CLS samples.

ABSTRACT: The open-pit mining process is generally made up of a sequence of unit operations including drilling, blasting, loading, hauling, and crushing. Drilling and blasting can have a major impact on the performance and cost of subsequent operations. The prime objective of these two operations is to obtain optimum fragmentation within safe and economical limits. As a result, a quick and accurate evaluation process is required to assess its effectiveness. Today, the most accurate method of measuring fragment size is sieving analysis. The drawback of this method is that it is a time-consuming and labor-intensive process. The disadvantage of the prediction methods is the lack of actual measurement of the fragments which may result in inaccurate assessment. There is a need for a more reliable and effective way of obtaining grain size distribution than by sieving analysis while providing more accurate results than the predictive methods. The problem of determining the grain size distribution of blast fragmentation from the surface of a pile of fragments has been studied by many researchers. This paper discusses the application of Doppler radar (Semi-automatic method) as the possibility of fragmentation material measurements during the blasting and the direct possibility of its further use in building other construction such as road embankments where grain size plays a decisive role. With this refinement, it is possible to omit additional crushing of the material, which is associated with financial costs. Effective use of residual material as well as mitigation of environmental impact by associated technologies would be achieved.

RÉSUMÉ: Le processus d'exploitation minière à ciel ouvert est généralement constitué d'une séquence d'opérations unitaires comprenant le forage, l'abattage à l'explosif, le chargement, le transport et le concassage. Le forage et le dynamitage peuvent avoir un impact majeur sur les performances et le coût des opérations suivantes. L'objectif premier de ces deux opérations est d'obtenir une fragmentation optimale dans des limites sûres et économiques. Par conséquent, un processus d'évaluation rapide et précis est nécessaire pour évaluer leur efficacité. Aujourd'hui, la méthode la plus précise pour mesurer la taille des fragments est l'analyse par tamisage. L'inconvénient de cette méthode est qu'il s'agit d'un processus qui prend du temps et nécessite beaucoup de main-d'œuvre. L'inconvénient des méthodes de prédiction est l'absence de mesure réelle des fragments, ce qui peut entraîner une évaluation inexacte. Il est nécessaire de trouver un moyen plus fiable et plus efficace d'obtenir la distribution de la taille des grains que l'analyse par tamisage, tout en fournissant des résultats plus précis que les méthodes prédictives. Le problème de la détermination de la distribution granulométrique des fragments d'explosion à partir de la surface d'une pile de fragments a été étudié par de nombreux chercheurs. Cet article traite de l'application du radar Doppler (méthode semi-automatique) pour mesurer la fragmentation des matériaux pendant le dynamitage et de la possibilité directe de l'utiliser dans la construction d'autres ouvrages tels que les remblais routiers, où la taille des grains joue un rôle décisif. Grâce à ce raffinement, il est possible d'éviter le concassage supplémentaire du matériau, qui est associé à des coûts financiers. L'utilisation efficace des matériaux résiduels et l'atténuation de l'impact sur l'environnement par les technologies associées seraient ainsi réalisées.

Keywords: Doppler radar; fragmentation; blasting; grain size distribution.

1 INTRODUCTION

The open-pit mining process is generally made up of a sequence of unit operations including drilling, blasting, loading, hauling and crushing. Drilling and blasting, being the first unit operations, can have a major impact on the performance and cost of subsequent operations. The prime objective of these two operations is to obtain optimum fragmentation within safe and economical limits.

The output from the blasting process depends on many parameters such as rock composition, layer thickness, type of explosives, etc. As a result, a quick and accurate evaluation process is required to assess its effectiveness. In addition, this evaluation process can be used to monitor blasting, optimize the blast design and assess loading conditions for scoops and shovels. One of the key indicators of the effectiveness of a blast is the size of the resulting fragments. Today, the most accurate method of measuring fragment size is sieving analysis. The drawback of this method is that it is a time consuming and labor-intensive process. This has led many researchers to use blasting parameters and rock mass properties to predict the fragment size distribution.

2 ACTUALITY AND IMPORTANCE OF THE WORK

Most open-pit mining operations employ blasting for primary breakage of the rocks. Since blasting is a major cost factor, both cases (under and over breakage) create additional costs reflected in the increase of the operation and maintenance of the machinery. To establish optimum cost values, it is important that the combined performance of the blast controllable parameters be acknowledged, complying with the ultimate goals of the overall mining operation. This is usually accomplished with the definition of a set of conditions minimizing total production cost per ton of rock blasted. The blasting process has been described in the Literature as a nonlinear process in which several parameters, often difficult to evaluate, dictate the outcome. Generally speaking, these parameters can be grouped into two categories: controllable parameters (explosives parameters), and uncontrollable parameters (rock parameters).

Fragmentation is one of the major parameters that affect the performance of the loading and hauling equipment deployed in a mine. Fragmentation is a relative term, and its desired values are equipment specific.

Since there are conflicting requirements (Figure 1) of drilling-blasting and loading-hauling equipment's deployed in a mine, the situation poses a difficult proposition. The whole scenario has been discussed by several workers and can be described in terms of optimization. For enacting an optimization schedule, it is essential to understand the level i.e. the system or sub-system level at which the optimization is anticipated. If the whole system is considered, the scenario becomes quite complicated, particularly, when costs of individual components of the system are to be considered.

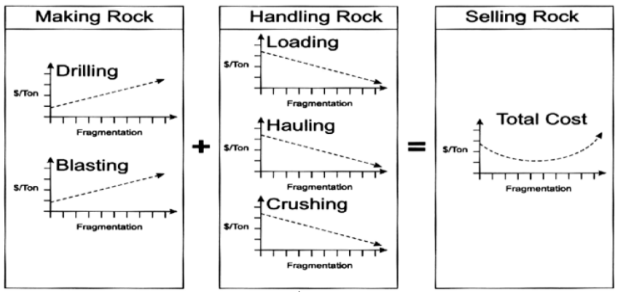

Figure 1. Relation of individual system components in mine system and the optimum thereof.

3 NEW IDEA FOR GRAIN SIZE MEASUREMENT

The key objective of production blasting is to achieve optimum rock fragmentation. The degree of rock fragmentation plays an important role in order to control and minimize the overall production cost including loading, hauling, and crushing costs (Figure 2). Optimum rock fragmentation improves the energy efficiency of crushing processes and thousands of kilowatt-hours energy per year can also be saved.

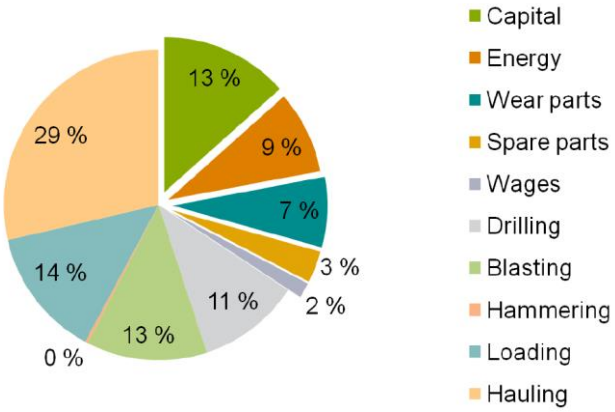

Figure 2. Example of quarrying costs (Product 0-20mm).

Blasting is the first step of the size reduction in mining, and it is followed by crushing and grinding unit operations (Figure 3). The efficiency of these unit operations is directly related to the size distribution of muck pile. Therefore, reliable evaluation of fragmentation is a critical mining problem. Production of finer fragments in blasting operation reduces the workload of primary crushers; therefore, increasing the crusher efficiency and reducing the crushing cost. Also crushing rate per hour will increase (Figure 4).

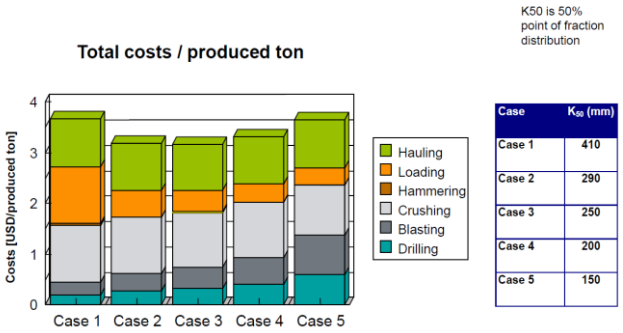

Figure 3. Comparison of different blasted fragmentations.

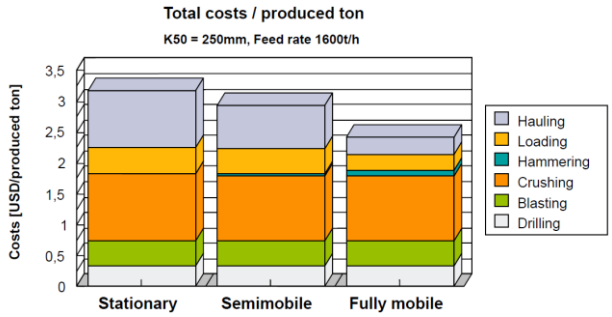

Figure 4. Comparison of different crushing methods.

The problem of determining the true size distribution of blast fragmentation from the surface of a pile of fragments has been studied by many mining researchers. In this thesis, an attempt is made to derive a reliable measure of fragments, based on Doppler radar measure of reflectivity of flying stones during blasting.

4 USING RADAR REFLECTIVITY TO DETERMINE GRAIN SIZE

The reflectivity, Z is the ratio between reflected and incident intensity as the size of energy for example electromagnetic waves (light current) or sound waves (sound pressure, sound field size).

Reflectivity is defined as the total reflecting area of small particles per cubic meter with a dielectric constant greater than zero. This value is proportional to the sixth power of the diameter of an object with a spherical surface. The reflectivity is the sum of all individual objects in a space of one cubic meter by a model of the distribution of the different grain sizes.

For our measurement was used modified micro rain radar MRR-2 was by the company METEK (Figure 5).

The relationship between waveform and blasting characteristics becomes clear when one looks more closely at the theoretical spectra of elementary results.

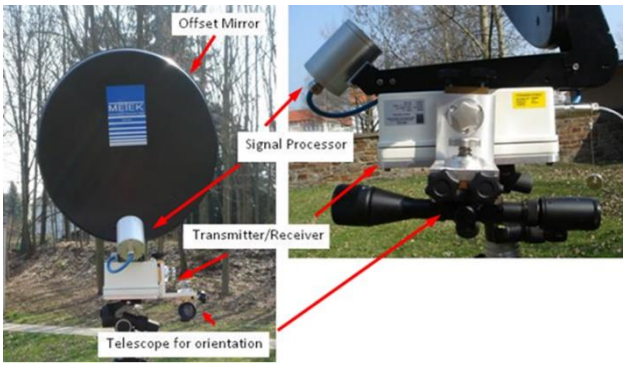

Figure 5. Setup of a radar station with additional schematic arrangements.

The example shows less idealized situation. There will be a directed blasting, in which the particles with speeds of 15 to 25 m/s fly at an opening angle of ± 50° around the radar beam (Figure 6).

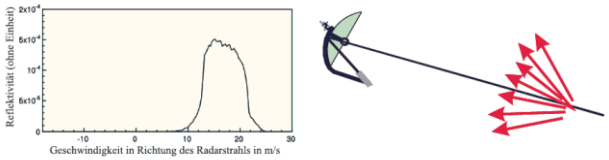

Figure 6. The theoretical spectrum of a directed explosion.

This example can be seen as a prototype of the spectrum for blasting. By blowing up the energy of the explosion is limited to a range of angles. Blasting is directed almost horizontally.

5 MEASUREMENT AND RESULT

Based on the experiments, it was possible to describe the dependence between reflectivity, velocity, and grain size.

The results of these measurements created a relationship between grain size (D) and reflectivity (Z) (Figure 6). Due to possible measurement error were determined the maximum and minimum values of reflectivity for measured grain size.

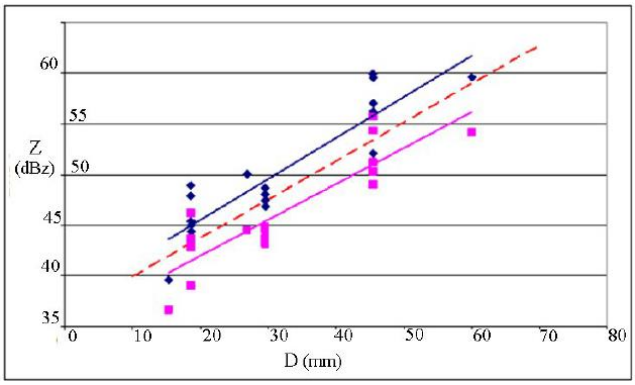

Figure 6. Change of reflectivity depends on changes in grain grains.

6 CHANGE OF THE WALL´S STRUCTURE DURING THE BLAST

Pulse period of Doppler radar is in all cases, 1 s. This means that the grain size distribution can be determined every second of the initiation of blasting and thus track the change of structure of the blast wall.

As an example, the measurement in the quarry Seifsdorf. This measure was supplemented by scanning the blasting wall with high-speed camera. The result is in Figure 7. It seems that the size of material changes every second. This change influences the quantities of the energy from the use of explosives.

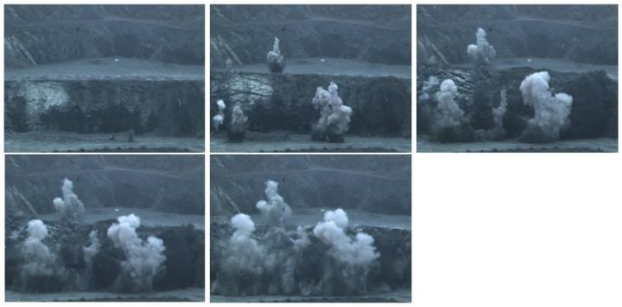

Figure 7. The progress of the blasting captured by a high-speed camera (the blast duration is 5 seconds).

Surface grain size analysis expresses the absolute value of the sum of all the measured reflectivity of flying particles, for the duration of the blasting from t = 1s to t + t_n (Figure 8).

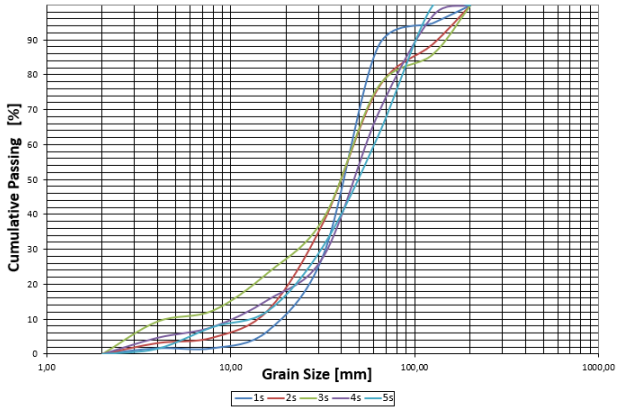

Figure 8. Complete analysis of blasting second after second.

7 USING OF CORRELATION RELATIONSHIP FOR GRAIN SIZE DISTRIBUTION

After the evaluation and comparison of the in situ measurement was possible to convert recorrections for the dependence of grain size and reflectivity. The result of this correction is introduced in Figure 9. The graphs represent the different geological environment. Comparison is in a log-linear coordinate system. The Red line is measured by Radar during the blast, the brown line is a measurement of surface grain size distribution with photo analysis, and the green line measurement by Radar after equipment correction.

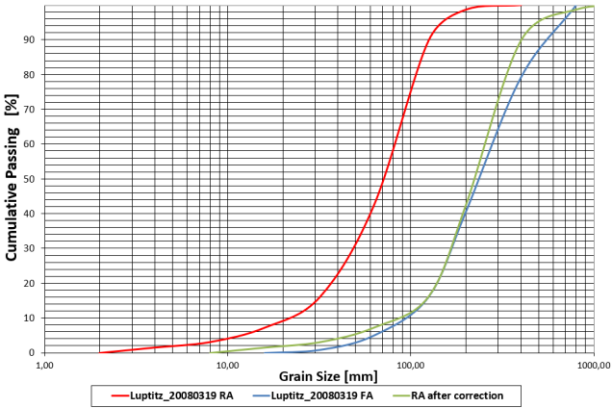

Figure 9. Grain size distribution for blast in rhyolite.

8 CONCLUSION

The idea of using a Doppler effect to detect objects in space is old more than one hundred years. Based on physical theories, its use can also be extended because its variability is currently not limited in any way.

In situ measurements were conducted in places with different material structures, which were conducted and analysed over 60 blasting with a very positive correlation result. After the establishment of a computational algorithm, the total time determining the grain size distribution decreased to about 2 minutes after the blast.

After setting the blasting parameters, it is possible to do a grain size analysis right after blasting and determine its use without unnecessary crushing. This optimization would be able not only to save financial resources, but also to a large extent mitigate the impact on the environment, which is represented by cyclic blasting.

ABSTRACT: This paper focuses on the importance of understanding and modelling water flow through concrete. To achieve this, the water retention curve (WRC) was determined for various concrete mixtures with different cement quantities and water-cement ratios. The pore system of concrete is complex and consists of open macropores and capillary pores, making it essential to use a bimodal function such as Fredlund and Xing (1994) bimodal model for WRC fitting. The theory of lateral shift was applied to estimate the wetting water retention curve from the drying WRC. The curves obtained are then used to calculate the permeability functions applying the Fredlund et al. (1994) model. To validate our results, finite element modelling of the standard test for watertightness was performed with Plaxis 3D, utilizing the calculated functions. The results of this study provide valuable information for investigating and modelling seepage through the pores of concrete, which is crucial for life-span analyses of underground structures such as hazardous waste storages.

RÉSUMÉ: Cet article met l'accent sur l'importance de comprendre et de modéliser l'écoulement de l'eau à travers le béton. Pour ce faire, la courbe de rétention d'eau (WRC) a été déterminée pour divers mélanges de béton avec différentes quantités de ciment et des rapports eau-ciment différents. Le système de pores du béton est complexe et se compose de macropores ouverts et de pores capillaires, ce qui rend essentiel l'utilisation d'une fonction bimodale telle que le modèle bimodal de Fredlund et Xing (1994) pour l'ajustement de la WRC. La théorie du décalage latéral a été appliquée pour estimer la courbe de rétention d'eau de mouillage à partir de la WRC de séchage. Les courbes obtenues sont ensuite utilisées pour calculer les fonctions de perméabilité en appliquant le modèle de Fredlund et al. (1994). Pour valider nos résultats, une modélisation par éléments finis du test standard d'étanchéité à l'eau a été réalisée avec Plaxis 3D, en utilisant les fonctions calculées. Les résultats de cette étude fournissent des informations précieuses pour l'investigation et la modélisation de l'infiltration à travers les pores du béton, ce qui est crucial pour les analyses de durée de vie des structures souterraines telles que les installations de stockage de déchets dangereux.

Keywords: Concrete; water retention curve; permeability function; lateral shift; numerical modelling.

1 INTRODUCTION

Numerous studies in existing literature demonstrate the applicability of unsaturated soil mechanics theories in computing and analysing water flow within various unsaturated porous materials, such as concrete, asphalt, and geotextile (Park and Fleming, 2006; Renken et al., 2016; Pap et al., 2018). This paper focuses on measuring the drying water retention curve and estimating the wetting water retention curve using the lateral shift technique (Fredlund, 2000; Pham, 2002; Pham et al., 2003; Zhai et al., 2015) for six distinct concrete mixtures. Additionally, the unsaturated permeability function, a crucial input for modelling water flow in concrete, was obtained based on the measured water retention curves.

Direct experimental measurements of the unsaturated permeability coefficient for porous media pose challenges due to their difficulty and time-consuming nature. Various estimation methods have been developed to calculate the permeability function, categorised into empirical, statistical, correlation, and regression models. Statistical models apply a physical model of pore channel arrangements through which water flows, relying on known saturated permeability coefficients and water retention curves (Fredlund et al., 2012). These models assume a close relationship between permeability function, water retention curve,

and pore-size distribution of the soil (van Genuchten, 1980; Fredlund et al., 1994; Zhai and Rahardjo, 2015).

The configuration of the water retention curve in certain porous mediums deviates from the unimodal characteristic. Some soils possess not only a single series of pores but also larger and smaller pores, resulting in at least two peaks in their grain size distribution curve (e.g., gap-graded soils) (Imre et al., 2012). These soils exhibit a bimodal or multimodal characteristic in the water retention curve (Figure 1).

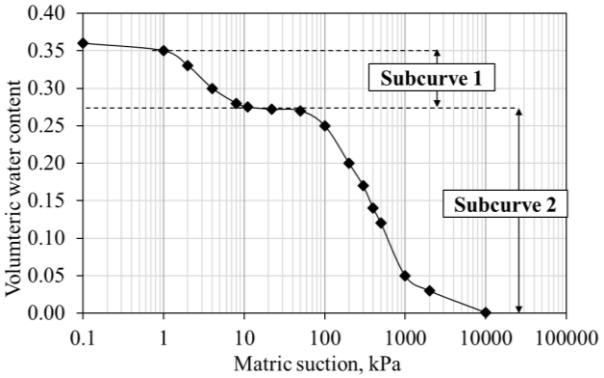

Figure 1. Characteristic of a bimodal water retention curve after Satyanaga et al. (2013).

In laboratory tests, only specific points on the water retention curve are typically measured precisely. Therefore, it becomes necessary to fit a mathematically descriptive function to the measured points for practicality. Various closed-form, empirical equations have been recommended to optimally align with laboratory data for water retention curves (Mualem, 1976; van Genuchten, 1980; Fredlund and Xing, 1994; Satyanaga et al., 2013).

The aim of this study was to furnish substantial input data, such as the water retention curve, unsaturated permeability function and saturated permeability coefficient, for the modelling of seepage in concrete. To evaluate the suitability of the measured data, we simulated the standard watertightness test using finite element software. During this test, a concrete specimen measuring 150×150×150 mm is subjected to a water pressure of 500 kPa on a circular part (75 mm in diameter) of one surface of the specimen for 72 hours. After this period, the specimen is sectioned, and the depth of water penetration is determined through visual inspection.

2 MATERIALS AND METHODS

2.1 Concrete types

We prepared six concrete mixtures for the laboratory tests, varying the water-cement ratio between 0.45 and 0.50. Portland cement composite (CEM II) with a strength class of 42.5 N was utilized.

The aggregates included washed, segregated, and dried sand, along with gravelly sand. The aggregate composition comprised 40% of 0/4 mm, 25% of 4/8 mm, and 35% of 8/16 mm fractions. For M5 and M15 concrete mixtures, polymer fiber was introduced to expand the range of concrete properties, with a fiber content of 0.35% by volume.

To achieve the desired consistency, a superplasticizer based on polycarboxylic solution was added to the concrete mix. For the M7 concrete mix, Penetron Admix, an integrated crystalline additive, served as a waterproofing admixture. The composition details of the tested concrete mixtures can be found in Table 1.

Table 1. Summary of concrete mixtures tested.

Mix No.	Cement (kg/m^3)	w/c ratio	Fiber used	Penet-ron
M1	360	0.50	-	no
M5	400	0.45	polymer	no
M7	360	0.50	-	yes
M13	360	0.40	-	no
M15	400	0.50	polymer	no
M17	400	0.45	-	no

2.2 Measuring methods for water retention curves

The drying water retention curve was determined using three different methods, chosen to accommodate the extensive range of suction values. Consequently, core samples were prepared from each concrete type, with a height ranging from 25 to 50 mm and a diameter of 50 mm, for the measurement. These samples were extracted and cut from concrete cubes measuring 150×150×150 mm. To prevent any mass changes resulting from healing during the tests, the prepared concrete specimens underwent testing after reaching an age of 100 days. At this point, the concrete exhibits recovered residual properties.

In a sand/kaolin box, water content was measured at pF 0, pF 1, pF 1.5, pF 2.0, and pF 2.5 (0.1 kPa, 1 kPa, 3.2 kPa, 10 kPa, and 31.6 kPa) suction values. Suction values were controlled during measurement by adjusting the water surface relative to the position of the tested samples. The determination of water content was conducted through weighing.

Water content at pF 3.4 and pF 4.2 (251.2 kPa and 1584.9 kPa) suction values was determined in a pressure membrane extractor using the axis translation technique. During the test, water pressure was controlled, creating an overpressure in the apparatus.

For high suction ranges, additional procedures are required to control suction. The vapor equilibrium technique, utilizing diverse chemicals and salts, allows for relative humidity control (Ng and Menzies, 2007). The principle involves equilibrium development between the water content of the samples and the surrounding relative humidity. In our measurements, four different chemicals were used to achieve relative humidity values of 95.6%, 90.0%, 75.3%, and 31.0% in a desiccator. Table 2 outlines the chemicals used and their corresponding pF values.

Table 2. Chemicals and corresponding suction values.

Chemicals	Temperature [°C]	Relative humidity (%)	pF value	Suction (kPa)
Sulfuric acid	20.0	95.6	4.79	6 208
Zinc sulphate	20.0	90.0	5.16	14 537
Sodium chloride	25.0	75.3	5.59	38 905
Calcium chloride	24.5	31.0	6.21	161 588

2.3 Determination of saturated permeability coefficient

The permeability coefficients were established through constant head permeability tests conducted in triaxial cell on concrete samples measuring 50 mm in diameter and 50 mm in height. Each sample undergoing three tests at head differences of 100 kPa, 300 kPa and 600 kPa. The average values of the permeability coefficients are summarized in Table 3.

The measured permeability coefficient values exhibited a range from 3.06×10^{-11} m/s and 4.85×10^{-10} m/s, indicating a relatively narrow span considering the diverse range of concrete types.

Table 3. Measured average permeability coefficients.

Mix No.	Average permeability coefficients, k (m/s)
M1	4.97×10^{-10}
M5	1.97×10^{-10}
M7	3.06×10^{-11}
M13	2.20×10^{-10}
M15	4.46×10^{-10}
M17	4.85×10^{-10}

3 INTERPRETATION OF WATER RETENTION CURVES

3.1 Fitting method of water retention curves

As previously mentioned, the water retention curve test allows for the measurement of only a limited number of points in the function. Therefore, it becomes imperative to fit a function to the measured points, facilitating the determination of the permeability function (Leong and Rahardjo, 1997). Analyzing the measured data and the complex pore size distribution of concrete reveals the potential bimodal characteristic in the water retention curve. This implies that formulas such as Satyanaga et al. (2013) or modified procedures (Zhang and Chen, 2005), capable of considering both large-pore and small-pore series, should be employed to accurately fit the measured data. Consequently, the fitting of the WRC to the measured data utilized the bimodal version of the Fredlund and Xing (1994) function, and the fitting process was executed using the Solver Add-in in Excel software.

The model developed by Fredlund and Xing (1994) has proven to be applicable for describing water retention curves not only in soils but also in non-soil materials (Park and Fleming, 2006). This formula incorporates a correction factor that extends the suction range from residual suction to a fully dry state. The bimodal model by Fredlund and Xing (1994) is as follows:

$$\theta(\psi) = \theta_{sl} \cdot \left[1 - \frac{ln\left(1+\frac{\psi}{\psi_{rl}}\right)}{ln\left(1+\frac{10^6}{\psi_{rl}}\right)}\right] \cdot \frac{1}{\left\{ln\left[e+\left(\frac{\psi}{a_l}\right)^{n_l}\right]\right\}^{m_l}} + \theta_{ss} \cdot \left[1 - \frac{ln\left(1+\frac{\psi}{\psi_{rs}}\right)}{ln\left(1+\frac{10^6}{\psi_{rs}}\right)}\right] \cdot \frac{1}{\left\{ln\left[e+\left(\frac{\psi}{a_s}\right)^{n_s}\right]\right\}^{m_s}} \quad (1)$$

where $\theta(\psi)$ is the volumetric water content at the given suction value (kPa), ψ is the suction value, θ_{sl} and θ_{ss} are the saturated volumetric water content for the large-pore and the small-pore series, a_l, n_l and m_l are fitting parameters for the large-pore series component, ψ_{rl} and ψ_{rs} is the value of suction to the residual volumetric water content for the large-pore and small-pore series (kPa), a_s, n_s and m_s are fitting parameters for the small-pore series component.

In Figure 2 the normalized volumetric water content is presented as a function of suction for the M1 concrete mixture, employing the bimodal equation by Fredlund and Xing (1994). Notably, the water content appears to decrease in two distinct steps. This characteristic in the water retention curve of concrete is attributed to the complex pore system inherent in

concrete, comprising both open macropores and capillary pores. At lower suction levels, the water is rapidly expelled from the open macropores due to the influence of gravity on water movement within the concrete.

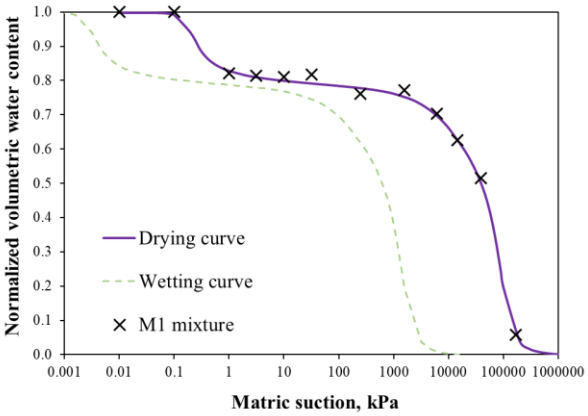

Figure 2. Drying and wetting water retention curve for M1 concrete mixture.

3.2 Estimation of wetting WRCs

The initial curve typically determined for a material is the drying water retention curve, given the quicker attainment of equilibrium on the drying side compared to the wetting side. Estimating the wetting curve often involves assuming a suitable lateral shift for the drying curve. Additionally, it is common to assume that the drying and wetting curves are parallel in the inflection point segment of the curves (Fredlund et al., 2011; Pham et al., 2003).

Consequently, the estimation of the wetting water retention curve involves a horizontal translation to the left in semi-logarithmic space. The fitting parameter *a* in the WRC equations typically governs the lateral shift of both drying and wetting curves.

The percent lateral shift of the WRCs, expressed as ξ, is mathematically represented as follows (Fredlund et al. 2011):

$$\xi = 100[log(\psi_{ad}) - log(\psi_{aw})] \qquad (2)$$

where ψ_{ad} is the suction at any point along the drying WRC (kPa), and ψ_{aw} is the suction at any corresponding water content on the wetting WRC (kPa). With the former formula, the lateral shift can be determined from any point at the curve.

Equation (2), which expresses the lateral shift of the water retention curve, can be rearranged to allow for the computation of suction on a congruent WRC from the drying curve. Subsequently, the modified form of Equation (2) is presented as follows (Fredlund et al. 2011):

$$\psi_w = 10^{(log\,\psi_d - \frac{\xi}{100})} \qquad (3)$$

In an analysis by Pham et al. (2003), the lateral shift between drying and wetting WRCs was examined for published data from various researchers. The results indicated the most substantial shift between drying and wetting curves for clay soils (50-100) and the smallest shift for uniform sand soils (15-35).

For the determination of wetting WRCs in concrete mixtures, previous studies were referenced. Pap et al. (2018) utilized the theory of lateral shift to estimate wetting WRCs. The findings revealed a higher lateral shift in concrete compared to soils, ranging between 145 and 215 for concrete prepared with CEM II AS 42.5 N. Based on this investigation, a mean value of 180 was employed as the lateral shift to estimate wetting curves from the measured drying curves. Figures 2 depicts the estimated wetting WRCs.

3.3 Determination of permeability function

Methods for estimating permeability functions can be categorized into various groups, with proposed models often relying on statistical assumptions regarding pore distributions and interpretation of the water retention curve. In this recent study, the model introduced by Fredlund et al. (1994) was utilized. Their procedure involves numerical integration along the WRC, performed using PTC Mathcad software. The equation is expressed in the following form:

$$k_r(\psi) = \frac{\int_{ln\,(\psi)}^{b} \frac{\theta(e^y)-\theta(\psi)}{e^y}\theta\prime(e^y)dy}{\int_{ln\,(\psi_{aev})}^{b} \frac{\theta(e^y)-\theta_s}{e^y}\theta\prime(e^y)dy} \qquad (4)$$

where *b* is the upper limit of integration, *y* is a dummy variable of integration representing the logarithm of suction, θ' is the derivative of the WRC equation, e^y is the natural number raised to the dummy variable power.

Figure 3 illustrates the normalized permeability functions for M1 concrete mix, revealing a substantial reduction in permeability with increasing suction by several orders of magnitude. This result emphasizes that it is crucial to have more measured points in the very low suction region and the transition zone. Additionally, due to the significant hysteresis of the curves, the permeability coefficient of concrete is notably smaller during the wetting process at the same suction value.

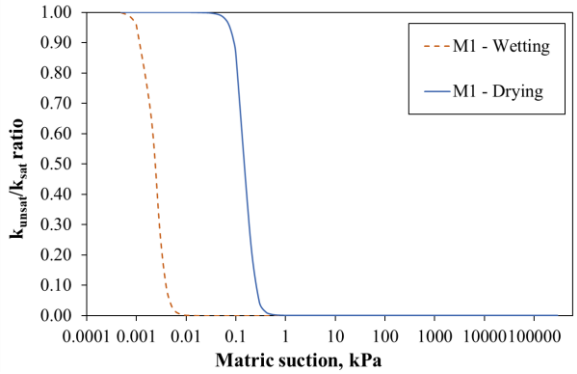

Figure 3. Normalized permeability functions for M1 concrete mixture.

4 NUMERICAL MODELLING OF STANDARD TEST FOR WATERTIGHTNESS

4.1 Geometry

Numerical analysis was conducted utilizing the Plaxis 3D Ultimate finite element software. To expedite calculations, the geometry was simplified by taking advantage of symmetry, modelling only a quarter of the sample (Figure 4). Tetrahedron finite elements were employed during mesh generation, with refinement determined by the water penetration location, as per previous studies. Specifically, refinement occurred on the vertical sides in the upper part of the model and on the horizontal plane on the quarter circle where water pressure was applied. In total, the model was divided into 24210 finite elements.

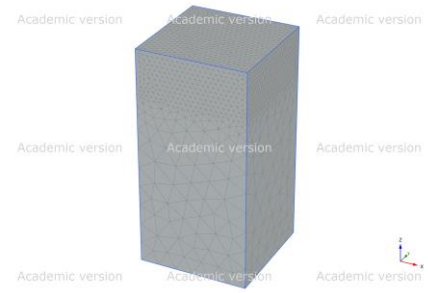

Figure 4. Model geometry of concrete specimen.

4.2 Material properties

Seepage analysis requires specific material properties, including saturated permeability coefficient, initial water conditions, and concrete functions such as WRC and permeability function. These parameters must be calibrated to ensure that the numerical model produces results consistent with the measured data. In the modelling process, the measured saturated permeability values were utilized, and isotropic seepage behaviour was assumed. For hydraulic model, the user-defined dataset was used.

Ensuring the accurate determination of the initial water condition, specifically the initial suction value, is crucial for obtaining appropriate results. In this study, the initial suction value was set to 200 kPa based on sensitivity analysis.

4.3 Boundary conditions

A water pressure of 5 bar was designated as the boundary condition on the quarter circle within the model, while closed seepage boundaries were assigned to the symmetry axes. Seepage within the concrete was computed as a transient flow, requiring specified time intervals. Given that the standard test for watertightness has a duration of 72 hours, the ultimate time step has already been established as 72 hours.

4.4 Results

The depth of water penetration, delineating the boundary between the saturated and unsaturated zones, was determined based on computed pore water pressure values. Figure 5 illustrates the negative pore water pressure values, defining the shape of water penetration for the M1 mix. Despite the model's arrangement suggesting that the maximum penetration depth would occur along the middle axis, the shape of penetration is irregular, resulting in the maximum depth being observed in a different section. Additionally, numerical uncertainties are evident along the boundary of the saturated and unsaturated zones and at the edge of the model. Therefore, further clarification of initial conditions and model setting is still needed.

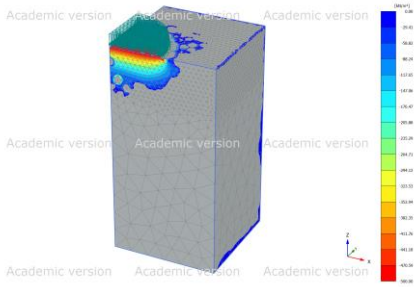

Figure 5. Shape of water penetration for M1 mix based on pore water pressure.

5 CONCLUSIONS

This study aims to furnish input data for modelling water flow in building materials, particularly concrete. A series of laboratory tests were conducted, examining different concrete mixtures for water retention using the sand/kaolin box method, pressure membrane

extractor, and vapor equilibrium technique. Due to the intricate pore system of concrete, the bimodal form of the Fredlund and Xing (1994) model was employed to approximate the water retention curve based on measured data points.

To establish the wetting water retention curve, a lateral shift was implemented, employing a shift value determined from prior studies. It has been demonstrated that the unsaturated permeability function for concrete can be defined using the Fredlund et al. (1994) model. The results emphasized that even a minor alteration in suction can lead to a significant reduction in permeability for concrete.

The numerical modelling has led to the conclusion that both the measured data and the calculated functions are applicable for modelling water flow in concrete. However, further investigations are required to address the effect of changes in initial suction value on the results of modelling.

ABSTRACT: The volume of solid waste has immensely increased over the last decades in Kathmandu Valley (KTMV), the main urban center of Nepal. The Sisdol site was initially developed as a sanitary landfill site in 2005 to accommodate only 150 thousand tons of municipal solid waste (MSW) for 2.5 years however it received more than 3 million tons (~6 million cubic meters) of MSW over the period of 14 years until it turned into a vulnerable dumpsite. When extending more than 300 m horizontal distance, about 80 m high waste dump has already been reached, which created multiple problems in surrounding areas. Therefore, a slope stability analysis of the waste dump was carried out using SLOPE/W before designing the post-closure and land utilization plan of the dumpsite and surrounding area. The factor of safety (FoS) was calculated in three different critical sections of the dumpsite for both static and seismic loading cases. The FoS obtained in sections for the earthquake loading case confirms the slope of the waste dump seems unstable, which is also in compliance with the observation made at the site. The findings of the slope stability analysis in this study indicate the risk of sliding of the dumpsite along the road connecting the new Bancharedanda Landfill, which needs to be minimized with proper stabilization measures before post-closure and sustainable utilization of land in the Sisdol dumpsite.

RÉSUMÉ: Le volume de déchets solides a énormément augmenté au cours des dernières décennies dans la vallée de Katmandou (KTMV), le principal centre urbain du Népal. Le site de Sisdol a été initialement développé comme site d'enfouissement sanitaire en 2005 pour accueillir seulement 150 000 tonnes de déchets solides municipaux (MSW) pendant 2,5 ans, mais il a reçu plus de 3 millions de tonnes (~ 6 millions de mètres cubes) de MSW au cours de la période de 2005. 14 ans jusqu'à ce qu'il se transforme en une décharge vulnérable. En s'étendant sur plus de 300 m de distance horizontale, on a déjà atteint une décharge d'environ 80 m de haut, ce qui a créé de multiples problèmes dans les zones environnantes. Par conséquent, une analyse de stabilité de la pente de la décharge a été réalisée à l'aide de SLOPE/W avant de concevoir le plan de post-fermeture et d'utilisation des terres de la décharge et de ses environs. Le facteur de sécurité (FoS) a été calculé dans trois sections critiques différentes de la décharge pour les cas de chargement statique et sismique. Le FoS obtenu par coupes pour le cas de chargement sismique confirme que la pente de la décharge semble instable, ce qui est également conforme à l'observation faite sur le site. Les résultats de l'analyse de stabilité des pentes dans cette étude indiquent le risque de glissement de la décharge le long de la route reliant la nouvelle décharge de Bancharedanda, qui doit être minimisé par des mesures de stabilisation appropriées avant la post-fermeture et l'utilisation durable des terres de la décharge de Sisdol.

Keywords: Dumpsite stability; municipal solid waste; leachate; post closure; SLOPE/W.

1 INTRODUCTION

Solid waste management (SWM) has become a major concern for municipalities of developing countries, like Nepal. With rapid and uncontrolled urbanization, lack of public awareness and poor management by municipalities has intensified environmental problems in towns of developing countries, where waste management is still limited to inadequate disposal (dumpsites on non-sanitary waste disposal sites) (Kaza et al., 2018; Ferronato and Torretta, 2019; Ma et al., 2022). For example, the 18

municipalities of Kathmandu Valley (KTMV), the main urban center of Nepal generates 1,262 tons per day (t/d) of municipal solid waste (MSW), roughly 25 percent of total MSW of Nepal, and 15 percent of KTMV's MSW is still uncollected (World Bank, 2023). At present, more than 800 tons/day of MSW from KTMV is being disposed of at the Sisdol dumpsite, which is about 63 percent of total produced solid waste (World Bank, 2023). The site was initially developed as a short-term sanitary landfill site in 2005 for two and half years as shown in Figure 1a. However, in the name of the capacity extension, waste was disposed of without a liner, leachate collection, treatment facilities and landfill gas management facilities for nearly 14 years until it was turned into a highly unstable vulnerable dumpsite as shown in Figure 1b (Pathak and Shahi, 2021).

Dumping of solid waste in non-engineered landfills is very common in developing countries. It generates leachate, a toxic by-product that can migrate into surface water and percolate into the groundwater (Costa et al., 2019; Ma et al., 2022). As the dominant waste fractions in the cities of developing countries is organic waste with high moisture content, it has more leachate generation potential (Zairi et al., 2014). Moreover, poor surface water management also adds the leachate volume significantly in such a dumpsite. A similar case can be observed in the Sisdol dumpsite, where the spring water sources were not diverted during the expansion of the dumpsite area and hence entered into the dumpsite, which is not only deteriorating the water quality and surrounding environment (Figure 1c) but also leads instability and sliding failure in dumpsite due to increase of pore pressure, increase unit weight and decrease the strength of body of waste.

Slope failure in MSW dumpsites is a common environmental disaster that poses serious ecological and health risks (Shu et al., 2022). In several cases poorly designed and operated landfills without considering several aspects of MSW mechanical behavior have caused landfill failures. The landfills of Rumpke in the USA (Zekkos, 2005), Dona Juana in Columbia (Caicedo et al., 2002), Payatas in Philippines (Merry et al., 2005) and Leuwigajah dumpsite in Indonesia (Koelsch et al., 2005) are examples of such catastrophic events, which doesn‘t only cause heavy economic losses and human casualties but also create immense sources of environmental pollution. A similar situation may have happened in the Sisdol dumpsite, which needs to be analysing the slope stability of the dumpsite before severe consequences in the surrounding environment. As the Sisdol dumpsite has already been saturated and overloaded, its post-closure management is needed and should be carried out soonest possible.

(c)

Figure 1. Sisdol Landfill site before operation in 2005(a), Existing situation of Sisdol dumpsite (b), Leachate flow at Sisdol dumpsite (c)(Source: SWMTSC/GoN).

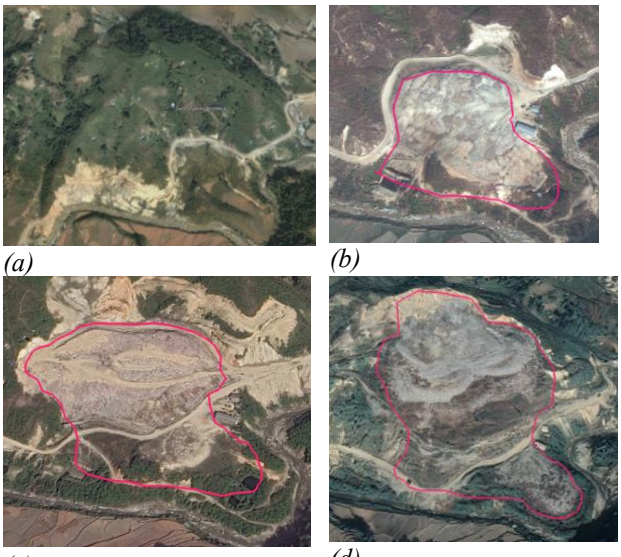
For post-closure management, stabilizing the steep slope of the Sisdol dumpsite is required. Therefore, this paper applies the SLOPE/W to carry out the slope stability analysis of the Sisdol dumpsite. For this purpose, we calculated the factor of safety (FoS) in three critical sections of the waste dump for both static and seismic cases using the procedures of slices method as described by Morgenstern-Price.

2 METHODS

2.1 Study Area

The dumpsite is located at Ward 2 of Kakani Rural Municipality about 18 km north-west from Kathmandu city centre, which is located very close to the Kolpu River.

Figure 2 shows the status of the Sisdol dumpsite before the start and after operation over the period of 2003 to 2022. When extending nearly 300 m horizontal distance, more than 80 m vertical height has already been reached. Moreover, there is an access road to connect the Bancharedada landfill site, a new landfill site about 3 km from this dumpsite. About 200 m length of road section lies on the existing dumpsite. Based on the topographic map of the original ground, it seems about 20m to 25 m compacted old solid waste fill below the existing



(a) *(b)* *(c)* *(d)*

Figure 2. Google image showing status of Sisdol dumpsite before and after operation over the period of 2003 to 2022-October, 2003- before construction (a), April 2010 (b), October, 2014- extension of dumpsite (c), November, 2022- turned into highly vulnerable dumpsite (d). Red line is boundary of dumpsite.

access road as shown in Figure 2d. In addition to this, the road is further critical due to the steep slope of the solid waste dump above access road. The protection of a slope of about 80 m high solid waste dump above the access road is very important for the use of this access road in an uninterrupted way for a long time.

2.2 Topographic survey of an existing dumpsite

A detailed topographic survey was conducted using a total station to capture and record the topography of the dumpsite together with both manmade and natural features which enabled in carrying out detailed assessment of slope failures of dumpsite and roadside slope.

2.3 Slope stability analysis of dumpsite

The geometry of the dump changes continuously due to the decay of organic materials, degradation of inorganic solids, and addition of waste daily. The top part is a relatively unconsolidated mix of waste and soil, whereas the bottom layer consists of the slightly consolidated and degraded solid waste mixed with soil. The slope stability issues on the Sisdol dumpsite are analyzed using SLOPE/W for both static and seismic loading cases as the study area is highly vulnerable to earthquakes. It was carried out in the three different critical sections as shown in Figure 3.

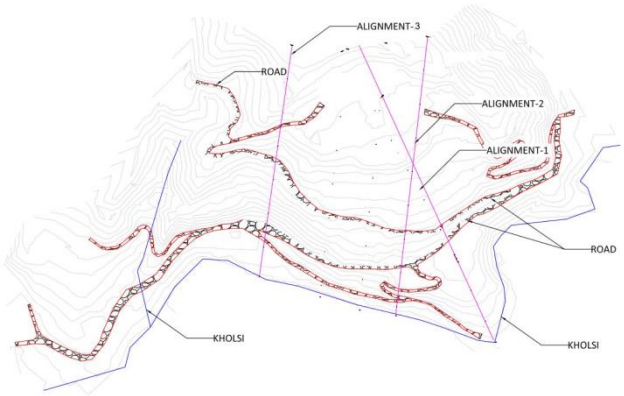


Figure 3. Topographic map of Sisdol dumpsite and three critical sections for stability analysis.

The geometry for the stability analysis is prepared based on the recent survey conducted on the dumpsite. In the Sisdol dumpsite, the MSW was disposed of from 2005 and deposited till 2007 to reach about 20 m high before its closure. In 2011, disposal of MSW again was continued at the same place due to the lack of alternative disposal sites and extended till 2022 to reach its total height of up to 80 m. Therefore, the dumpsite in the model has been divided into four layers, including the geological layer, depending upon the age of deposited MSW (Table 1).

Table 1. Summary of soil properties used in stability analysis of dumpsite.

Solid waste layer	**Unit Weight (kN/m^3)**	**Eff. Cohesion, c' (kPA)**	**Eff. Friction Angle (ϕ')**
Top layer (<20 m)	8.6	29.1	15
Middle layer (20 m - 50m)	12	18.3	22
Bottom Layer (>50m)	14	17	32
Geological layer	18	12	38

As no geotechnical explorations are carried out during this study, literature review and experience with similar waste materials of similar regions have been used to adopt the pertinent shear strength properties and unit weight of the MSW (Feng et al., 2017; Machado et al., 2010; Ramaiah et al., 2017; Iqbal et al., 2022). Feng et al. (2017) reported that the friction angle and cohesion varied from (15.7 degrees, 29.1 kPa) to (21.9 degrees, 18.3 kPa) as the depth increased from 4 to 16 m, while the unit weight increased from 7.2 and 12.5 kN/m3. According to Ramaiah et al. (2017), with the aging of the solid waste, a decrease in cohesion and an increase in

friction angle were observed in the MSW samples collected from the Ghazipur and Okhla dumps at Delhi. The shear strength of the MSW obtained in the above studies was lower than the reported values in developed countries because of the less fibrous materials and more organic materials in the MSW in the cities of developing countries, which is a similar case in our context and very relevant to use these geotechnical properties of MSW for stability analysis of Sisdol dumpsite.

3 RESULTS AND DISCUSSION

3.1 Existing situation of Sisdol dumpsite

Google imagery and field observations show nearly 300 meters of extension from the center of the previous landfill site. Although the government initially developed a sanitary landfill site to accommodate only 150 thousand tons of MSW for 2.5 years, it received more than 3 million tons (~6 million cubic meters) of MSW over 14 years (Figure 4) until turning into a vulnerable dumpsite. Disposal of an immense volume of MSW with high organic fractions and poor operation of the Sisdol dumpsite not only polluted water and soil in surrounding areas but also adversely affected the people in nearby communities due to the unpleasant odor and diseases borne vectors from the dumpsite.

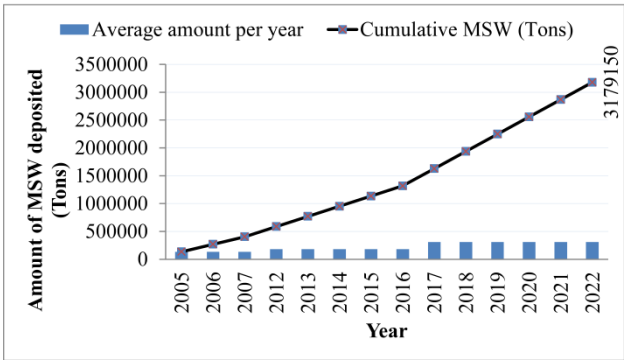

Figure 4. Annual and cumulative volume of MSW disposed at Sisdol dumpsite over 14 years period.

NAST (2020) reported a high concentration of toxic metals (heavy metals) such as arsenic and cadmium. The reason for the maximum arsenic and cadmium concentration in surface water may be probably due to the direct discharge of leachate in the river (Kolpu River). Similarly, BOD and COD values have also significantly increased from 2009 to 2018 in the leachate of the Sisdol dumpsite. Amano et al. (2021) also reported high levels of Cadmium (Cd) and turbidity in surface and groundwater sources within the surrounding area of the waste landfill site in Kumasi, Ghana. The test results of soil samples near the Sisdol dump site also reveal that cadmium, lead, and nickel in the soil are beyond the recommendations required for agricultural land.

3.2 Findings of stability analysis

The result of the stability analysis is presented in Figures 5(a-g) for two cases using MSW shear strength parameters respectively. During the monsoon season, after MSW gets saturated mass movement has been frequently observed.

As shown in the following figures, the slope profiles under static loading conditions seem stable since FoS is above 1 for all sections. And, for section-2, the FoS is higher than 1 even in seismic loading case. However, FoS in the section-1 and section-3, the FoS for the seismic loading case is less than 1, indicating unstable during earthquake, which is also in compliance with the observation made at the site.

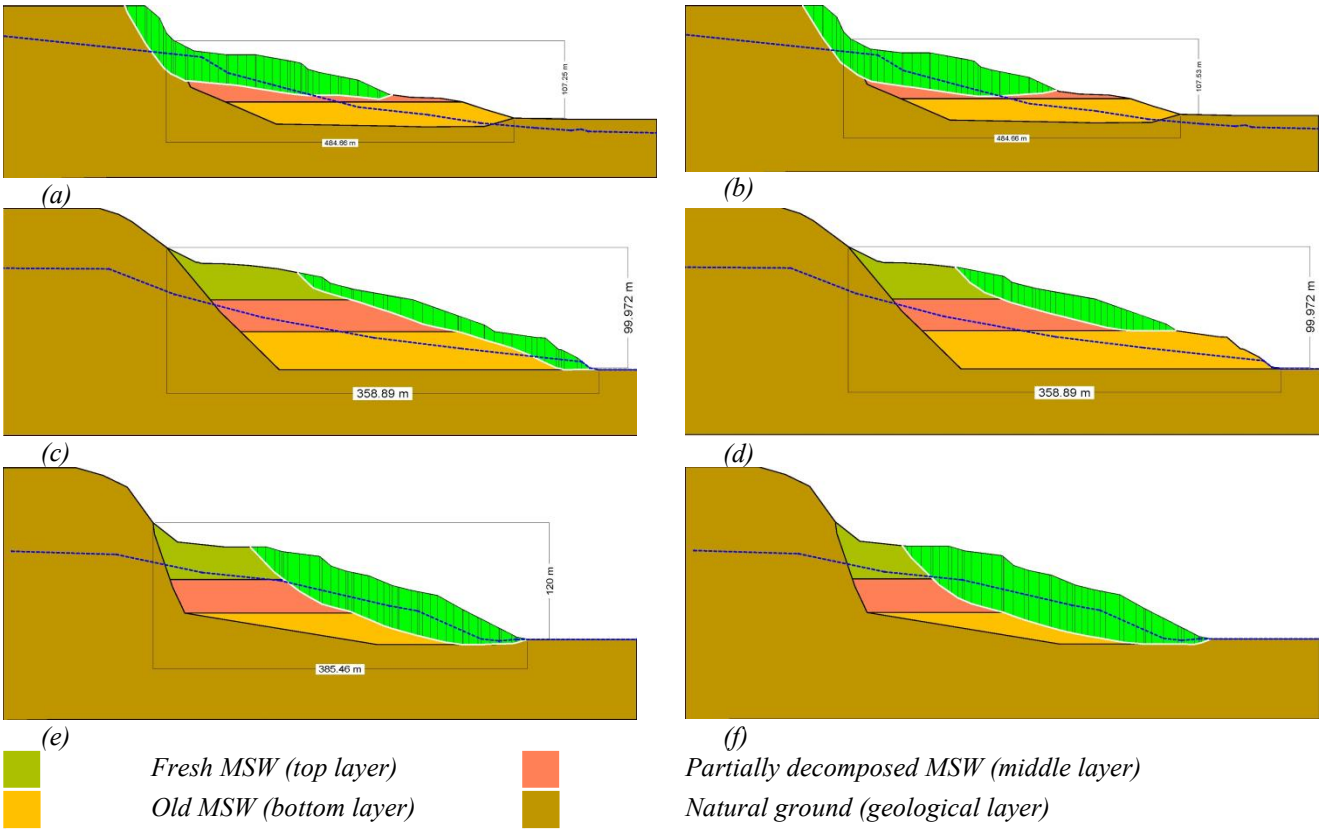

Figure 5. Stability analysis at different critical sections of the Sisdol dumpsite using Morgenstern-Price method-Factor of Safety (FoS) at section-1 for static loading case=1.37 (a), FoS at section-1 for seismic loading case=0.89 (b), FoS at section-2 for static loading case=1.96 (c), FoS at section-2 for seismic loading case=1.28 (d), FoS at section-3 for static loading case=1.52(e), FoS at section-3 for seismic loading case=0.96 (f).

Over the last few years, there was a frequent slope failure along section-3 in line with the modelling results. This supports the assumption of the materials parameters of the landfill material for stability analysis. However, the properties of dump materials change with depth and time. The geometry of the slope modelled may change in a short time span. A detailed geotechnical analysis is required to evaluate the exact geotechnical and other field properties of solid waste layers in different depths and locations of the Sisdol dumpsite for precise stability analysis which helps for both stabilizing road section on the existing dumpsite and sustainable post-closure plan. The slope stability analysis in this study indicates the risk of sliding the dumpsite along the road connecting the new Bancharedanda landfill site, which needs to be minimized with proper stabilization measures before post-closure and sustainable utilization of land in the Sisdol dumpsite.

4 CONCLUSIONS

This paper assessed how a sanitary landfill site has been gradually turned into a highly vulnerable dumpsite over the period of 2005 to 2022 with the help of satellite images, field data and observation. The adverse impacts on agricultural land, water and the surrounding communities due to poorly managed dumpsites were assessed. Moreover, slope stability analysis of the Sisdol dumpsite was also carried out using the limit equilibrium software, SLOPE/W from Geostudio before developing post-closure and land utilization plans for the dumpsite and surrounding area. The factor of safety obtained at the section (section-1 and section-3) with a steep slope seems unstable. In recent years there was a slope failure along the same section indicated by modelling results, which supports the assumption of the properties of waste materials in this study. However, detailed investigations for the evaluation of the geotechnical properties of materials in waste dumps are recommended.

The slope stability analysis in this study indicates the risk of sliding the dumpsite along the road connecting the new Bancharedanda landfill site. The risk should be minimized with proper stabilization measures along the slope profile as well as within the road itself. The steep slope at the hillside of the road as in the critical section should be trimmed to flatten the slope. The flattened slope should be supported by a gabion wall at the toe and a series of wooden or

concrete posts are to be driven to reinforce the outer layer of the waste fill before post-closure design.

ABSTRACT: Groundwater lowering in the inner city of Copenhagen, Denmark, is generally not permitted due to the sensitive nature of the foundations of existing buildings, and to avoid spreading existing groundwater contamination. Outside the inner-city, groundwater lowering is often undesirable due to risks towards settlement of infrastructure, nature and contamination. To ensure dry conditions during construction of shafts and other large excavations, and to protect nearby buildings as well as the environment, groundwater control systems have been established in each of the 28 underground stations/shafts of the Cityringen metro, including the Nordhavn and Sydhavn extensions. The temporary groundwater control systems have comprised of cut-off walls and a network of pumping and recharge wells. There is often a notable discrepancy between the discharge rates predicted by modelling in the design phase, and those measured during construction. Possible explanations for this discrepancy include differences between the modelled design and the actual constructed dewatering system, quality of the cut-off wall, inadequate ground investigations or misinterpreted results, pressure-dependent ground permeability and uncertain assumptions regarding anisotropy. This paper describes the basis for the dewatering activities and the outcome of the three-dimensional (3D) groundwater models developed during the detailed design and compares this with the observed groundwater monitoring data. Inconsistencies between the design and observed behaviour of the groundwater control systems are reviewed and the potential reasons are investigated.

RÉSUMÉ: Le rabattement de nappe dans le centre-ville de Copenhague n'est généralement pas autorisé en raison de la nature sensible des fondations des bâtiments existants et pour éviter la propagation de contamination existante des eaux souterraines. A l'extérieur du centre-ville, le rabattement de nappe est souvent indésirable en raison du risque vis-à-vis d'affaissement d'infrastructure, des zones naturelles et de la contamination. Pour garantir des conditions sèches lors de la phase de construction de puits et d'autres larges excavations, et pour protéger des bâtiments avoisinants ainsi que l'environnement, des systèmes de contrôle des eaux souterraines comprenant à la fois des parois étanches et un réseau de forages de pompage et de réinfiltration ont été établis dans chacune des 28 stations souterraines/puits du métro « Cityringen », incluant les extensions Nordhavn et Sydhavn. Il existe souvent un écart notable entre les débits de pompage prédits par modélisation dans la phase de conception et ceux observés pendant la construction. Les explications possibles pour cet écart comprennent des différences entre le design modélisé et le système de rabattement de nappe construit, la qualité de la paroi étanche, des investigations inadéquates du sous-sol ou des résultats mal interprétés, une perméabilité du sol dépendante de la pression et des hypothèses erronées concernant l'anisotropie. Cet article décrit le fondement pour les activités de rabattement de nappe et le résultat des modélisations 3D d'écoulement des eaux souterraines développées pendant la conception détaillée, et compare cela avec les données de suivi de niveaux des eaux souterraines observés. Les inconsistances entre la conception et le comportement observé des systèmes de contrôle des eaux souterraines sont examinées et les raisons potentielles sont étudiées.

Keywords: Groundwater control; 3D groundwater modelling; Copenhagen metro; limestone, urban hydrogeology.

1 INTRODUCTION

The expansion of the metro network in Copenhagen has taken place over the last 12 years, has entailed the construction of 28 underground structures (stations and shafts), with abstraction and recharge of groundwater via dedicated groundwater control systems. A large amount of data has been collected in the monitoring database (Kronos) that was in operation during and after construction. This paper aims to analyse the information gathered, and then give a first evaluation of the substantial discrepancy between the yield rates predicted by modelling in the detail design phase and those measured during construction. This paper also offers some explanations and hypotheses that can be further confirmed and extended in future ad-hoc papers/studies. Previous publications on this topic include Bonde et al. (1997), Raben-Levetzau et al. (2004), Bock and Markussen (2007) and Markussen et al. (2019).

2 COPENHAGEN GROUND CONDITIONS

The geology of Copenhagen, see Figure 1, comprises glacial clay till and meltwater sand/gravel deposits overlying Paleocene limestone (Copenhagen Limestone and Bryozoan Limestone). This geology forms the main geological unit in which the metro tunnels and stations are constructed.

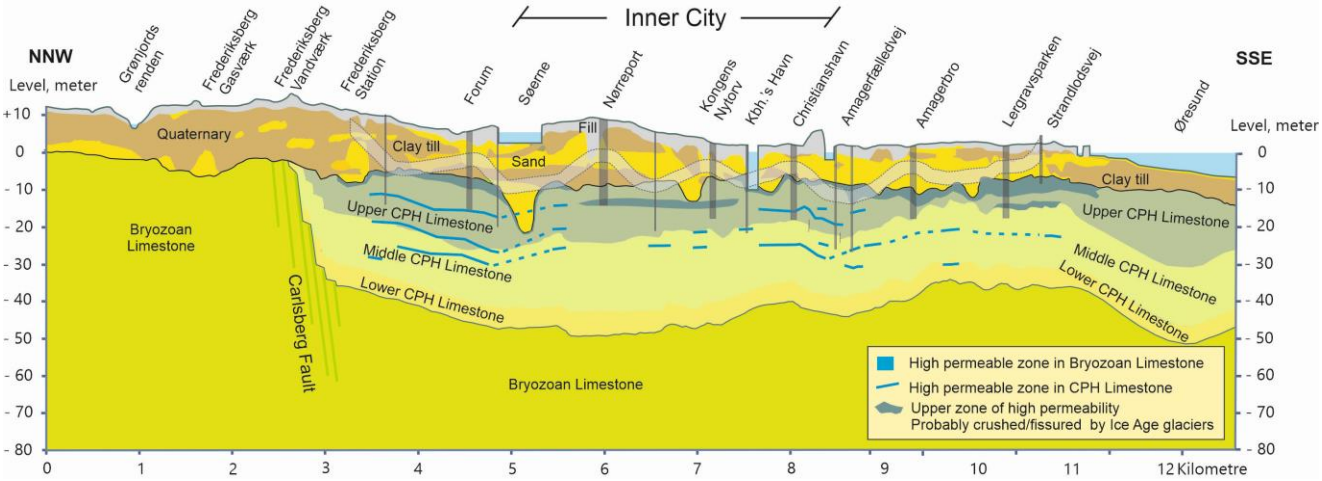

Figure 1. Copenhagen ground conditions in a profile along the M1 metro line.

The primary aquifer in the region is the upper part of the limestone, together with sand and gravel deposited directly above the limestone. The average hydraulic conductivity of the limestone generally falls in the range from 10^{-6} m/s to 10^{-4} to m/s with the majority of the flow occurring in fractures. The piezometric level of the aquifer is typically a few meters below the ground surface. Secondary aquifers are present in the overlying glacial and marine sand and gravel deposits and within the fill. Because the metro stations are situated below the groundwater table, significant dewatering works have been required for their construction.

There are several NNW-SSE oriented faults and folds in the region, the most notable in Copenhagen being the Carlsberg Fault and the Svanemølle Fault. These are known to have significant impact on limestone transmissivity (Frederiksen et al., 2002).

The primary aquifer is a source for domestic water supply with abstraction taken place in the Carlsberg fault zone where the water bearing-capacity is high. Parts of the metro alignment lie within the catchment zone associated with this abstraction.

3 COPENHAGEN METRO

The Copenhagen metro is a light rail system running 24/7 within the municipalities of Copenhagen, Frederiksberg and Tårnby. There are presently four operational lines. M1 and M2 opened in 2002 with further extensions completed in 2003 and 2007. Seventeen stations were then added in 2019, together with the M3 'circle line' (referred to as Cityringen, i.e. CR). Two of the M4 line stations opened in 2020 (referred to as Nordhavn, i.e. NH) while the remaining five stations are under construction and due to become operational in 2024 (referred to as Sydhavn, i.e. SH). This paper focuses on the M3 and M4 underground stations, and describes the temporary dewatering required to enable their construction.

The typical underground station footprint in plan is 60x20m though larger footprints are needed for crossovers or run-over tracks. The typical excavation

depth is between 18m to 25m, though a few CR stations and shafts are as deep as 35m such as the Marmorkirken and Nørrebroparken stations.

4 GROUNDWATER CONTROL SYSTEM

The city of Copenhagen was founded more than 800 years ago. It is situated at the coast, and large parts of the inner city are founded on fill as the city reclaimed land from the sea. Many residential and public buildings are old and are often listed as historical monuments. The old harbour, and the many lakes and canals, form an important part of the city identity.

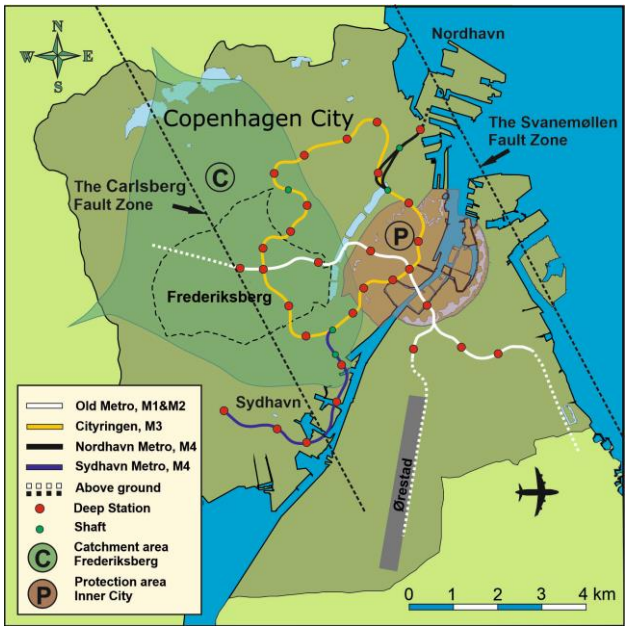

Figure 2. Copenhagen metro system.

Dewatering of deep excavations can cause:

- Settlement damage to buildings which are founded directly in fill.
- Damage to buildings which are founded on timber piles or other wooden constructions.
- Draining of city lakes
- Damage to urban drinking water interests due to pollution spreading and saltwater intrusion.
- In 1991 the Copenhagen city authorities decided to limit groundwater lowering in the entire inner city area where the risk of settlements and deterioration of wooden foundations is greatest, see Figure 2. In this area, any lowering of the upper groundwater to more than 0.3m above sea level is not allowed.

To ensure dry conditions in excavations during metro construction, and to avoid groundwater lowering in the surrounding area, a groundwater control system was established for each deep excavation. The system comprised of cut-off walls and a network of pumping and recharge wells; see conceptual layout in Figure 3.

Groundwater levels were primarily controlled by the installation of impermeable reinforced concrete secant pile cut-off in the quaternary layers and the upper part of the limestone, constructed to below excavation level. This provided a complete cut-off in the glacial layers and resulted in seepage into the excavation only occurring from the limestone. The actual cut-off depth was determined by results from pumping tests and flow logs combined with groundwater modelling.

The amount of water pumped from the sites had to be balanced by pumping back a similar amount of abstracted water into the limestone outside the secant pile wall, via the construction of recharge wells.

Monitoring was an important part of the groundwater control operation. The purpose of monitoring was twofold. Firstly, the monitoring was necessary for the actual groundwater control. Regular monitoring of groundwater levels in monitoring wells, combined with data on dewatering pumping and recharge volumes were necessary to evaluate the effect of groundwater lowering. These data were also a necessary input to the calibration of the groundwater model. Secondly, an efficient system of regular reporting to the authorities was necessary both to meet demands and to ensure efficient and professional communication with the authorities. The monitoring used the Kronos monitoring database system developed by Geodata (Rabensteiner et al. 2015).

5 DATA SET SUMMARY

Ground investigations (GI) were planned by Metroselskabet (MS) and/or their consultants to form the basis for concept design, Environmental Impact Assessment (EIA) and tender design. All the metro projects were tendered as “design and build” and therefore the contractors have often supplemented with additional GI.

For a standard station on CR, NH and SH the dewatering-related GI typically included three cored boreholes to well below the base of the excavation, one or two long-duration pumping tests, complete with multiple observation wells, three short duration pumping tests and four flow logs. These were typically made both in open hole and in the screened borehole. The GI was interpreted by both the consultants and the contractors.

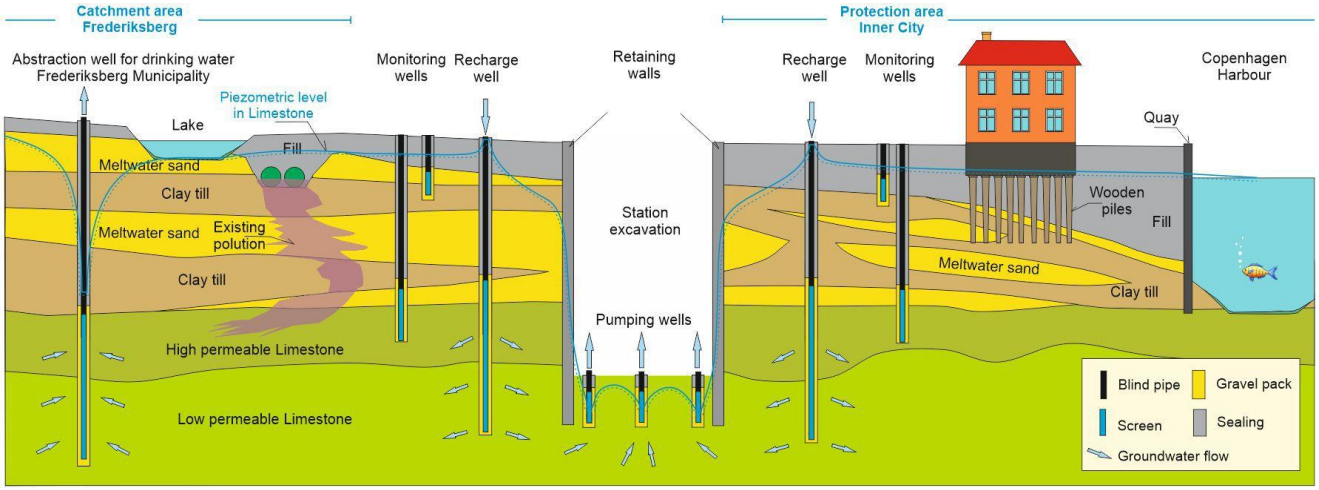

Figure 3. Typical dewatering system for metro station/shaft construction in Copenhagen.

For approximately half the stations on CR, the contractor supplemented the GI with additional boreholes and one long-duration pumping test. For NH and SH only limited additional investigations were made by the contractor.

Both MS's consultants and contractors developed their own 3D groundwater models for EIA, tendering and detailed design respectively. All models were calibrated in transient mode against the long duration-pumping tests. For CR and SH the consultant used GMS Modflow, while the contractor used Feflow for CR and GMS Modflow for SH.

The consultant used the models to determine the required minimum depth of retaining walls, expected yields, requirements of recharge rate, and locations to be reserved for recharge etc.

The contractors used the models as part of their detailed design of the dewatering system with respect to quantity and location of pumping and recharge wells, expected yields to be used for the design of water treatment, and authority applications.

6 COMPARISON OF YIELD RATES

The simulated yields (from Hydrogeological Design Reports) and measured yields (from Kronos) for the 28 underground stations/shafts were compared. The relationship between the two datasets is presented in Figure 4 and Figure 5. The yields refer to the total pumped yields from all pumping wells at the different locations.

The impact of factors such as required groundwater lowering, transmissivity, depth of cut off walls below the excavation, quality of cut off walls, limestone excavation depth, number of pumping tests, size of excavation etc. was assessed.

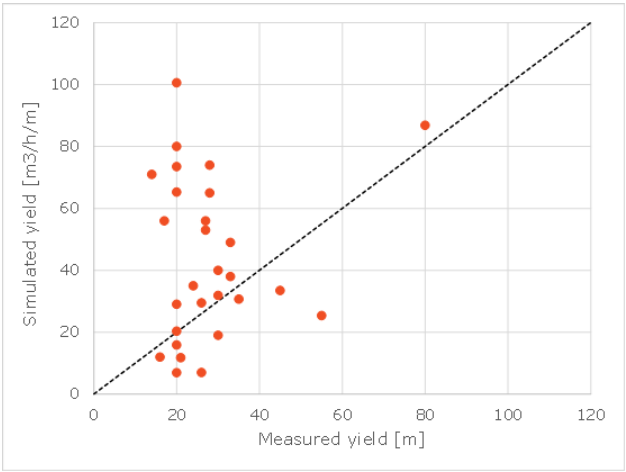

Figure 4. Relationship between simulated and measured yield.

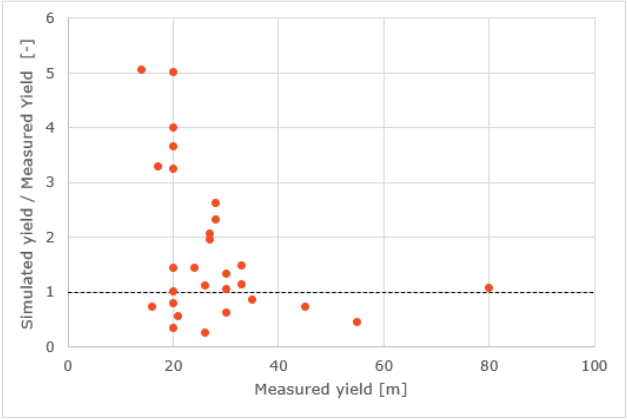

Figure 5. Relationship between simulated / measured yield and measured yield.

Figure 6 depicts the simulated and measured pumping yields when plotted against groundwater lowering.

As can be seen in the figure, the recurrent measured yield is c.20-30 m^3/h, seemingly independent of the required drawdown. The simulated yields are more variable but (besides a few exceptions) and often significantly higher than the measured ones.

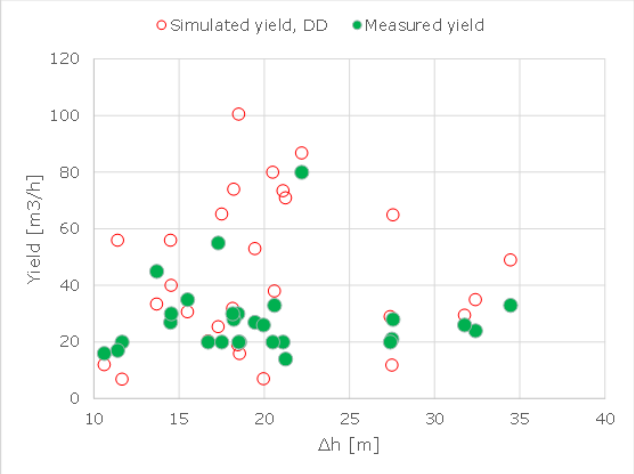

Figure 6. Relationship between simulated/measured yields and groundwater lowering.

In Figure 7, the pumping yields per meter of drawdown are plotted against groundwater lowering. No observable relationship can be seen between the yields and required drawdown.

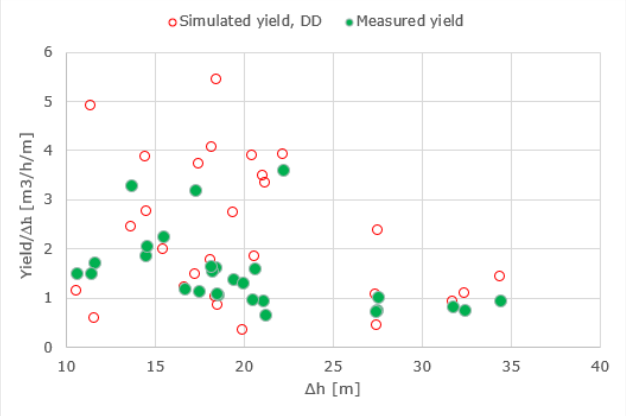

Figure 7. Relationship between simulated/measured yields per meter of groundwater lowering and groundwater lowering.

Similar to the lack of clear relationship between yield and required drawdown, no observable relationship between the yields and the other assessed factors was found.

7 DISCUSSION

A possible explanation for the recurrent 20-30 m^3/h measured yields may be that the deeper limestone, below cut-off level, is relatively homogenous across the whole Copenhagen area, in the locations where the underground metro stations have been built. The inflows are therefore steady once the upper glacially disturbed and more permeable part of the limestone is cut off. It shall be noted that the type of limestone formation being dewatered (e.g. Upper Copenhagen Limestone, Middle Copenhagen Limestone or Bryozoan Limestone) has no clear impact on the yields.

The measured yields for three stations/shafts, Mozart's Plads (45 m^3/h), Enghave Brygge/Ørestedsværket (55 m^3/h) and Sluseholmen (80 m^3/h) stations of the SH extension, exceeds the standard range. Possible explanations for the higher inflows at these locations may be proximity to geological structures (faults) and/or to the harbour.

Though no clear relationship between excavation size (area) and yield can be observed from the dataset, most excavations are of similar size with the exception of Enghave Brygge/Ørestedværket, which is twice the size of the other stations/shafts, and size is therefore likely to be part of the reason for the higher yields in this location.

At Mozart's Plads, another reason for the observed higher yields is inflow to the adjacent shallow excavation which contributed significantly to the overall yield. Investigations and dewatering design for shallow excavations in addition to the main shaft dewatering should therefore not be overlooked.

The data analysis shows that there is a notable discrepancy between simulated and measured yields. The horizontal to vertical permeability ratio (K_v/K_h) utilised in the simulation models is a key factor to estimate yields. In the Cityringen models, the assumption has typically been that K_v is a factor of 5 or 10 less than K_h which typically equates to K_v in the order of 10^{-6} m/s. Based on pumping tests and modelling of limestone in Malmø, which is similar to limestone in Copenhagen, the K_v value in the limestone has been estimated to be $3x10^{-7}$ m/s (Citytunnelkonsortiet, 2000). This could explain the deviation between simulated and measured yields. Another possible explanation is pressure dependant permeability, i.e. water bearing fissures contracting when the pressure is reduced, as postulated by Markussen et al. (2019).

8 CONCLUSIONS

Following the review of dewatering systems for the construction of 28 underground metro stations/shafts in the central part of Copenhagen, it is noted that the measured yields are relatively steady, around 20-30 m^3/h, with no observable relationship between the yields and factors such as transmissivity or required drawdown. This may be due to the deeper limestone

below cut-off level being relatively homogenous. With this in mind, determining the depth to less permeable limestone e.g. through flow logs, is considered key to assessing the required cut-off depth and thus achieving manageable yields.

The size of excavation, proximity to geological features and the harbour, are likely to be contributing causes to inflows exceeding the standard range.

Uncertain assumptions regarding anisotropy and pressure dependent permeability may explain the deviation between simulated and measured yields. Additional studies are planned to determine what 3D model parameters need to be adjusted for the models to better match the measured yields.

Despite the observed inconsistences between simulated and measured yields, 3D groundwater modelling remains a powerful tool to design groundwater control systems and provides an essential requirement to obtain the permits required by various authorities to carry out dewatering in urban areas.

ABSTRACT: Red mud (RM) is an extractive waste from Bayer process in alumina production. The most conventional methods of RM disposal are tailing dams, or dry storage, both of which raise environmental concerns due to the high alkalinity of RM and the presence and leaching of potentially hazardous elements (PTEs). Due to its fine-grained nature and poor mechanical properties, as well as leaching of potentially hazardous substances, RM cannot be used by itself. Properties of the RM can be improved, by mixing it with hydraulic or pozzolanic binders, such as calcareous ashes or steelmaking slag, to produce mechanically stable and durable composites for earthworks. On the other hand, RM can also serve as an immobilization additive for remediation of contaminated soils. Two different approaches for useful utilization of RM are presented based on results of laboratory research and a real case study, opening of new possibilities for conserving natural resources and reducing environmental hazards of RM deposits.

RÉSUMÉ: La boue rouge (RM) est un déchet extractif issu du procédé Bayer de production d'alumine. Les méthodes les plus conventionnelles d'élimination des MR sont les barrages à résidus ou le stockage à sec, qui tous deux soulèvent des préoccupations environnementales dues à l'alcalinité élevée des RM et au lessivage d'éléments potentiellement dangereux (PTEs). En raison de sa nature à grains fins et de ses mauvaises propriétés mécaniques, ainsi que de la lixiviation de substances potentiellement dangereuses, la RM ne peut pas être utilisée seule. Les propriétés du résidu de la RM après extraction peuvent être améliorées, en le mélangeant avec des liants hydrauliques ou pouzzolaniques, tels que des cendres calcaires ou des scories sidérurgiques, pour produire des composites mécaniquement stables et durables pour les travaux de terrassement. D'autre part, la RM peut également servir d'additif d'immobilisation pour l'assainissement des sols contaminés. Deux approches différentes pour une utilisation utile de la RM sont présentées sur la base des résultats de recherches en laboratoire et d'une étude de cas réel, ouvrant de nouvelles possibilités pour la réduction des dépôts de la RM conservant ainsi les ressources naturelles et réduisant les risques environnementaux liés aux gisements problématiques de la RM.

Keywords: Red mud; recycling; geotechnical composites; environment.

1 INTRODUCTION

Red mud (RM) is an extractive waste from Bayer process in alumina production. The process is based on digestion of the bauxite ore in a hot NaOH solution. The alumina-rich solution is then separated from the solid residues, which consist of Fe and Al (hydr)oxides and are referred to as RM. Production of RM worldwide amounts to more than 160 million tonnes annually (Zalar Serjun et al., 2018, Zeng et al., 2020, IAI, 2022). The large amount of generated RM creates several disposal problems due to the absence of appropriate storage methods (Jha et al., 2020). The most conventional methods of RM disposal are to pump the slurry into ponds behind "tailing dams", or disposal of dewatered RM by dry stacking. In both approaches, large areas of land are needed (Samal, 2021), posing a threat related to potential instability and collapsing of RM deposits and raising environmental concerns due to the high alkalinity of RM, the presence and leaching of PTEs, and alkaline airborne dust emissions (Jha et al., 2020, Samal, 2021). Potential applications for the utilisation of RM need to be explored to minimise the associated negative environmental impacts (Zalar Serjun et al., 2018, Jha et al., 2020). However, the chemical and physical properties of RM vary considerably, reflecting their different sources (differences in bauxite composition and processing plant operation). This means that the potential recycling of each deposit of RM has to be considered separately, in its own case study (Oprčkal et al., 2020). RM is not only a source for recovery of metals, such as Fe, Ti, Mn, Na, K and also rare earth elements, such as Sc, Y, Hf, Zr, and Ti (Samal, 2021), but can also be a valuable construction material (Jha et al., 2020, Samal, 2021). Due to its fine-grained nature and poor mechanical properties, as well as the environmental concerns, RM cannot be used as construction material by itself.

The properties of the RM residue can be improved, by mixing it with hydraulic or pozzolanic binders, such as calcareous ashes or steelmaking slag, to produce mechanically stable and durable composites for earthworks. On the other hand, RM can also serve as an immobilization additive for remediation of contaminated soils (Zalar Serjun et al., 2018, Oprčkal et al., 2020).

Two different approaches for the useful utilization of RM are presented, based on the results of laboratory research and a real case study, opening new possibilities for the reduction of RM deposits.

2 RED MUD AS AN ADDITIVE FOR REMEDIATION OF CONTAMINATED SOILS

Data presented in the literature show that RM's high sorption capacity for PTEs is due to the large specific surface area of its constituent mineral phases, which enables two main immobilization mechanisms: (a) surface complexation of PTEs with Fe and Al ox/hydroxides, and (b) adsorption by alumosilicates. The RM was used as an immobilisation additive for the preparation of a stable, technically and environmentally acceptable geotechnical composite. It was intermixed to contaminated soil (CS) from one of Slovenia's largest heavily contaminated areas (Zalar Serjun et al., 2018, Oprčkal et al., 2020).

2.1 Materials

The RM was sampled from an open disposal site nearby alumina plant in Podgorica, Montenegro. The RM was dried at 105 °C in a convection oven and ground to a particle size below 2 mm. The mineralogical analysis showed that the RM is composed of calcite, hematite, gibbsite, boehmite and a phase that belongs to the feldspathoid group of minerals (cancrinite / vishnevite). Goethite, quartz, ilmenite, illite/muscovite, perovskite, rutile and dolomite present its minor constituents.

Samples of contaminated soil (CS) were obtained from a 17 ha large brownfield at the Old Zinc-Works site, which is located in the central part of the town of Celje, in eastern Slovenia. According to the European Union's List of Waste (EC, 2014), excavated soil from this location was regarded as a hazardous waste. The CS consisting of silty-sandy gravel was sampled, and then crushed in a jaw crusher to a grain fraction below 16 mm.

2.2 Experimental

The geotechnical composite was prepared by blending the CS with 25 wt.% of the RM and optimal water content, followed by subsequent compaction. The optimal water content was determined by means of the Modified Proctor Compaction Test (SIST, 2013), in order to achieve maximum dry density of the composite. Monolithic test specimens of the composite were cured in a climatic chamber (20°C and 98% humidity) for 3, 7, 28, and 56 days for subsequent analyses.

To investigate the immobilization properties and efficiency of the RM, the characterisation of the RM and the CS by surface area and microstructure by X-ray fluorescence (XRF), X-ray powder diffraction (XRD), and scanning electron microscopy equipped with energy dispersive spectroscopy (SEM/EDS), as well as changes in leachate composition were studied. The BET surface areas of the RM and the CS were determined by N_2 sorption tests. Their total elemental composition was studied by XRF and corresponding phase and microstructural analyses were performed by XRD, and SEM/EDS.

The tank leaching procedure (SIST, 2002), was applied to the test specimens of the RM, CS, and composite (CS/RM). Selected PTEs in the eluates were determined by an inductively coupled plasma mass spectrometer (ICP-MS), whereas the content of Cl^- and SO_4^{2-} were investigated by the UV-Vis absorption spectrophotometry.

In addition to the basic characterization and leaching tests for environmental acceptability studies, also some basic geotechnical properties of the CS/RM composite were evaluated, namely unconfined compressive strength (SIST, 2004) and water permeability (SIST, 2019a).

2.3 Results and discussion

The most abundant PTE in the CS was Zn, which was present in concentrations of up to 15 %, whereas Si was the second most abundant element (11%), followed by Fe, Ca, Al, S, and Mg. The most problematic parameters in the eluate of the CS were water soluble Cd, Pb, and Zn, and SO_4^{2-}, which concentrations exceeded the limit values according to the present Slovenian landfilling legislation (GS, 2016) by factors of 10.5, 2.0, 16.6, and 1.35, respectively. The CS therefore has to be regarded as hazardous waste.

For the used RM a large BET specific surface area was determined, i.e. 20.1 m^2/g. According to the results of the XRF total elemental analysis, the most abundant constituent in the RM is Ca, which makes up almost 15 %. Other major constituents are Fe, Al,

Si and Ti, followed by an array of minor constituents. The results of the performed chemical analysis of the eluate indicated that, according to the present Slovenian landfilling legislation (GS, 2016), this RM is a non-hazardous waste.

The phase composition of the CS/RM composite reflects the combination of minerals from the RM and the CS, since no new mineral phases were identified by the XRD. The eluates from the CS/RM composite show a time-dependent decrease in conductivity. The measured concentrations of the PTEs in the eluates from the CS/RM were all below the limit values for inert materials (GS, 2016), which shows the immobilization effectiveness of the used RM. The immobilization of the PTEs in the investigated composite was attributed to the fact that the goethite and gibbsite mineral phases, as well as the hematite from the RM, provide numerous adsorption sites due to their large specific surface areas, resulting in the high adsorption capacity.

The unconfined compressive strength of the CS/RM composite was determined after 3, 7, 28, and 56 days of curing, and amounted to 0.5 to 0.7 MPa with no time-dependent trends. This is in agreement with findings that no new mineral phases formed in the composite that could contribute to the binding of grains. Water permeability (SIST 2019a), determined after 28 days of curing on intact monolithic test specimens, amounted to 7.88×10^{-8} m/s.

3 RED MUD AS CONSTRUCTION MATERIAL

Relatively few attempts have been made on the effective utilization of RM for the geotechnical application alone or, its combination with several chemical and waste stabilizers (Jha et al., 2020). Recycling of the RM for the production of geotechnical composite construction materials was studied. Since the applied RM residue was in a form of slurry, it needed to be treated with the addition of binder to obtain solidified, mechanically stable and the environmentally acceptable geotechnical composite material with properties suitable for use in earthworks.

3.1 Materials

In this case the RM from the Podgorica pond was first processed with gravitational and magnetic large-for extraction of metal phases, which are used as raw materials in metallurgy. The residue or the RM after extraction was in the form of slurry with a 42 wt.% of solids. The mineralogical analysis showed that it is composed of hematite, gibbsite, cancrinite, calcite, boehmite and aluminium fluoride.

Ash (PA) was obtained from a paper mill VIPAP Videm Krško, Slovenia. It is a waste that can be used as a binder with hydraulic or pozzolanic properties for soil remediation, solidification and stabilization. It is a highly alkaline material that contains a latent hydraulically active phases. The composition and properties of PA are highly dependent on the type of fuel burned, the combustion technology used, and the combustion conditions.

3.2 Experimental

The geotechnical composite (RM/PA) was prepared by mixing the RM with the PA. The amount of the PA required to achieve the appropriate consistency for compaction was determined on basis of laboratory trials. To prepare the RM/PA, 0.75 kg of PA was added to each 1 kg of RM residue slurry with a water content of 139 wt.% and homogenized. Prior to the RM/PA specimen preparation, the mellowing period of 24 hours was required to allow the chemical reactions to take place and to achieve a suitable consistency - workability of the mixture. During the mellowing period, the mixture was stored in an airtight plastic container at ambient temperature and then homogenized again. The test specimens were prepared by compaction in the molds (SIST, 2005) using the standard Proctor compaction effort (SIST, 2013). The specimens were cured at 22 °C and 98% humidity for 2, 7, and 14 days. The prepared specimens were used to determine the geotechnical, mineralogical and chemical properties of the investigated geotechnical composite at selected curing times.

Basic geotechnical properties of the composite were determined, such as unconfined compressive strength - UCS (SIST, 2004), consolidation properties - oedometer test - E_{oed} (SIST, 2017), water permeability - k (SIST, 2019a) and shear strength - ρ', c' (SIST, 2019b). Mineralogical composition was determined by XRD, while environmental acceptability by PTEs concentrations in leachate (SIST, 2002), which were determined with ICP-MS.

3.3 Results and discussion

According to the results of the XRD analysis the PA consists of calcite, lime, amorphous phase, quartz, portlandite, magnetite, gehlenite, anhydrite and feldspars. Leachate analysis of the PA showed that concentrations of all selected PTEs are below permissible levels (GS, 2022).

Mineral phase of the RM/PA composite was analysed at different time intervals, after 2, 7, and 14

days. The XRD analysis showed that during the curing new mineral phase – ettringite was formed. This phase is a member of the typical hydration products mineral group, formed in systems with latent hydraulic active materials (i.e., the used PA).

Geotechnical properties of the composite are time dependant and are presented in Table 1

Table 1. Geotechnical properties of the RM/PA composite.

Parameter	After 2 days	After 7 days	After 14 days
UCS (kPa)	144	3548	4939
E_{oed} at 100kPa (MPa)		79.4	
k at 100kPa (m/s)		5.5×10^{-11}	
ρ', c'(°, kPa)		51.5, 0,0	

From the point of view of the evaluated geotechnical properties, the investigated composite shows similar geotechnical properties as high quality natural silts, sands or gravels, that confirms its applicability as construction materials in earthworks. The results of the chemical analyses showed that the geotechnical composite RM/PA is environmentally acceptable and does not pose any risk to the environment when used as a construction material for earthworks (GS, 2022).

4 CONCLUSIONS

Two applications of the RM in construction were studied. It was shown that the RM can be effective immobilizer for PTEs in contaminated soils, thus transforming contaminated soils in useful construction material. On the other hand, the RM can also be used as construction material when stabilized with paper mill fly ash. In both cases prepared composites exhibits adequate geotechnical properties for earthworks, as well as environmental acceptability according to the Slovenian legislation.

ABSTRACT: The construction sector is a significant contributor to greenhouse gas (GHG) emissions, mainly because of the emission intensive construction materials. Integrating carbon accounting and management into the geotechnical design process of infrastructure projects can effectively reduce embodied carbon from land use planning through to the detailed design phases. A low-carbon geotechnical approach includes appropriate ground investigations, soil and rock mass coordination and comparisons of different foundation and soil improvement methods. In the detailed design phase, chosen foundation and soil improvement methods can be optimized for carbon emissions through material choices, transport planning, and considering life cycle durability. This paper presents the possibilities of geotechnical engineering solutions to decarbonise the infrastructure sector. Carbon emissions and costs for various ground improvement and foundation methods, including alternative solutions with recycled materials, are reported, and compared. The considered case studies and scenarios represent infrastructure projects located in Finland.

RÉSUMÉ: Le secteur de la construction est un contributeur significatif aux émissions de gaz à effet de serre (GES), principalement en raison de l'utilisation intensive de matériaux de construction émetteurs de carbone. Intégrer la comptabilisation et la gestion du carbone dans le processus de conception géotechnique des projets d'infrastructure peut efficacement réduire l'empreinte carbone dès la planification de l'aménagement du territoire jusqu'aux phases de conception détaillée. Une approche géotechnique à faible émission de carbone comprend des investigations géotechniques, une coordination des masses de sol et de roche, ainsi que des comparaisons de différentes méthodes de fondation et d'amélioration du sol. Dans la phase de conception détaillée, les méthodes de fondation et d'amélioration du sol choisies peuvent être optimisées en termes d'émissions de carbone grâce aux choix de matériaux, à la planification du transport et à la prise en compte de la durabilité sur l'ensemble du cycle de vie. Cet article présente les possibilités des solutions de génie géotechnique pour décarboniser le secteur des infrastructures. Les émissions de carbone et les coûts pour diverses méthodes d'amélioration du sol et de fondation, y compris des solutions alternatives avec des matériaux recyclés, sont rapportés et comparés. Les études de cas et les scénarios pris en considération représentent des projets d'infrastructure situés en Finlande.

Keywords: Carbon management; carbon emissions; ground improvement; low-carbon geotechnical engineering; design optimization.

1 INTRODUCTION

To align with the established net-zero greenhouse gas emissions (GHGs) target outlined in the Paris Agreement for 2050 and to address the predictions concerning climate impact as presented in the Intergovernmental Panel on Climate Change (IPCC) (2023) report, various sectors, notably the construction industry, must take proactive measures to attain net-zero emissions and to mitigate the resultant global warming effects. Built environment is a major source of greenhouse gas emissions globally – directly through the construction, operation, and maintenance of assets and indirectly through operations (Thacker et al., 2021). Further, construction affects globally available resources and infrastructure consumes more than 50% of the world's projected materials annually (IRP, 2022).

Infrastructure projects are large and long-lasting engineering projects, with associated environmental impacts throughout their lifecycle. This article investigates the significance of decarbonising infrastructure projects, focusing on the utilization of geotechnical engineering solutions in Finland to tackle emissions-intensive components and construction phases.

2 CARBON MANAGEMENT IN INFRASTRUCTURE SECTOR

2.1 Overview on carbon management

The carbon footprint of an infrastructure project is mostly determined by its embodied carbon, representing greenhouse gas (GHG) emissions

throughout the lifecycle of materials, encompassing extraction, manufacturing, transport, construction, reuse, recycling, and disposal. Materials like concrete and steel are notable contributors to embodied carbon emissions. Given the significant material consumption in infrastructure projects, key strategies to minimize embodied carbon involve reducing material usage and employing alternative materials.

Carbon management and accounting are approaches to optimise and verify low-carbon design solutions. Carbon management involves proactive reduction of project carbon footprints using carbon accounting as a numerical method. Internationally recognized standards include PAS 2080 (BSI, 2023), EN 17471 (DS, 2022), and ISO 14001 (DS, 2015). Carbon accounting identifies embodied carbon origins strategically and systematically, applicable at both project and strategic levels.

2.2 Embodied carbon in geotechnical solutions

Geotechnical solutions such as foundation engineering and ground improvement often use carbon intensive materials and thus have potential for CO_2 reduction. For instance, according to the analysis conducted by the City of Helsinki (2022a), the top five sources of embodied carbon emissions in Helsinki's infrastructure projects account for over 80% of total embodied emissions of infraconstruction projects. The primary sources of emissions are earth and aggregate materials, and transportation (36%), column stabilization (23%), natural stones (9%), concrete structures (6%), and asphalt pavements (8%).

A similar study was conducted for Espoo, another major city in the Helsinki metropolitan area (2023). In Espoo's infrastructure construction, embodied carbon arises mainly from ground improvement (including structures related to insulation, barriers, and drainage) (28%), earth cuttings and excavations (22%), pavement structures (20%), and foundations (8%). Column stabilization stands out as the largest contributor, constituting 25% of emissions, followed by steel-made sheet pile walls at 16%. The significant emissions from sheet pile walls are attributed to their widespread use and the intensive emissions from steel.

2.3 Low-carbon geotechnical engineering

Carbon management in geotechnical engineering emphasizes decarbonization and circularity principles, prioritizing reduced construction and material demand, material recycling, and the adoption of low-carbon techniques and materials. Design optimization, applicable across all design stages, serves as an efficient method to decrease embodied carbon in all lifecycle phases (FIDIC, 2023). Optimization occurs at both strategic and site-specific levels, encompassing land use planning, project scheduling, and chosen ground improvement methods. Comprehensive ground investigations further support design optimization, facilitating the development of technically sound yet resource-efficient solutions.

Emissions related to ground improvement can be reduced already during the land use planning stage by focusing on identifying optimal locations for structures according to soil conditions. Meanwhile, when construction is performed on low bearing soil conditions, geotechnical-related emissions are determined by available time. Low-carbon ground improvement methods, such as preloading embankment, require sufficient time frame.

If time-consuming ground improvement methods cannot be used the most efficient approach to reduce GHGs is to minimize material demand inside the chosen method and to seek alternative, low-carbon or recycled materials. Dosage of binder i.e., for deep mixing can be studied and reduced using multiple laboratory tests for site-specific solutions or by combining the method with lightweight aggregate structure or preloading with embankment. The carbon footprint of concrete can be reduced by up to nearly 70% by using recycled materials such as fly ash or blast-furnace slag. Similarly, steel industry aims to develop a fossil-free steelmaking process by 2030 (SSAB, 2023), which would potentially reduce significantly GHG emission arising from foundations.

The design optimization methods are being utilized in the development of a new residential area, Malminkenttä, Helsinki. Scheduled for construction between 2020 and 2050, the objective is to reduce emissions from ground improvement preconstruction activities by 50 percent by the year 2030 (City of Helsinki, 2022b).

Earthworks material coordination principles are applied in many construction projects in Finland. Coordinating soil and rock materials from earthworks inside the project and with neighbouring projects reduces virgin material extraction and related emissions, and transport emissions. Similarly, in demolition projects, concrete from demolished buildings can be used in the structural layers of street and thus reduce emissions from manufacture of stone aggregates.

3 CARBON AND COST OPTIMIZED GEOTECHNICAL SOLUTIONS

3.1 Carbon emissions and costs for different ground improvement methods

Figure 1 compares different ground improvement methods with respect to their carbon emissions and costs. Furthermore, additional preloading time before use-phase is considered, resulting in reductions in both emissions and costs. The calculation is done for a 100 × 100 m area with a 1.5 m dry crust clay layer and a 10 m soft clay layer beneath the ground surface. The fictitious site is in Helsinki. Embankment height after the construction is designed to be 2.5 m, covering the whole area. (Perttu, 2023) Emission data was gathered mainly from the Finnish national emission database (co2data.fi) and cost data from Ihku software (Ihku, 2023).

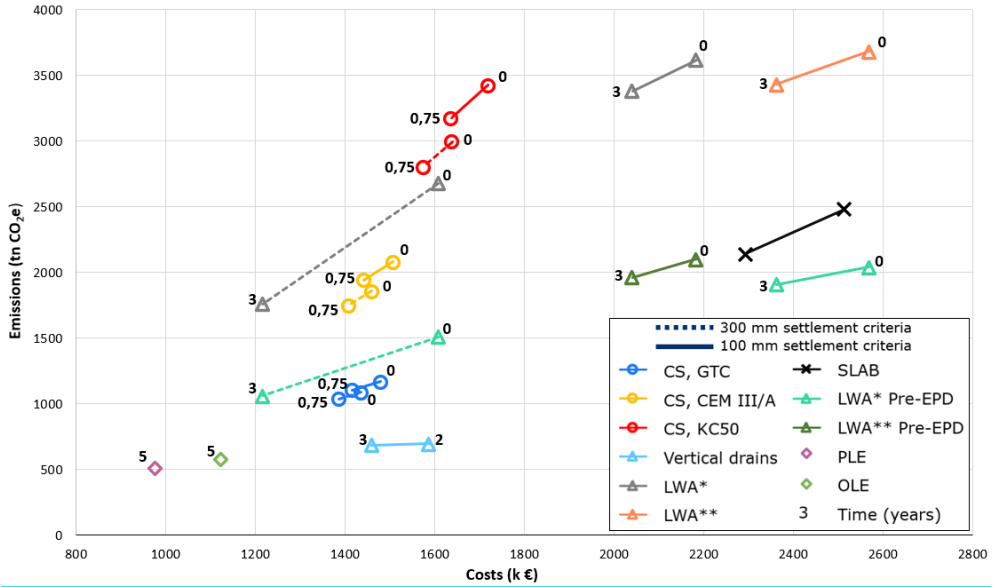
In the case example column stabilization was studied with 3 different binders: Nordkalk Terra KC50, Finnsementti CEMIII/A, and Nordkalk Terra GTC. Column stabilization was designed for both 100 mm and 300 mm use-phase settlement criteria, and preloading intervals of 0 and 9 months were considered. Lightweight aggregate (LWA, light expanded clay aggregate) was studied with preloading intervals of 0, 1, 2, and 3 years. For preloading embankments (with or without surcharge), the required preloading time was approximately 5 years. Preloading combined with vertical drains require 2-3 years of preloading. To ensure sufficient stability, staged construction is needed. In addition, a reinforced concrete slab with concrete piles was studied to compare with the ground improvement methods. The slab was designed with 2 different pile lengths, extending 3 and 10 m below the clay layer.

The study presented here focuses on both monetary and GHG parameters. A comprehensive comparison of various methods entails considering factors such as equipment availability, other environmental impacts, and long-term stability.

3.2 Emission and cost reduction potential

With column stabilization, the choice of binder has the largest impact to overall emissions. In terms of optimization, preloading time and the chosen settlement criteria affect both emissions and costs. The savings vary by clay layer depth and embankment height. With lightweight aggregates, preloading can have a significant impact on both emissions and costs. Preloading the lightweight embankment for 3 years can halve the costs compared to no preloading, as the amount of required aggregate is greatly reduced. Whether the excavated soil can be used on the site, or must be transported for further treatment, can have a significant impact on costs, as seen in Fig. 1 (Cost difference between orange and grey lines for example). Conventional preloading embankment (with or without surcharge) has the lowest costs and emissions but require a long preloading time. Vertical drains will speed up the process but require more materials and work hours.

In addition to the results in Figure 1, clay layer depths of 6.5, 16.5 and 20 meters and embankment heights of 1.5 and 4 meters were studied in the thesis (Perttu, 2023). The most emission- and cost-effective ground improvement method for a given case is determined by clay layer depth, embankment height,



CS: Column stabilization, three different binders were studied
LWA: Lightweight aggregate embankment (=excavated soil used on site, **=excavated soil transported for disposal (60 km). Pre-EPD (Environmental Product Declarations) refers to updated but unconfirmed emission data.*
SLAB: Reinforced concrete slab & piles, chart line illustrates emission/cost increase with pile length extending below clay layer 3-10 meters
PLE: Preloading embankment, 300 mm settlement criteria
OLE: Overloading embankment, 300 mm settlement criteria
Time: Preloading time (years) between construction and use-phase. Studied preloading times vary by method.

Figure 1. Emissions (tn CO2e) vs costs (k €). Clay layer depth 11.5 m. Embankment height 2.5 m.

settlement criteria, and available preloading time as presented in Table 1. In addition to descriptive sensitivities to parameters, increase in prices and emissions by clay layer depth are depicted as functions, which are compiled from the same dataset as Fig. 1 (Perttu, 2023).

Low-carbon and cost-efficient geotechnical solutions are bound to material usage and settlement criteria. Note that the study was conducted for a site in Southern Finland, so emissions and costs can vary in other locations, as well as in the course of time as material availabilities change and technologies advance. Having more preloading time available increases the options to choose from and allows the usage of less emission- and cost-intensive solutions within a chosen method. In general, given there is time available, methods combined with pre-loading are recommended. Choosing low-carbon materials has a large impact on emissions, and recycled materials such as recycled lightweight aggregate are often also less expensive.

Table 1. Sensitivity to parameters, varying methods. Effects to prices and emissions were calculated with 100 mm settlement criteria. 1.5, 2.5 and 4 m refer to embankment height.

Method	Clay layer depth	Load (embankment height)	Settlement criteria	Effect to price (increasing clay layer thickness) €/m²	Effect to CO_2-emissions (increasing clay layer thickness) kg CO_2/m²
Pile Slab	* (pile length)	* (pile density and diameter)	-	1.5 m: 2x+175 2.5 m: 3.2x+215 4 m: 7.2x+300	1.5 m: 4.1x+165 2.5 m: 5x+190 4 m: 10x+270
Lightweight aggregate	* (LWA quantity)	** (LWA quantity)	** (LWA quantity)	1.5 m: 1.8x+120 2.5 m: 1.9x+220 4 m: 2x+380	1.5 m: 2.7x+205 2.5 m: 2.9x+405 4 m: 3.1x+730
Column Stabilization (GTC)	** (column length)	** (column spacing)	* (column spacing)	1.5 m: 5.4x+25 2.5 m: 10x+35 4 m: 11.7x+105	1.5 m: 4.2x+15 2.5 m: 10x+10 4 m: 10x+200
Column Stabilization (CEM III)	** (column length)	** (column spacing)	* (column spacing)	1.5 m: 5.5x+25 2.5 m: 10.3x+35 4 m: 12.2x+105	1.5 m: 9x+10 2.5 m: 21.6x-20 4 m: 29.6x+65
Column Stabilization (KC50)	** (column length)	** (column spacing)	* (column spacing)	1.5 m: 6.6x+25 2.5 m: 13.0x+25 4 m: 15.9x+110	1.5 m: 16x+0 2.5 m: 37.8x-60 4 m: 52.8x+70
Preloading and overloading embankments	** (time)	** (time)	** (time)	-	-
Spacing of vertical drains	-	* (time, counter embankment size)	-	1.5 m: 1.6x+80 2.5 m: 2.8x+120 4 m: 3.7x+125	1.5 m: 0.4x+40 2.5 m: 0.8x+60 4 m: 1.1x+110

Notes: Variable x in the functions refer to clay layer thickness (e.g. pile slab foundation with 1.5 m embankment and 10 m clay layer costs roughly 2*10+175=195 €/m²). - = No effect, * = Affected a little, ** = Largely affected.

4 CONCLUSIONS

Geotechnical engineering can be a crucial factor in the carbon budget of an infrastructure project, particularly when dealing with soft or challenging soil conditions. Structures like stabilized columns, and steel sheet pile walls often rely on emission-intensive materials such as cement and steel. Additionally, earthworks require a significant amount of machinery and transportation, contributing substantially to emissions in large projects.

Efficient methods for reducing greenhouse gas (GHG) emissions in geotechnical engineering during the design phase include design optimization and carbon management. Most emissions in this field stem from the use of emission-intensive materials in deep mixing, sheet piles, and other heavy foundation methods. Techniques like pre-loading and surcharge embankments, combined with the use of low-emission materials such as binders based on industrial side stream products, are effective ways to decrease the overall emissions of infrastructure projects, in soft soil conditions.

It is crucial to communicate low-emission methods within each technical field associated with the project, preferably during the early design phases. Identifying key decision-making steps and allocating sufficient resources and time for implementing low-carbon and resource-efficient solutions is essential. Integrating carbon emissions as a design consideration for geotechnical solutions can lead to reduced project costs and emissions.

Combining carbon management with design optimization is not a standard procedure, and national and international guidelines are required to incorporate GHG emissions into the decision-making process. Understanding the hotspots of GHG emissions in infrastructure is fundamental, and this knowledge should be integrated into standard practice. More research is needed to understand the mechanisms and connections from land use planning to construction and further asset management for profound low-carbon and resilient infrastructure outcomes.

Sustainability assessment of a geotechnical site investigation in Holocene deposits: A case study from northern Germany

Évaluation de la durabilité d'une étude de site géotechnique dans les dépôts Holocènes: Une étude de cas du nord de l'Allemagne

**wolf.pfeiffer@baw.de*

ABSTRACT: The current and projected state of earth's climate, resources and ecosystems require a substantial push towards sustainability, well above what is currently employed. The construction sector is a major contributor to the global emission of greenhouse gases and a consumer of scarce natural resources. In this work an environmental impact assessment of a geotechnical site investigation of the planned Lüneburg Lock in Northern Germany is presented. A comprehensive ground investigation was carried out comprising of 78 geotechnical exploration drillings and 81 CPTs. The total primary energy expenditure of the surveys was calculated to be 1.69×10^6 MJ. Emissions contributing to the global warming potential (GWP) are estimated at 9.77×10^4 kg CO_2-eq.

RÉSUMÉ: L'état actuel et projeté du climat, des ressources et des écosystèmes terrestres nécessitent un effort substantiel en faveur de la durabilité, bien au-delà de ce qui est actuellement mis en œuvre. Le secteur de la construction est un contributeur majeur aux émissions mondiales de gaz à effet de serre et un consommateur de ressources naturelles rares. Dans ce travail, une évaluation de l'impact environnemental d'une investigation géotechnique du site du futur écluse de Lüneburg, dans le nord de l'Allemagne, est présentée. Une enquête approfondie du sol a été réalisée, comprenant 78 forages géotechniques et 81 essais de pénétration statique. La dépense totale d'énergie primaire des enquêtes a été calculée à $1{,}69 \times 10^6$ MJ. Les émissions contribuant au potentiel de réchauffement planétaire (PRP) sont estimées à $9{,}77 \times 10^4$ kg CO_2-eq.

Keywords: Sustainability; geotechnical site investigation; life cycle assessment.

1 INTRODUCTION

International (UN 2015) and national (e. g. Bundesregierung 2021) policies are aimed at reducing our footprint on earth in terms of resource use and emissions. Environmental indicators are defined to quantify the emissions and resources used, such as the so-called global warming potential (GWP) measured in kg CO_2-eq. (UN 2023).

Based on these indicators, life cycle assessments (LCAs) can be carried out, to determine environmental impacts of products or processes, such as civil engineering projects. However, very little research has been published so far on the sustainability impact of geotechnical site investigations. Purdy et al. (2022) are the notable exception, providing an assessment of different sampling techniques and their individual impact for (generic) case studies in Canada.

In this paper an environmental impact assessment based on LCA data is carried out for the geotechnical site investigations of a planned ship lock in Northern Germany (Henze & Schulz 2019). The aim of this study is to identify and characterise missing processes and data required in order to carry out a comprehensive LCA as well as developing an understanding of the key factors contributing to emissions, resource use and energy expenditure.

2 METHOD, DATA & ASSUMPTIONS

In a first step all available data, such as field logs, were evaluated. Additional information had to be collected through personal communication with field staff and analysis of photographs to fill knowledge gaps arising from inaccurate or missing documentation.

2.1 Local geology & site investigations

The local geology is composed of holocene deposits, consisting mostly of dense to very dense sands and an interbedded cohesive silt layer of varying thickness.

Site investigations using drill-type (geotechnical exploration drillings with continuous sampling) and direct-push (Cone Penetration Tests, CPTs) techniques where launched in 2010 and 2019. The geotechnical

exploration drillings were carried out using rotary drilling techniques with continuous sampling and hydraulic loading using fresh water when drilling below the water table.

35 and 43 boreholes were drilled in 2010 and 2019 respectively. Average borehole depth was 46.7 m with the deepest borehole reaching 80.5 m. Drilling was conducted using 5 and 8 drilling rigs in 2010 and 2019 respectively. Working days across all drilling rigs were 251 in 2010 and 459 in 2019. Drilling diameter depended on the target drilling depth (219 - 512 mm). 36 of the boreholes were completed as groundwater observation wells.

CPT data was at 35 and 46 locations in 2010 and 2019, respectively. The depth ranged from 11.9 m to 68.3 m (av. 35.8 m). If advancement was not possible due to increased friction, rotary drilling with water as drilling fluid was used to clear out the already probed section. A single CPT rig was used in both campaigns.

Boreholes were backfilled using either sand, gravel, Bentonite, or a ready-to use clay-cement mixture (Brutoplast©) depending on the stratigraphy and the geohydraulic conditions. Most boreholes were at least partially grouted, using the aforementioned clay-cement mixture.

2.2 Environmental impact analysis

The environmental indicators set out in DIN EN 15804:2022-03 were used in this study, of which only a selection is shown and discussed. Process and product data were taken from the ÖKOBAUDAT 2023-I (BMWSB 2023), GaBi Professional 2023 (Sphera 2023) and ecoinvent 3.91 database (Wernet 2016, ecoinvent 2023). Unfortunately, geotechnical process data is mostly missing from databases, requiring the approximation of drilling and CPT operations. All processes used are given in Table 1.

Table 1. Process and EPD data used in this study.

Process name	Datebase
Diesel at filling station	GaBi Pro.
Diesel burned in building machine	ecoinvent
Truck	ÖKOBAUDAT
Car (Diesel) EURO 4	ÖKOBAUDAT
Pumping of concrete	ÖKOBAUDAT
Drinking water	ÖKOBAUDAT
Sand 0/2 (dried)	ÖKOBAUDAT
Bentonite granular	GaBi Pro.
Average cement D	ÖKOBAUDAT
Polypropylene pipe	ÖKOBAUDAT

The methods used in 2010 and 2019 were grouped into the categories d*rilling*, *CPT with additional drilling* and *CPT without additional drilling.* For evaluation, the geotechnical site investigations are divided into three phases of operation:

- Mobilization – the movement of equipment and people to, from and on the job site
- Advancement – the actual drilling / direct push probing incl. sampling
- Sealing & Completion – backfilling/grouting of boreholes and completion of wells

2.2.1 Mobilization

The mobilization phase includes the one-time deployment to and return from the site of each drilling and CPT rig. The remobilization between borehole/CPT locations on site was also considered, excluding the first location. Furthermore, it was assumed that each rig required a support staff of two, traveling to and from the site on each work day by car. Traveling distance of the support staff was assumed to be the distance from the company's HQ to the site.

The mobilization of the drilling and CPT rigs was calculated as a standard diesel truck, while transport/travel of the support staff was calculated assuming a EURO 4 diesel car (Table 1).

The distances between the HQs and the job site were 47.5 and 50 km in 2010 for the drilling rigs and the CPT rig, respectively. In 2019 mobilization distances were significantly greater at 169 km (drilling rigs) and 260 km (CPT rig). Mobilization distances of the support staff of more than 100 km were deemed unfeasible for daily trips. Thus for 2019 the distance to the nearest city (9 km) was taken instead, assuming overnight stays in hotels. Remobilization on the jobsite was estimated to be 500 m indifferent of the actual location. The mass of the drilling/CPT rigs were estimated at 20 tons.

2.2.2 Advancement

The amount of diesel required for and water consumed during the advancement was used in order to quantify the impact on the LCA indicators. The impact of the production of diesel fuel and the subsequent use on the job site were quantified by mass and energy, respectively. First the energy required for advancement was estimated for each drilling/probing location as:

$$\mathrm{E}_{diesel} = \frac{\mathrm{z}_{tot} \cdot P_{rig} \cdot \eta_{load} \cdot \eta_{engine}}{\bar{v}_{adv}} \qquad (1)$$

with E_{diesel} (kWh) the required energy, z_{tot} (m) the drilling/probing depth, $\bar{v}_{adv}$ (m/h) the average advancement including auxiliary work, P_{rig} (kW) the power rating of the rig's engine, η_{load} (-) the engine load as the percentage the rig's engine is running at its

nominal power rating and η_{engine} (-) the efficiency of the engine. Subsequently the mass of diesel was calculated based on the lower calorific value (LCV) of diesel, which is 11.9 kWh/kg (UN 2017).

The advancement of a CPT must be 2 cm/s (±0.5) according to DIN EN ISO 22476-1:2023-04. Factoring in auxiliary work required, e.g. adding/removing tubing, CPT advancement was set to 36 m/h. The average drilling advancement was assumed to be 2 m/h for a geotechnical exploration drilling with continuous sampling. Engine loads were set to 0.6 for rotary drilling with sampling and 0.9 for CPT advancements (including necessary drilling operations). In the absence of detailed information, a nominal power rating of 200 kW and an engine efficiency of 0.35 was assumed for all rigs.

Water was used for drilling, either to maintain a specified head (drilling with sampling) or to remove the drilling material from the borehole (CPT with drilling). For the former water use was assumed to be equal to the borehole volume, i.e. a function of the drilling depth and diameter. For the latter, water consumption was assumed to be four times the borehole volume.

2.2.3 Sealing & completion

The impact of the sealing and completion is calculated by the mass of materials used. Required interval length, dimensions of each borehole and materials used are calculated from field data (logs). The clay-cement mixture used contains 70% Kaolinite clay and 30% cement. Approx. 613 kg of dry mixture and 766 kg of water is required per m³ of void space to be grouted. The required LCA data is mostly available, using Bentonite instead of Kaolinite (Table 1). Given the very similar properties of sand and gravel in terms of their LCA data, only sand was used in the calculations. Dry bulk densities of Bentonite and sand are approximated to be 1100 and 1600 kg/m^3, respectively. The piping used for the completion of the observation wells was assumed to be of polypropylene with a wall thickness 0.01 m and a density of 930 kg/m^3. Pumping of the clay-cement mixture was estimated by the process of pumping concrete, which only quantifies the impact of the pump, not the pumped fluid mixture.

3 CASE STUDY RESULTS

Primary energy consumption of the examined geotechnical site investigations is calculated to be 1.69x10^6 MJ (Figure 1, Table 2). Most of the primary energy is required for advancement, accounting for 53.2% (9.00x10^5 MJ), followed by sealing of boreholes at 33.2% (8.52x10^4 MJ) and mobilization at 13.6% (2.3x10^5 MJ). Normalized to probing depth, energy expenditure is 379.58, 153.55 and 34.97 MJ per m for drilling, CPTs with add. drilling and simple CPTs respectively.

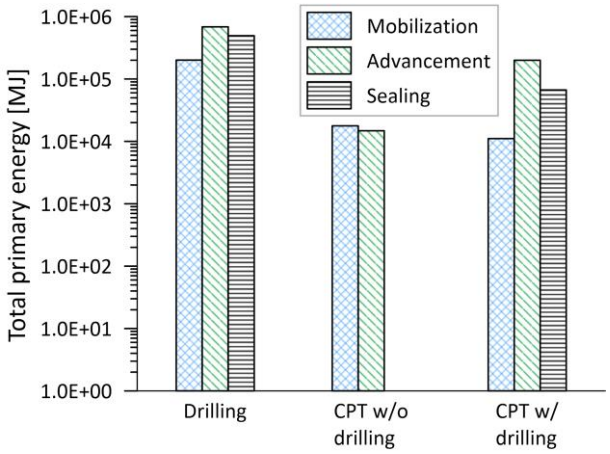

Figure 1. Total primary energy consumption of the geotechnical site investigations in 2010 and 2019.

Table 2. Results for the two surveys and selected indicators.

Indicator	Value
Renewable primary energy	9.93x10^4 MJ
Non-renewable p. energy	1.59x10^6 MJ
Global warming pot. (GWP)	9.77x10^4 kg CO_2-eq.
Acidification potential	5.56x10^2 mol H^+-eq.
Eutrophication (terrestrial)	2.53x10^3 mol N-eq.
Eutrophication (marine)	2.27x10^2 kg N-eq.
Eutrophication (freshwater)	1.26x10^0 kg P-eq.
Use of fresh water	1.19x10^3 m^3

In terms of environmental emissions, sealing is generally the largest contributor followed closely by advancement (Figure 2). For example, GWP related emissions are 4.36x10^4 kg CO_2-eq. for sealing and 3.82x10^4 kg CO_2-eq. for advancement, which is 83.7% of the total. Cement usage alone causes 1.96x10^4 kg CO_2-eq. to be emitted, which is 31% of the total GWP related emissions. Mobilization of the equipment and staff contributes 1.59x10^4 kg CO_2-eq. to the total GWP related emissions (16.3%). The same holds true to the other environmental impact indicators. However, simple CPTs require no sealing and provide efficient probing, thus mobilization becomes more important, contributing 65.9% of the GWP related emissions from this technology.

Of the resource indicators studied, only the use of fresh water is shown here, the biggest factor being the use of the clay-cement mixture (Figure 2, Table 2).

Normalized to the meters probed, drilling and CPTs with additional drilling cause emissions of 21.94 and 8.86 kg CO_2-eq. per m, respectively. The CO_2-footprint of a simple CPT is 2.01 kg CO_2-eq. per m.

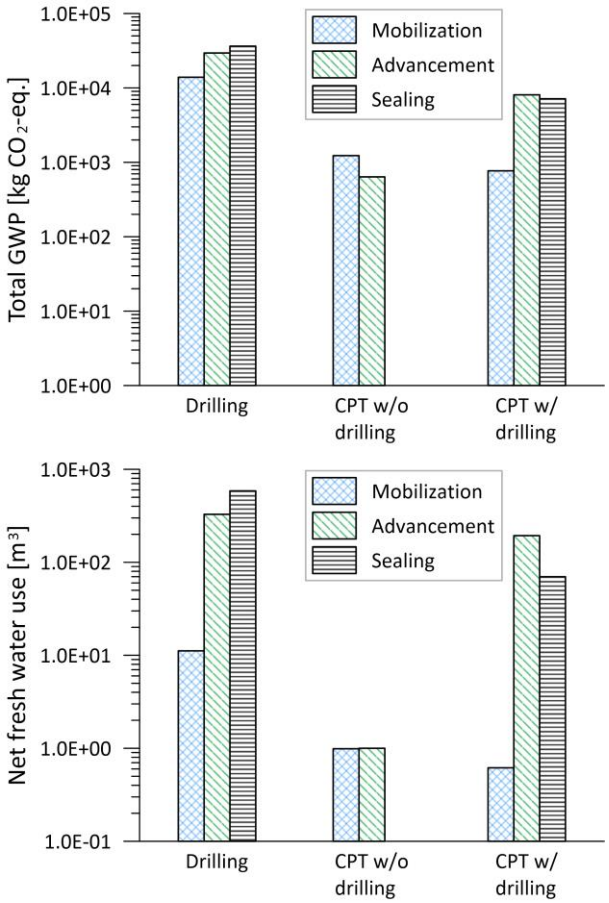

Figure 2. Total GWP and net fresh water consumption.

4 DISCUSSION & CONCLUSIONS

The results indicate that the sealing of boreholes and the actual advancement of the drilling/probing equipment are the most significant factors influencing energy expenditure, environmental emissions, and resource use. However, contributions from mobilization are not insignificant and become dominant for simple CPTs, where no sealing is required and advancement is generally quick. Given the available data, quantification of the sealing processes most likely only carries a small error. Unfortunately, calculating the impact of mobilization and advancement requires significantly more assumptions. For example, simply increasing the arbitrarily defined limit on the daily mobilization distance from 100 to 169 km to allow daily returns of the drilling crew during the 2019 campaign would make mobilization the second largest contributor to GWP related emissions with 4.07×10^4 kg CO_2-eq. The lack of knowledge on additional mobilization, such as deliveries of materials or support machinery, is a pitfall in this study. Thus, the impact of mobilization may only be considered as a lower bound estimate.

Interestingly, replacing the clay-cement mix with pure clay results in slightly increased GWP related emissions (+4.8%). This is a result of the higher bulk density of pure clay compared to the clay-cement mixture and the comparatively small difference in GWP related emissions between clay and cement.

Normalizing the results to develop an a-priori assessment tool was investigated. However, the results were not promising, showing large deviations in estimated and calculated GWP emissions. Regardless, development of such a tool might be useful for future applications. A larger and more controlled database would be favourable for such a development, which requires a more detailed logging of processes and operations on the job site, e.g. the exact amount of diesel used and actual mobilization distances covered.

A coupled thermo-hydro-mechanical hypoplastic model for fine-grained soils accounting small strain effects

Un modèle couplé thermo-hydro-mécanique hypoplastique pour les sols à grains fins prenant en compte les effets des petites déformations

M. Pico*, D. Mašín
Charles University, Prague, Czech Republic
**picoduam@natur.cuni.cz*

ABSTRACT: Several geotechnical applications such as nuclear waste disposal storage, buried high-voltage cables, pavements and geothermal energy are subjected to non-isothermal loading stages. The prediction of their behaviour requires constitutive models able to reproduce its response under a wide range of loading and thermal conditions. This paper is devoted to the development of a coupled thermo-hydro-mechanical hypoplastic model for fine-grained soils with the consideration of small-strain effects. Its formulation is based on the coupled-hydro-mechanical hypoplastic model by Wong and Mašín (2014) extended to account for temperature effects. The resulting constitutive model predicts large strain asymptotic behaviour and small-strain path-dependent effects on unsaturated conditions at different temperatures. Selected simulations were carried out to validate the proposed model based on the experimental results of constant water cyclic triaxial tests under suction- and temperature-controlled conditions, performed by Ng and Zhou (2014) on a completely decomposed tuff subjected to constant water cyclic triaxial loading at suction and temperature-controlled conditions. The comparison between experimental and simulation results suggests that the proposed constitutive model accurately reproduces the influence of temperature on the accumulation rates of strain under cyclic loading at partially saturated conditions.

RÉSUMÉ: Plusieurs applications géotechniques telles que le stockage des déchets nucléaires, les câbles haute tension enterrés, les chaussées et l'énergie géothermique sont soumises à des phases de chargement non isothermes. La prédiction de leur comportement nécessite des modèles constitutifs capables de reproduire leur réponse dans une large gamme de conditions de chargement et de conditions thermiques. Cet article est consacré au développement d'un modèle hypoplastique thermo-hydro-mécanique couplé pour les sols à grains fins avec prise en compte des effets de petites déformations. Sa formulation est basée sur le modèle hypoplastique couplé hydro-mécanique de Wong et Mašín (2014) étendu pour prendre en compte les effets de la température. Le modèle constitutif qui en résulte prédit le comportement asymptotique des grandes déformations et les effets dépendants du chemin des petites déformations dans des conditions non saturées à différentes températures. Des simulations sélectionnées ont été effectuées pour valider le modèle proposé sur la base des résultats expérimentaux d'essais triaxiaux cycliques à eau constante dans des conditions d'aspiration et de température contrôlées, réalisés par Ng et Zhou (2014) sur un tuf complètement décomposé soumis à une charge triaxiale cyclique à eau constante dans des conditions d'aspiration et de température contrôlées. La comparaison entre les résultats expérimentaux et de simulation suggère que le modèle constitutif proposé reproduit avec précision l'influence de la température sur les taux d'accumulation de déformation sous chargement cyclique dans des conditions partiellement saturées.

Keywords: Temperature; unsaturated fine-grained soils; hypoplasticity; cyclic loading.

1 INTRODUCTION

Given the growing demand for new alternative energy sources, energy piles have been developed as an eco-friendly solution for heating and cooling buildings. This represent an example where the soil undergoes thermo-hydro-mechanical loading, which can vary in a cyclic manner.

Constitutive models that are robust and well-validated are essential for accurately reproducing this behaviour. Among these models, the one of the first within the hypoplastic family to account for the effects of temperature and suction in soil response was developed by Mašín and Khalili (2012). In addition, for reproducing small strain stiffness effects, hypoplastic models have been enhanced with various concepts, including the intergranular strain (Niemunis and Herle, 1997; Wegener and Herle, 2014), ISA (Poblete, Fuentes, and Triantafyllidis, 2016), and the so-called ISI (Duque et al., 2020). Consequently, Wong and Mašín (2014) combined the IS concept with the formulations from Mašín and Khalili (2008) and Mašín (2010) to capture small strain stiffness effects in partially saturated fine-grained soils.

In the present work, the constitutive model by Wong and Mašín (2014) was further enhanced by incorporating the ISI concept by Duque et al. (2020) along with a new modification for capturing the effects of temperature and suction on fine-grained soils subjected to cyclic mechanical loading. The numerical model was validated by comparing the results of element tests simulations with the experimental results from Ng and Zhou (2014), who conducted constant water content cyclic triaxial tests on a silt (ML) at three suctions $s = \{0, 30, 60\}$ kPa and temperatures $T = \{25, 40, 60\}$°C. The results suggest that the model is able to capture the coupled thermo-hydromechanical effects of partially saturated fine-grained soils when subjected to cyclic loading.

2 BRIEF DESCRIPTION OF THE MODEL FORMULATION

The constitutive model presented in this paper was developed hierarchically from previous hypoplastic models. It evolves from the coupled hydromechanical hypoplastic model for predicting small strain stiffness developed by Wong and Mašín (2014). The model can reproduce asymptotic and large strain behaviour for partially saturated soils, and it predicts the effects of temperature at large strains following the formulation proposed by Mašín and Khalili (2012). The model is defined using the effective stress approach by Khabbaz and Khalili (1998) and it integrates a modified temperature-dependent smoothed hysteretic water retention curve proposed by Svoboda et al. (2023) for predicting coupled thermo-hydro mechanical effects.

Furthermore, the ISI concept by Duque et al. (2020) was modified and incorporated into the model formulation to predict small strain behaviour under different temperatures and suction magnitudes.

The general rate form of the model is given by

$$\dot{\boldsymbol{\sigma}} = [f_s(\mathcal{L}: (\dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}^{TE}) + f_d\, \mathbf{N}\, \|\dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}^{TE}\|] + f_u\, (\mathbf{H}_\mathrm{s} + \mathbf{H}_\mathrm{T}) \quad (1)$$

where $\dot{\boldsymbol{\sigma}}$ represents the stress rate tensor, $\mathcal{L}$ and $\mathbf{N}$ correspond to the fourth and second order hypoplastic constitutive tensors, respectively, $\dot{\boldsymbol{\varepsilon}}$ is the Euler stretching tensor, $\mathbf{H}_\mathrm{s}$ and $\mathbf{H}_\mathrm{T}$ are second order tensors for predicting wetting and heating induced collapse, respectively, and $\dot{\boldsymbol{\varepsilon}}^{TE}$ is a second order tensor that accounts for fully reversible strains resulting from thermal expansion. The latter follows:

$$\dot{\boldsymbol{\varepsilon}}^{TE} = \frac{1}{3}\, \alpha_s \dot{T} \quad (2)$$

where α_s corresponds to the thermal expansion cofficient of the soil.

2.1 Small strain stiffness effects

The constitutive model predicts small strain stiffness effects using the ISI concept by Duque et al. (2020), which allows accurate predictions of accumulation rates under cyclic loading. For its incorporation, Equation (1) can be rewritten as:

$$\dot{\boldsymbol{\sigma}} = \mathcal{M}: (\boldsymbol{\varepsilon} - \dot{\boldsymbol{\varepsilon}}^{TE}) + f_u(\boldsymbol{H}_s + \boldsymbol{H}_T) \quad (3)$$

where $\mathcal{M}$ corresponds to the tangent stiffness tensor and its calculation is given according to

$$\mathcal{M} = [\rho^{\chi_g} m_T + (1 - \rho^{\chi_g}) m_R] f_s \mathcal{L} + \begin{cases} \rho^{\chi_g}(1 - m_T) f_s\, \mathcal{L}: \widehat{\boldsymbol{\delta}}\widehat{\boldsymbol{\delta}} + \rho^{\chi_g} f_s f_d \boldsymbol{N}\widehat{\boldsymbol{\delta}} & \text{for } \widehat{\boldsymbol{\delta}}: (\boldsymbol{\varepsilon} - \dot{\boldsymbol{\varepsilon}}^{TE}) > \mathbf{0} \\ \rho^{\chi_g}(m_R - m_T) f_s \boldsymbol{\mathcal{L}}: \widehat{\boldsymbol{\delta}}\widehat{\boldsymbol{\delta}} & \text{for } \widehat{\boldsymbol{\delta}}: (\dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}^{TE}) < \mathbf{0} \end{cases} \quad (4)$$

The ISI concept includes a function for describing the value of χ_g as follows:

$$\chi_g = \chi_0 + \Omega\, (\chi_{max} + \chi_0) \quad (5)$$

where χ_0 and χ_{max} are model parameters under saturated and ambient temperature conditions. While, Ω corresponds to an internal state variable that evolves according to the number of cycles performed. ($\Omega \to 1$) when the intergranular strain is not mobilized and becomes 0 during monotonic paths according to

$$\dot{\Omega} = C_\Omega (1 - \rho^{\gamma_g} - \Omega) \|\dot{\boldsymbol{\varepsilon}}\| \quad (6)$$

where χ_g governs the stiffness degradation of the material and the strain accumulation upon cyclic loading. The effects of temperature and partial saturation on cyclic loading were incorporated into the model by reformulating the parameter χ_{max} from Equation (5) dependent on temperature, according to the following:

$$\chi_{\max}(S_r, T) = \chi_{\max} \mathrm{S_r}^{\vartheta_w} (\ln\left(\frac{T}{T_{ref}}\right) \vartheta_\mathrm{T} + 1) \quad (7)$$

where ϑ_T is a new model parameter that captures the effect of temperature in strain accumulation during cyclic loading. In addition, ϑ_w controls the influence of partial saturation upon cyclic loading.

3 MODEL CALIBRATION AND ELEMENT TESTS SIMULATIONS

The model was calibrated and validated using experimental data available in the literature on a completely decomposed tuff (Ng et al., 2009; Ng and Xu, 2012; Ng and Zhou, 2014; Zhou, 2014). This material is classified as a low plasticity silt (ML) according to the Unified Soil Classification System.

Table 1. Calibrated parameters.

Basic model	**Thermo-hydro mechan-ical**	**WRC model**	G_{tp0} **model**	**ISI model**
φ_c	n_s	s_{en0}	A_g	R
35°	0.035	-58 kPa	4220	0.0002
λ^*	l_s	e_0	n_g	β_r
0.054	0.0001	0.568	0.55	0.06

				0.6

Isotropic compression tests at three suction magnitudes were employed for calibrating the parameters corresponding to the basic hypoplastic model (λ^*, κ, N) and the parameters controlling the unsaturated mechanical effects (n_s, l_s, m). The parameters governing the smoothed hysteretic water retention model $(s_{en0}, e_0, \lambda_{p0}, a_e)$ were calibrated using water retention curves measured with a modified triaxial volumetric pressure plate system at two confining pressures. Triaxial tests under constant p^{net} conditions with bender element measurements were employed to calibrate the parameters controlling the very small strain behaviour under unsaturated conditions $(\varphi', \nu_{pp}, \alpha_G, A_g, n_g, m_g, k_g, m_{rat})$.

To calibrate the parameters related to the ISI concept $(R, \beta_r, \chi_0, \chi_{max}, r_m, \gamma_g, C_\Omega, \vartheta_w, \vartheta_T)$, six cyclic constant water content cyclic triaxial tests were used at three suction magnitudes $s = \{0, 30, 60\}$ kPa and three temperatures $T = \{25, 40, 60\}$° C. Typical values were used for the rest of the parameters as there was no available information for its calibration. The numerical model was implemented in the in-house software TRIAX (Mašín, 2023) for element tests simulations. The software also enables the user a direct incorporation of the subroutine into open-source finite element software. The final values of the calibrated parameters are presented in Table 1.

3.1 Results of element tests simulations

In this section, the results of the element tests simulations are compared with laboratory tests results.

3.1.1 Cyclic constant water content triaxial simulations

The parameters of the constitutive model controlling the behaviour under small strains were calibrated based on the experimental results of cyclic constant water content triaxial tests conducted by Ng and Zhou (2014). The experiments were performed at three constant suctions $s = \{0, 30, 60\}$ kPa and three constant temperatures $T = \{25, 40, 60\}°C$, for a total of nine experiments.

In general, the constitutive model showed reasonable predictions of the soil response under cyclic mechanical loading at various suction and temperature magnitudes. Figure 1 presents a comparison of the experimental and numerical results in terms of deviatoric stress versus shear strain for saturated conditions $\{s = 0$ kPa$\}$ at three different temperatures $T = \{25, 40, 60\}° C$, respectively. The numerical predictions are in agreement with the experimental data, as the model is able to predict an increase in the total shear strain as temperature increases.

Figure 2 presents the results of the numerical predictions and experimental tests evaluated in terms of the accumulated shear strain versus the number of cycles for each suction magnitude $s = \{0, 30, 60\}$ kPa, respectively. The shading between the lines correspond to the accumulated shear strain between the maximum and minimum strain of the applied deviatoric stress at each loading cycle. As observed, the model can qualitatively reproduce the increase in accumulated shear strain with increasing temperature under constant suction conditions. Despite consistently predicting trends, the model underpredicts the accumulated strain at a suction magnitude of 30 kPa. Additionally, at a suction of suction of 60 kPa, the highest accumulated strain was observed at a temperature of 40°C, contradicting most observed trends during the experiment.

Another important observation is the ability of the constitutive model to capture the non-linear dependency of the accumulated strain rate on the number of cycles. This is achieved through the

incorporation of the ISI concept in the model formulation, which allows the non-linear evolution of the accumulated strain with the increase on the number of cycles. See Figure 2.

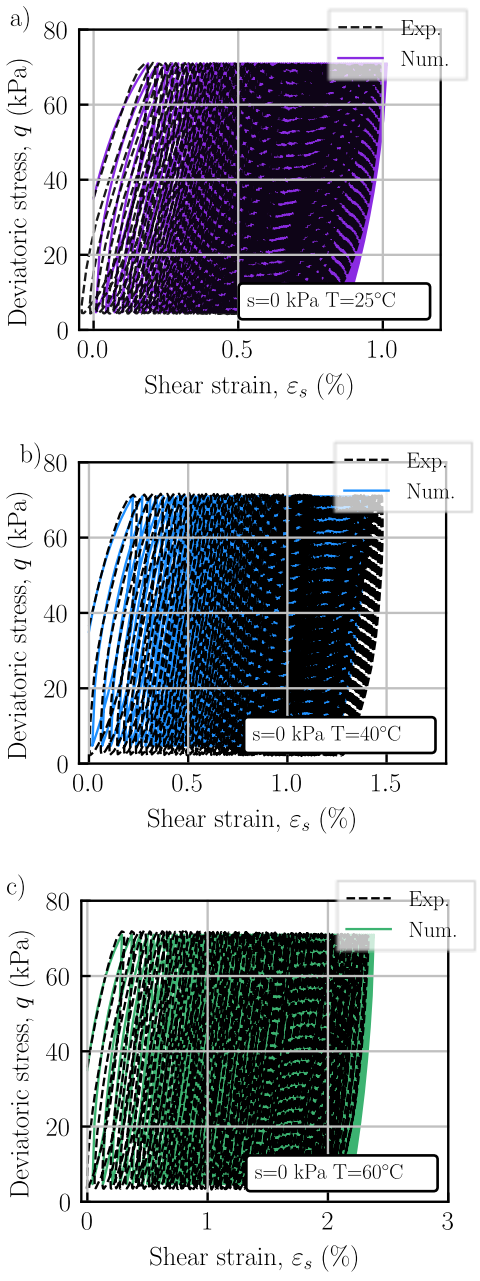

Figure 1. Results of cyclic constant water content triaxial tests at a) $T = 25°C$ b)$T = 40°$ C c) $T = 60°C$.

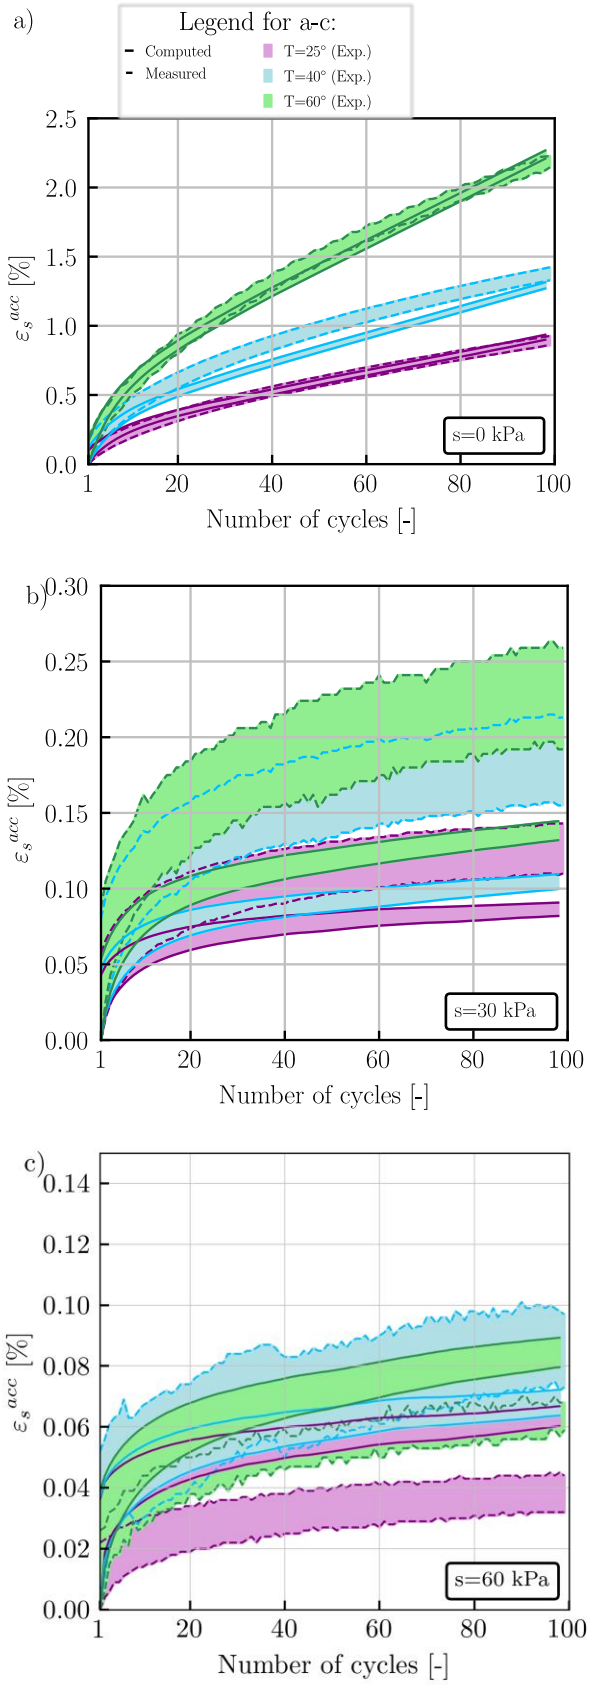

Figure 2. Comparison of accumulated shear strain vs. number of cycles at $T = \{25°, 40°, 60°\}$ at three suction magnitudes a) s= 0 kPa, b) s=30 kPa, c) s= 60 kPa.

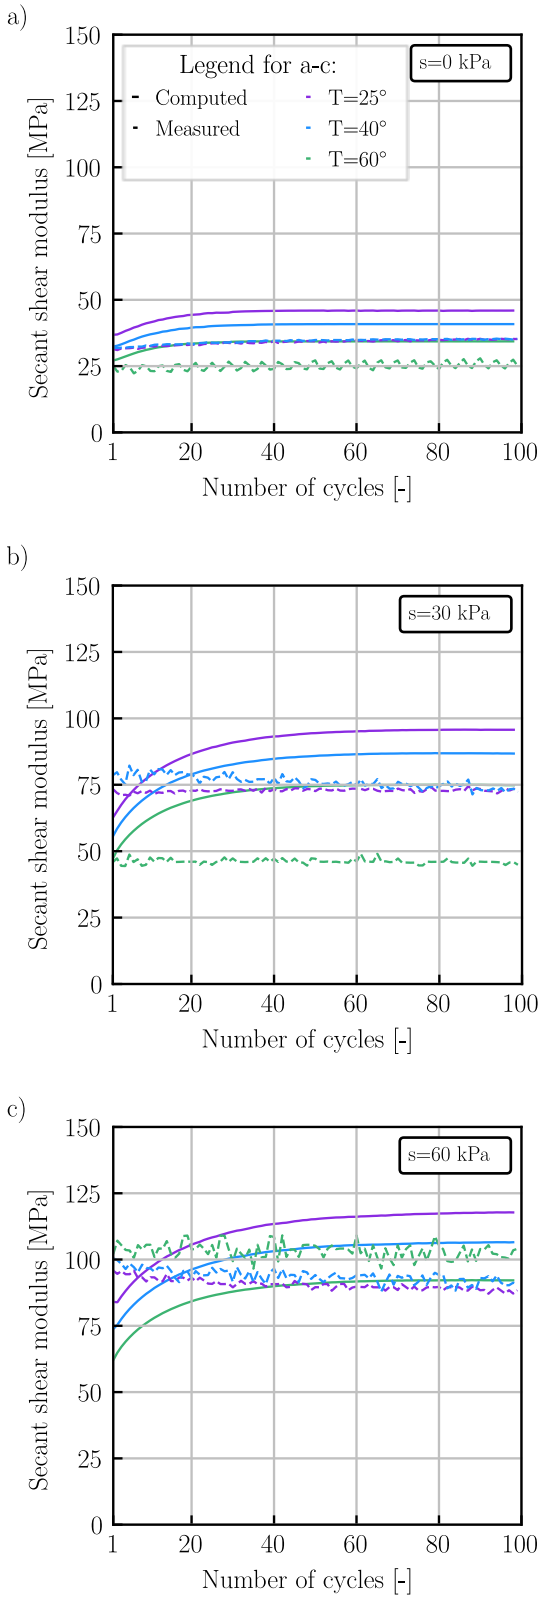

Figure 3. Comparison of secant shear modulus vs. number of cycles at $T = \{25°, 40°, 60°\}$ at three suction magnitudes a) s= 0 kPa, b) s=30 kPa, c) s=60 kPa. (C=computed, M=measured).

In addition, the values of strain at the maximum and minimum of the applied deviatoric stress in each cycle were employed to calculate the secant shear modulus. Figure 3 presents the results for each suction magnitude. The magnitude of the secant shear modulus is captured fairly well by the constitutive model. Moreover, a decreasing magnitude is predicted as temperature increases, which is in agreement with additional experimental observations (Bentil and Zhou, 2022; Zhou et al., 2015)However, the experimental data predicts and increase in the secant shear stiffness from 0 cycles to 20 cycles that is not observed in the experimental data.

4 CONCLUSION

In this work, a coupled thermo-hydro-mechanical hypoplastic constitutive model accounting for small strain stiffness effects for fine-grained soils is introduced. The constitutive model from Wong and Mašín (2014) was further enhanced to include temperatures effects on soil response. Furthermore, the ISI concept was introduced into the model with a new modification for accounting for the effects of temperature and partially saturated conditions at small strains.

The constitutive model was validated by comparing the results of element tests simulations with experimental data from constant water content cyclic triaxial test performed at three different suctions and three temperatures by Ng and Zhou (2014). The results suggest that the constitutive model reproduces fairly well the effects of temperature and suction on the soil response. The constituve model predicts higher total strains as the temperature increases, as the stiffness of the soil reduces at higher temperatures. Additionally, the consitutive model captures the non-linear dependency of the strain accumulation rate with the number of cycles. The results were also evaluated in terms of the secant shear modulus, and the consitutive model follows the decreasing trend in stiffness with the increment in temperature at each suction magnitude.

Despite the consistent predictions observed with the consitutive model, some limitations were also found. For instance, the consitutive model under-predicts the accumulated strain at a suction magnitude of 30 kPa. The ongoing efforts of the authors involve evaluating the constitutive model‘s capabitities for capturing the soil behaviour under cyclic temperature changes to further apply the constituive model for predicting the response of energy geo-structures.

ABSTRACT: The execution of the Caniçada dam new complementary spillway, demanded the construction of a temporary cofferdam to allow the excavation of the discharge tunnel, at the dam south side. The cofferdam with about 20m height and 135m length, intersected weathered to very weathered granite, granite residual soils, fills and sands, with medium average hydraulic conductivity. This scenario led to the execution of a hybrid cofferdam solution: 7m concrete gravity wall over a 30m maximum depth cut-off curtain, using micropiles (tube à manchette) combined with 1m diameter, spaced 0.70m, double row jet grouting columns. The main design and execution criteria are presented, as well as the main QC/QA procedures.

RÉSUMÉ: L'exécution du nouveau déversoir d'inondation complémentaire du barrage de Caniçada, a exigé la construction d'un batardeau temporaire pour permettre l'excavation du tunnel de déchargeur, du côté sud du barrage. Le batardeau, d'une hauteur d'environ 20 m et d'une longueur de 135m, a recoupé des granites altérés à très altérés, des sols résiduels granitiques et des sables, avec une perméabilité moyenne. Ce scénario a conduit à la réalisation d'une solution de batardeau hybride: un mur de gravité, en béton non armée, de 7m de hauteur, sur un écran d' étanchéité de 30 m de profondeur maximale, à l'aide de micropieux (tube à manchette) combinés avec colonnes de jet grouting 1m de diamètre, double rangée et espacés de 0.70m. Les principaux critères de conception et d'exécution sont présentés, ainsi que les principales procédures de CQ/QA.

Keywords: Cofferdam; jet grouting; micropiles; cut-off.

1 INTRODUCTION

The Caniçada dam is a double curvature concrete arch dam with a height of 76m above the foundation level and a crest length of 246m, located at the Cávado river, Peneda Gerês National Park, at Braga District, North of Portugal. The dam was built in 1955 and is resting over the granite bedrock (Figures 1 and 2).

The execution of the Caniçada dam new complementary spillway, demanded the construction of a cofferdam to allow the excavation of the new discharge tunnel portal, at the left abutment of the dam. With this objective, the cofferdam was built with about 20m height and 135m length using a hybrid solution: a concrete gravity wall over a cut-off curtain constituted by jet grouting columns (type 2) and micropiles.

Figure 1. Caniçada dam location.

Figure 2. Construction of Caniçada dam reinforced concrete arch over granite bed rock (courtesy of Rodio).

2 GEOLOGICAL SCENARIO

The geological scenario at the Caniçada dam new complementary spillway is very heterogeneous. After an intensive geological and geotechnical campaign, the following four geotechnical zones were established, from the surface (Figure 3 and 4):

- ZG4 – Fluvial beach sands and heterogeneous fills, with medium to high average permeability.
- ZG3 – Granite residual soil with boulders, with medium permeability.
- ZG2 – Granite rock mass (W3-4 and F3-2 to F3-4) with low average permeability.
- ZG1 – Granite rock mass (W2-3 and F2-3).

Figure 3. View of granite boulders at the Caniçada slopes.

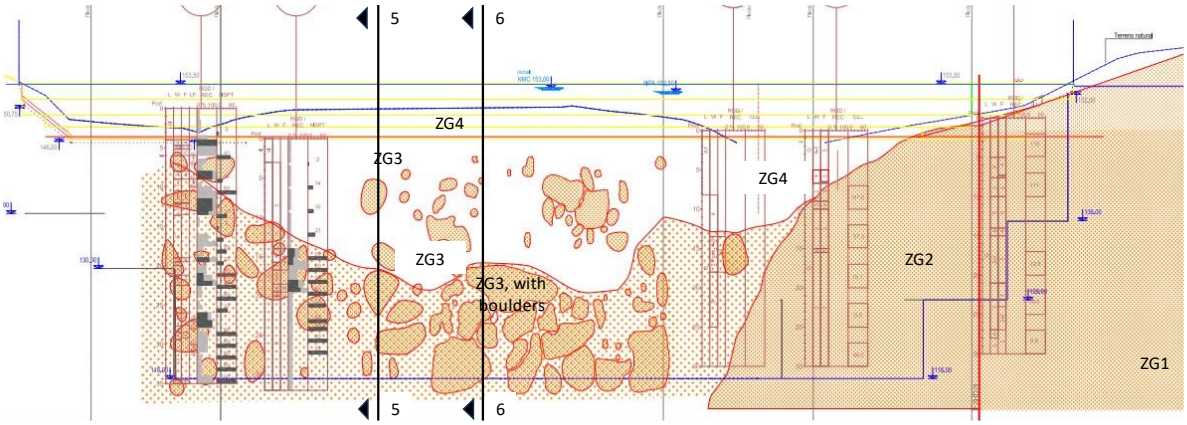

Figure 4. Geological profile (from upstream).

3 COFFERDAM SOLUTION

Considering the geological and hydrogeological complexity, as well as both cofferdam geometry and temporary nature, a cut-off curtain solution, combining jet grouting columns (Croce and Modoni, 2007) and injection micropiles (tube à manchette) with 30m maximum depth was built. A concrete gravity wall was built over the cut-off curtain with its crest level 0.5m above the dam maximum water level.

At the cofferdam most representative cross section (ZG3 intersection), the following solutions were adopted, with the double function of cut-off curtain and gravity wall foundation (Figures 5, 6 and 7):

- At the downstream side: two rows of ϕ1000mm jet grouting columns, spaced, respectively, 0.70m and 0.80m in the longitudinal and transversal alignments, with triangular distribution, were built. The micropiles were installed at the jet grouting columns intersections with sleeves at each 1m.
- At the upstream side: one alignment of inclined micropiles (HEB160 steel profiles) and vertical micropiles (HEB140 steel profiles), both spaced 1.6m.

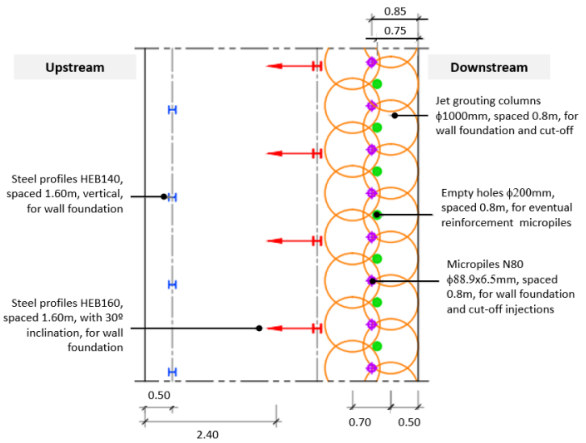

Figure 5. Plan distribution of HEB profiles and cut-off jet grouting and micropiles at the gravity wall foundation.

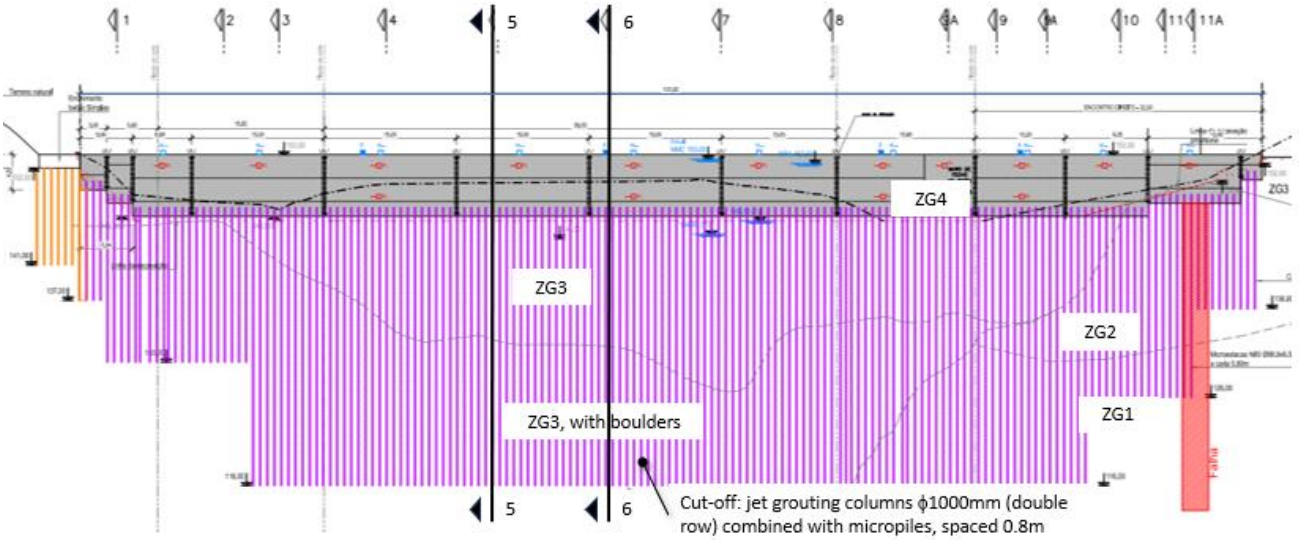

Figure 6. Cofferdam solution elevation (from upstream).

The excavation works inside protected by the cofferdam were performed with 1.25(h):1.00(v) slopes lined with shotcrete, nailed, and drained (Figures 7 and 8).

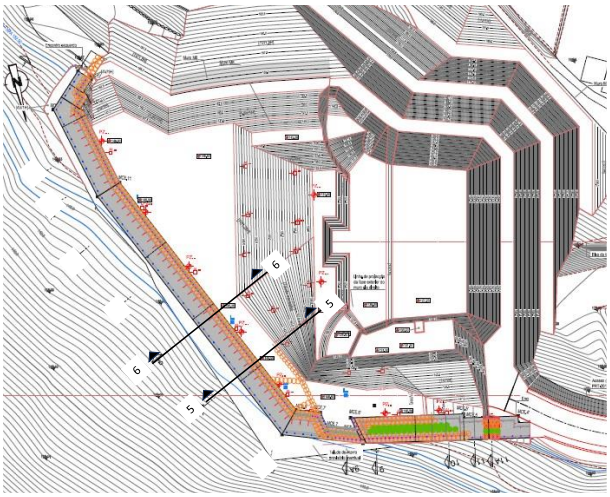

Figure 7. Cofferdam plan with the excavation slopes.

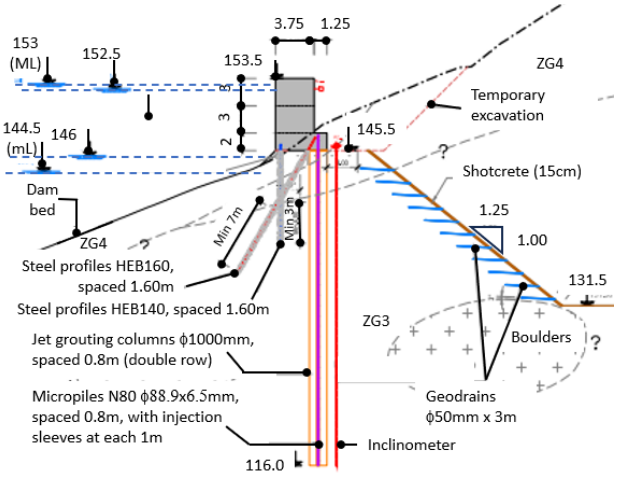

Figure 8. Cofferdam cross section 6-6 (ZG3 intersection).

4 DESIGN

4.1 Cofferdam overall stability

The cofferdam overall stability, including the excavation slope, was checked for several cross sections using SLIDE software, FEM with seepage analysis (Figure 9).

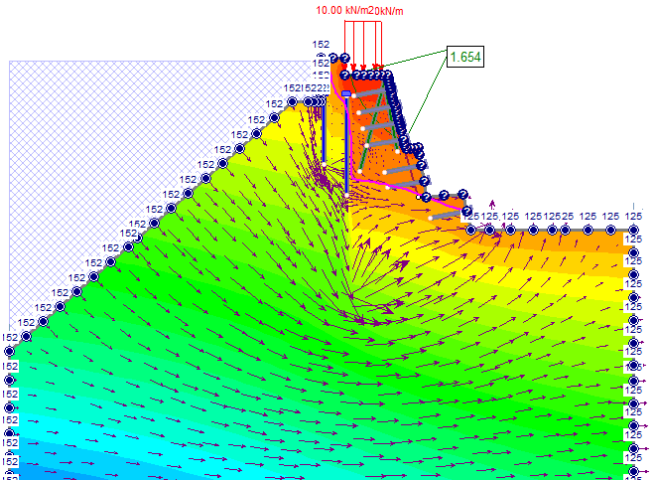

Figure 9. Safety factor for global stabiliy (1.654) at the final excavation level, considering the water inflow, cross-section 5-5.

4.2 Cofferdam hydraulic stability

The cofferdam hydraulic stability, mainly against internal erosion at the excavation base, was also checked for several cross sections using SLIDE software, FEM with seepage analysis. The safety factor for internal erosion was estimated considering the ratio between the critical hydraulic gradient (approximately 1.0) and the estimated hydraulic gradient at the excavation base exit (Figure 10).

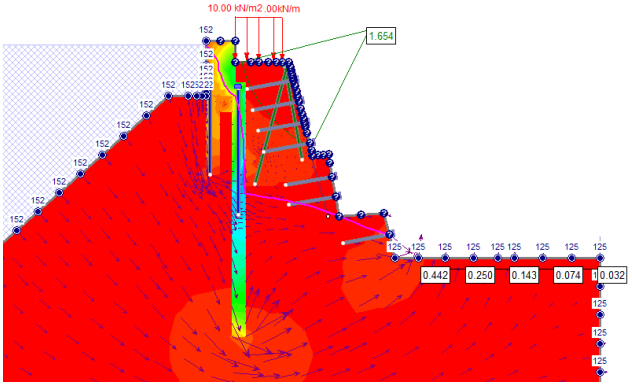

Figure 10. Hydraulic gradients at the excavation base, cross section 5-5.

5 JET GROUTING QUALIY CONTROL AND QUALITY ASSURANCE

5.1 Trial columns

Trial columns were performed to check both the columns geometry and strength at the ZG4 and ZG3. The columns strength and deformability (Young's modulus) were confirmed through UCS tests, performed at 28 days cores and compared with the design parameters: 4MPa and 1GPa, respectively, for 450kg/m^3 of cement consumption (Figure 11).

Figure 11. Trial column's view.

5.2 Execution parameters

All jet grouting execution parameters were recorded using automatic devices and compared with those established based on the trial columns.

5.3 Columns position and verticality

All jet grouting columns position and verticality were confirmed using GPS and digital inclinometer devices.

5.4 Columns integrity

Jet grouting columns integrity was checked by excavation (Figure 12), coring about 5% of the columns, sounding, cross- hole and Lugeon tests.

Figure 12. View of jet grouting excavated around columns.

6 FINAL REMARKS

The presented case study allowed to confirm the advantages of water cut-off solutions for temporary cofferdams using jet grouting columns combined with micropiles in complex geological and hydrogeological scenarios. As main advantages, compared with more conventional solutions, such as diaphragm walls, can be pointed out the following: minimum ground extraction, behaviour predictability and ease demolition (Figure 13).

ABSTRACT: Energy piles, which harness geothermal energy for efficient space heating and cooling, have gained significant popularity as a means of reducing the carbon footprint of buildings. Thermal properties of soil play a pivotal role in accurately predicting heat exchange performance, primarily contingent upon factors such as water content, temperature, and soil porosity. The drastic seasonal temperature shifts attributed to climate change, coupled with cyclic temperature variations induced by heat exchange operations, can profoundly alter soil moisture content, consequently affecting its thermal properties. Hence, it is imperative to account for moisture content variations in soils to precisely forecast the long-term efficacy of energy piles. This study aimed to develop a model setup to investigate the impact of temperature and moisture content variations around energy piles on their long-term geothermal performance. To facilitate this, a moisture content measurement sensor was developed, and a model-scale test setup was designed with several different sensor deployments to monitor changes in soil temperature and moisture content through the application of thermal cycles ranging from 5 to 50°C. The first temperature measurements from the model-scale test are presented in this study.

RÉSUMÉ: Les pieux énergétiques, qui exploitent l'énergie géothermique pour le chauffage et la climatisation efficaces des espaces, ont gagné en popularité en tant que moyen de réduire l'empreinte carbone des bâtiments. Les propriétés thermiques du sol jouent un rôle crucial dans la prédiction précise de la performance d'échange de chaleur, principalement en fonction de facteurs tels que la teneur en eau, la température et la porosité du sol. Les changements drastiques de température saisonnière attribués au changement climatique, associés aux variations cycliques de température induites par les opérations d'échange de chaleur, peuvent profondément altérer la teneur en humidité du sol, affectant ainsi ses propriétés thermiques. Il est donc impératif de prendre en compte les variations de la teneur en humidité dans les sols pour prévoir précisément l'efficacité à long terme des pieux énergétiques. Cette étude visait à développer une configuration de modèle pour étudier l'impact des variations de température et de teneur en humidité autour des pieux énergétiques sur leur performance géothermique à long terme. Pour ce faire, un capteur de mesure de la teneur en humidité a été développé, et une configuration de test à l'échelle du modèle a été conçue avec plusieurs déploiements de capteurs différents pour surveiller les changements de température et de teneur en humidité du sol grâce à l'application de cycles thermiques allant de 5 à 50 °C. Les premières mesures de température de la configuration de test à l'échelle du modèle sont présentées dans cette étude.

Keywords: Thermal cycles; energy piles; water content; model-scale test.

1 INTRODUCTION

The concept of energy piles has become increasingly recognized as an effective method for decreasing the environmental impact of buildings in recent times.
This method involves integrating circulation loops within deep foundations to efficiently harness nearby geothermal energy from the ground's surface for heating and cooling buildings (Brandl, 2006). Energy piles enable the process of transferring surplus heat into the ground during summer, effectively cooling the buildings. Conversely, energy piles extract heat from the ground during winter to provide heating for the buildings. It presents an energy-efficient substitute for traditional heating and cooling approaches (Sani et al. 2019, Sutman et al. 2020).

Thermal conductivity plays an important role in analyzing the heat transfer phenomenon, crucial for accurately predicting geothermal performance. In the context of heat transfer within porous media, such as soils, it is vital to recognize that the overall thermal conductivity of the medium stems from distinct contributions of soil grains, water, and air. Considering that the thermal conductivity of soil grains is around 10 times the one of water and 300 times the one of air, conductive heat transfer in soils highly depends on the water content and porosity (Hashemi and Sutman, 2022). During summer operation of energy piles, soil temperature increases due to heat injection into the ground. Temperature increase leads to a decrease in the viscosity and density of the water in soil pores, which may result in the water to flow away from the heat source and leading to a decrease in thermal conductivity. An inverse behaviour is expected during winter operations. Furthermore, the process of injecting heat into unsaturated soils is complex, involving the interplay of thermal energy causing both liquid and vapor water flow, coupled with the transfer of latent heat associated with phase changes (Smits et al. 2013, Lu & Dong, 2015, Moradi et al. 2016, Xu et al. 2019).

Consideration of the variations of soil thermal properties during the lifetime of energy piles is of paramount importance for the long-term analysis of their geothermal performance. Yet, most numerical simulations assume that the thermal properties are constant despite variations in water content and temperature. Thus, this study aims to develop a model-scale test setup to investigate the impact of temperature and moisture content variations around energy piles on their long-term geothermal performance.

2 TEST SETUP

A model-scale tank setup has been planned to observe the changes in the thermal conductivity of the soil based on temperature and water content variations triggered by operation of a model-scale energy pile. The dimensions of the model tank are 75×75×100 cm. The soil used in the test consists of 93% silica sand and 7% kaolin clay mixture. The hydraulic conductivity of the mixture was determined to be 1×10^{-7} m/s through the constant head permeability test. Compaction tests were conducted to determine the optimum water content value of the mixture, and a water content value of 8% was chosen for the test.

In the model-scale test, an energy pile with a diameter of 2 cm and a length of 70 cm is employed. Heat transfer is accomplished by connecting copper pipes, placed at the centre of the pile, to the thermal bath, which is capable of applying both heating and cooling episodes. Thermistors have been strategically placed for temperature measurements at both the centre and the bottom of the pile.

Within the tank, numerous sensors have been strategically positioned for measurements of water content, thermal conductivity, temperature, and suction. The employed sensors include six water potential sensors, two thermal conductivity sensors, three equitensiometer probes, eight thermocouples (one of them is placed outside of the tank to measure ambient temperature), seven thermistors, and seven water content and thermistor sensors. Before the test setup, the positions of sensors have been drawn to scale, including the cables, to ensure they do not impede the flow during the testing process, which is shown in Figure 1.

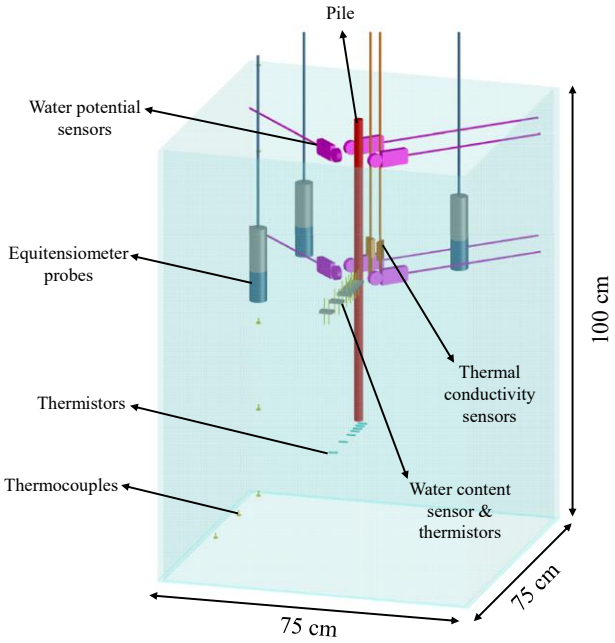

Figure 1. 3D view of the experimental setup.

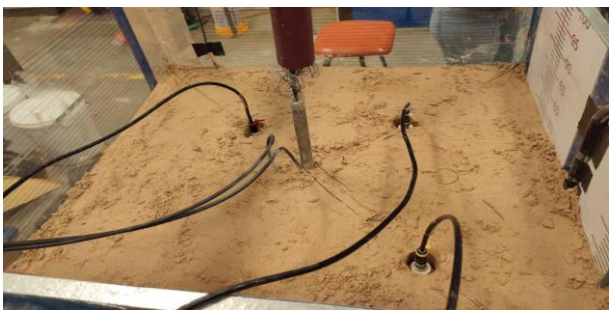

Figure 2. View of the 4th level of the setup.

In the tank setup, the soil is arranged in five levels, and the level heights are determined considering the sensor positions. A picture from the end of the 4th level of the setup can be seen in Figure 2. Compaction

was applied at each level, and sensors were placed at appropriate depths. The goal was to achieve a consistent compaction ratio by measuring the quantity and volume of material used at each level. After the compaction process at each level, the compatibility of water content values was verified with samples taken. Following the placement of piles, soil, and sensors into the tank, the top surface of the tank was insulated with suitable material to prevent evaporation. Subsequently, all surfaces of the tank were covered with thermal insulation, as illustrated in Figure 3.

In the initial stage of the test, a constant temperature of 50°C was applied.

Table 1. Locations and elevations of sensors.

Sensors	Location	Elevation (cm)
Water Potential	2 cm to the pile	55 cm
	4 cm to the pile	55 cm

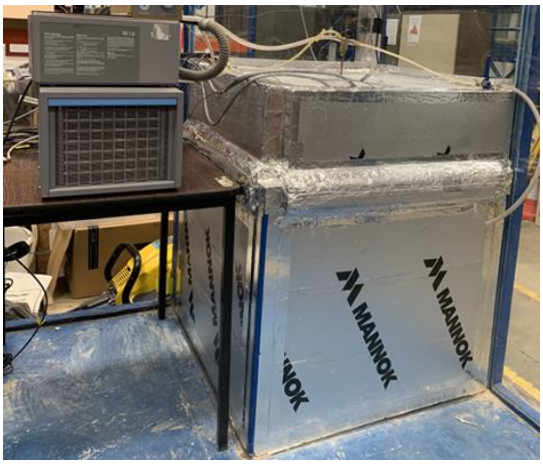

Figure 3. View of the thermally insulated tank.

3 RESULTS

Throughout the test, the temperatures measured at the pipe inlet and outlet are depicted in Figure 4. Despite the application of a constant temperature of 50°C in the test, the measured value at the pipe inlet averaged 48°C. This deviation is attributed to the fact that the connection pipe between the thermal bath and the pile is outside the tank insulation and is affected by the ambient temperature, resulting in a 2°C temperature loss. The pipe outlet temperature was measured at an average of 38°C.

The temperatures measured by the thermistors inside the pile are depicted in Figure 5. At the mid-level of the pile, the temperature values average around 42°C, while at the lower level, they have risen to an average of 36°C.

Of the eight thermocouples used in the test, seven were placed on the lower and side surfaces inside the tank. The remaining thermocouple was used to measure the ambient environment, aiming to assess insulation performance. The thermocouple measurements taken during the test are presented in Figure 6. While ambient temperatures can vary up to 6°C throughout the day, this variation is limited to approximately 1°C on the inner surfaces of the tank, close to the boundary.

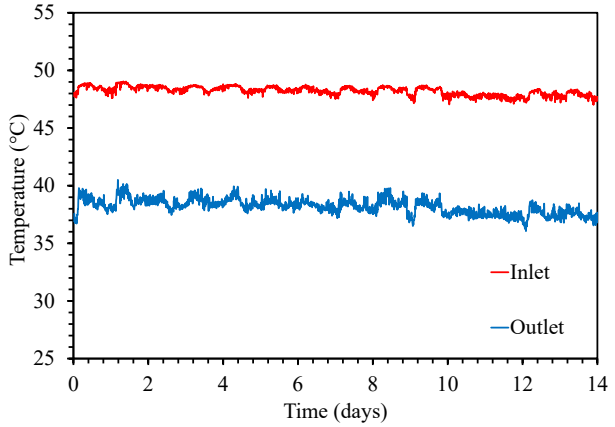

Figure 4. Inlet-outlet temperatures of the pipe.

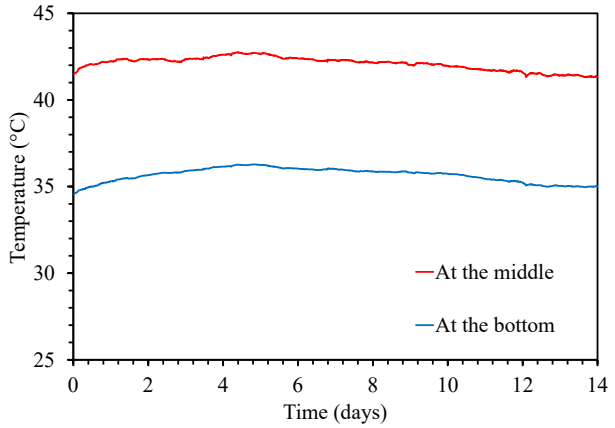

Figure 5. Temperatures at the middle and bottom of the pile.

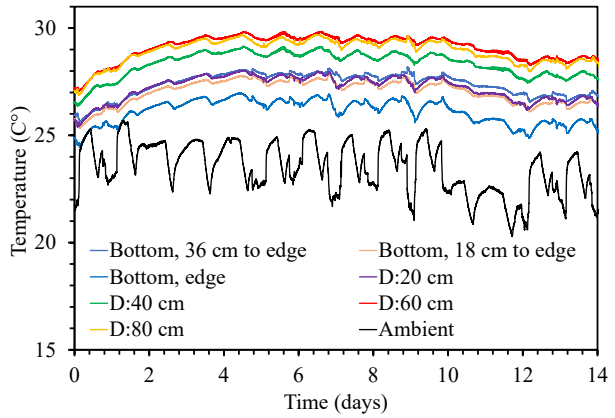

Figure 6. Temperatures at the boundaries of the tank.

4 CONCLUSIONS

Long term performance of energy piles is depended on soil thermal properties and therefore, it is a changing property with respect to the temperature and volumetric water content of the soil medium. As heating-cooling cycles occur, soil thermal conductivity might increase or decrease. Therefore, this paper develops a comprehensively instrumented model-scale test setup for long-term investigation of this phenomenon.

The test was initiated with the stabilization of the entire system by applying continuous heating. It was recorded that amount of temperature increase is different with respect to the sensor-pile relative positions. The greatest increase was observed at the vicinity of the pipe inlet while the lowest increase was obtained the bottom model boundaries, expectedly. The test is ongoing and the water potential, thermal conductivity and suction within the soil are continuously recorded, the interdependency of which will be identified by heating-cooling episodes.

On the influence of jack-up footprints on the dynamic behaviour of offshore foundations

Influence de l'empreinte des jack-up sur le comportement dynamique des fondations offshore

T. Pucker*
HafenCity University, Hamburg, Germany
**tim.pucker@hcu-hamburg.de*

ABSTRACT: Jack-up vessels are frequently used to install offshore structures. These vessels are shipped to the construction site and then lifted out of the water using their legs to create a stable working platform. Shallow foundations, so-called spudcans, are attached to the legs and pressed into the ground until sufficient bearing capacity is achieved. When the construction work is finished, the spudcan is pulled out of the ground again and usually a footprint remains representing a hole in the seabed. As the installation of offshore structures usually consists of several construction phases, several jack-up vessels are placed around the structure at different times and each vessel leaves several footprints. The influence of footprints on the dynamic behaviour of offshore structures is exemplified by the foundation of offshore wind turbines. The investigations were carried out with numerical simulations using the FEM. The influence of the footprint location as well as its distance to the structure is investigated. General recommendations are given and how this influence can be addressed in the design of the structure.

RÉSUMÉ: Les navires de type "jack-up" sont fréquemment utilisés pour l'installation de structures offshore. Ces navires sont transportés jusqu'au site de construction, puis soulevés hors de l'eau à l'aide de leurs pieds afin de créer une plate-forme de travail stable. Des fondations peu profondes, appelées "spudcans", sont fixées aux jambes et enfoncées dans le sol jusqu'à ce que la capacité portante soit suffisante. Lorsque les travaux de construction sont terminés, le spudcan est à nouveau retiré du sol et il ne reste généralement qu'une empreinte représentant un trou dans le fond marin. Étant donné que l'installation de structures offshore se compose généralement de plusieurs phases de construction, plusieurs navires autoélévateurs sont placés autour de la structure à différents moments et chaque navire laisse plusieurs empreintes. L'influence des empreintes sur le comportement dynamique des structures offshore est illustrée par les fondations des éoliennes offshore. Les recherches ont été menées à l'aide de simulations numériques utilisant la méthode des éléments finis. L'influence de l'emplacement de l'empreinte et de sa distance par rapport à la structure est étudiée. Des recommandations générales sont données sur la manière dont cette influence peut être prise en compte dans la conception de la structure.

Keywords: Offshore; jack-up; spudcan; FEM.

1 INTRODUCTION

Jack-up vessels are extensively used oil and gas exploration and in the offshore wind sector for the installation of wind turbines. These vessels are transported to their designated deployment sites, where they lower their legs to elevate the platform above the seawater level. This operational method ensures a higher degree of safety compared with conventional floating vessels, as the impact of sea conditions and water levels on jack-up vessels is less pronounced.

In oil and gas applications, jack-up legs can reach lengths of up to 170 m, with spudcan diameters reaching 20 m (refer to Figure 1). However, in the offshore wind industry, where water depths are shallower and the focus is solely on tower and turbine installation, the dimensions of jack-up vessels are significantly smaller. This fast-paced industry demands layout flexibility when positioning turbines offshore, considering various constraints such as seabed features such as cables and crane length limits. Consequently, it is imperative to assess the stability of jack-up vessels and load-bearing capacity of their spudcans across different soil types and layers.

On certain occasions, jack-up vessel spudcans may penetrate several meters of soft soil, significantly disturbing the soil and creating footprints with crater-like depressions. In scenarios where vessels revisit the same location for repeated jack-up activities, the necessity of reusing the same footprint for spudcan re-installation arises. This aspect has been investigated by

researchers such as Stewart and Finnie (2001), Cassidy et al. (2009), Qiu et al. (2013), and Jun et al. (2018).

All of these studies involve centrifuge testing and numerical modeling utilizing the Coupled Eulerian-Lagrangian method. They collectively conclude that spudcan resistance, both vertically and horizontally, decreases after reinstallation within a footprint area.

Additionally, researchers, including Leung et al. (2012), Liang et al. (2020) and Molina Mesa et al. (2023) have extensively evaluated the induced load on existing foundations resulting from adjacent spudcan penetrations and the impact of footprints on the vertical bearing capacity of nearby piles. Notably, this study delves into a comprehensive examination of horizontal capacity, particularly for relatively short foundations such as suction caissons.

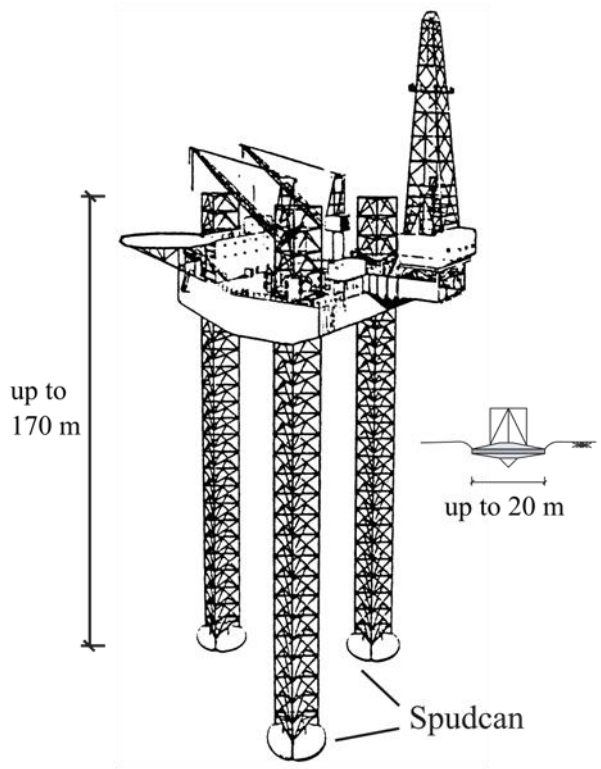

Figure 1. Illustration of a jack-up platform with three legs and spudcans including a detailed spudcan with central tip (modified after Reardon, 1986).

2 NUMERICAL MODEL

Numerical analyses are performed using the finite element software package Plaxis 3D Version 2023.2.0.1059. To save computational time, as the geometry is symmetrical, only half of the monopile and footprint is modelled.

2.1 Soil

A homogenous soil profile consisting of a single sand layer is selected for this study. The material parameters for the sand are listed in Table 1. The Hardening Soil Small Strain Model is used as material model for the sand to account for the stress dependency of the stiffness, loading history and small strain effects.

Table 1. Material parameter for the Hardening Soil Small Strain Model.

Parameter	Value
$\gamma \,/\, \gamma'$	19.6 / 9.6 kN/m^3
E_{50}^{ref}	30000 kN/m^2
E_{Oed}^{ref}	30000 kN/m^2
E_{ur}^{ref}	100000 kN/m^2
ν_{ur}	0,20
m	0,50
φ'	40°
c'	0.001 kN/m^2
ψ	0.0
G_0^{ref}	120000 kN/m^2
$\gamma_{0.7}$	0.00045
p_{ref}	100 kN/m^2

2.2 Monopile

The monopile has a penetration depth of 30 m and a free length above the seabed level of 50 m. The free length is chosen to consider a realistic combination of lateral and moment loading magnitudes at the seabed level. The outer pile diameter is 8 m. The pile is modelled using plate elements and the wall thickness is assumed to be 70 mm.

To evaluate the lateral stiffness of the monopile, the head of the monopile is moved horizontally while the reaction force is calculated. The lateral displacements at the seabed level are evaluated and compared with calculations with and without the footprint of a spudcan.

The load level of the monopile is taken as 1.5 MN in the fatigue limit state (FLS) and 10.0 MN in the ultimate limit state (ULS).

2.3 Soil pile interaction

The soil pile interaction is modelled using interface elements. The material for the interface elements is taken from the surrounding soil considering a wall friction angle of 2/3φ'.

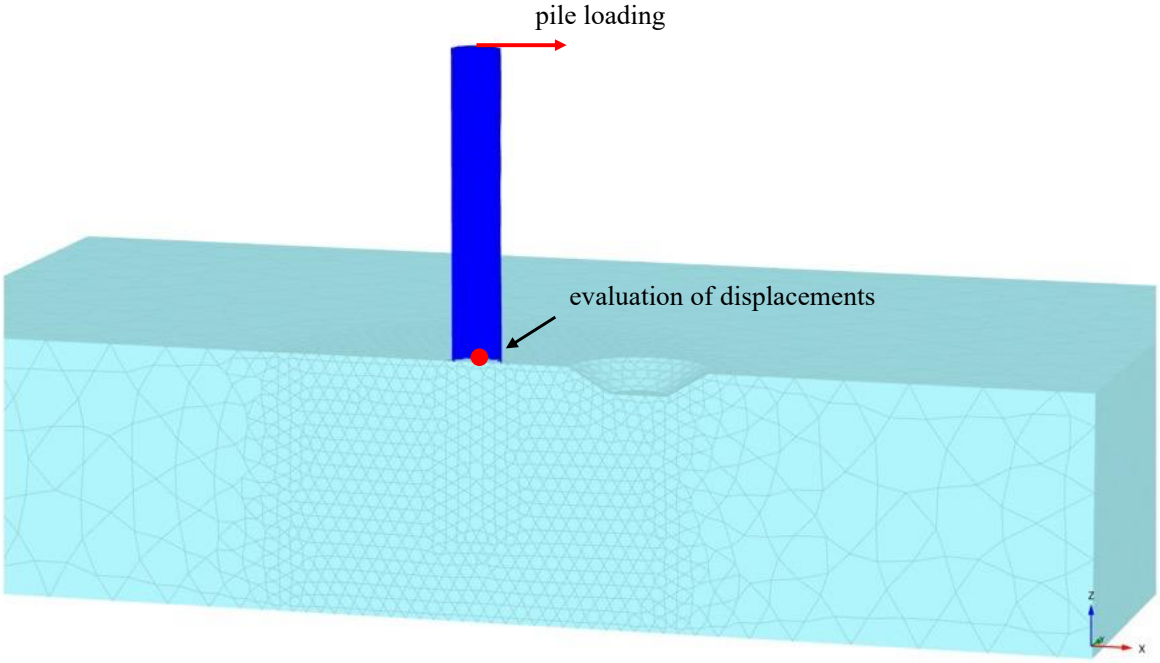

Figure 2. Numerical model of soil and pile including a footprint in 15 m distance.

2.4 Footprint

The geometry of the footprint is chosen based on offshore measurements of real footprint geometries. The geometry of the footprint is simplified as a truncated cone. The depth of the footprint is assumed to be 4 m while the diameter at the bottom of the footprint is 9.5 m and the diameter at the seabed level is 23.0 m. The distance between the footprint and monopile is varied in this study between 5.0 and 20.0 m.

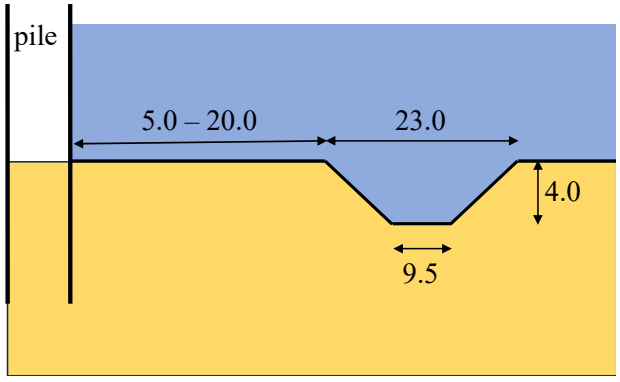

Figure 3. Geometry of the footprint and distance to monopile.

3 RESULTS

The load deflection curves for the ULS load are shown in Figure 4. As expected, decreasing the distance between the footpad and monopile increased the pile deflection at the seabed level. Hence, the horizontal stiffness of the pile soil interaction decreases resulting in a softer load response of the monopile.

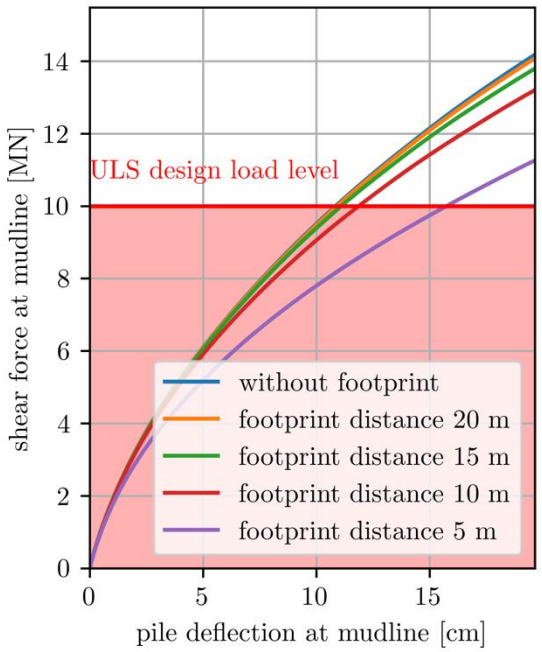

Figure 4. Load deflection curve for ULS load level considering multiple distances between monopile and footpad.

A detailed illustration of the effect of the footprint on the initial stiffness at lower load levels, such as the FLS load level, is shown in Figure 5. The influence on the initial stiffness of the pile soil interaction is much smaller than that on the stiffness at the ULS load level for distances larger than 10 m.

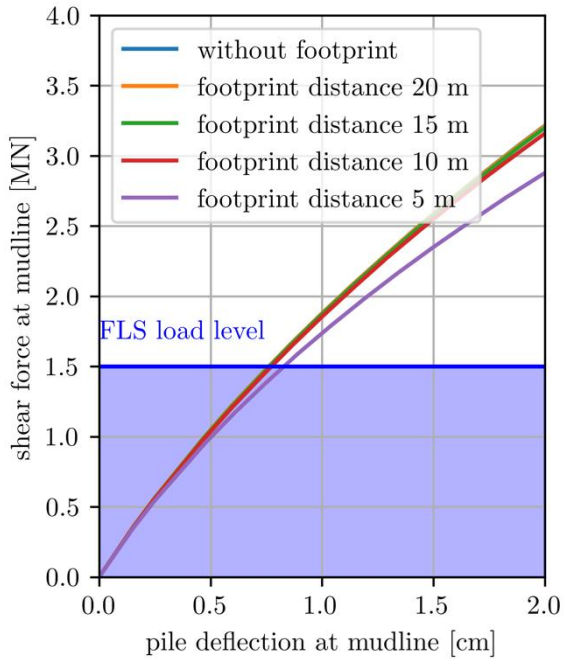

Figure 5. Load deflection curve for FLS load level considering multiple distances between monopile and footpad.

The relative change in lateral stiffness depending on the distance between the monopile and the footprint is shown in Figure 6.

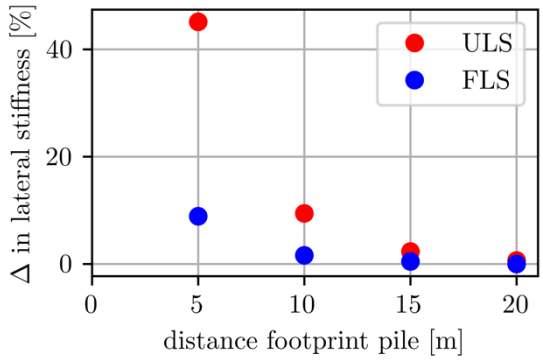

Figure 6. Change in lateral stiffness at the seabed level for multiple distances between monopile and footprint.

4 CONCLUSIONS

The present study presents an approach for estimating the influence of a spudcan footprint on the lateral stiffness response of a monopile foundation. It could be demonstrated, that for the investigated sand profile, the influence on the initial stiffness at FLS level seems to be subordiante for larger distances while the influence at the ULS level is more obvious. Nevertheless, the influence of the change in stiffness should be proven for the actual design by taking it into account for load simulations, fatigue calculations etc. In addition, it must be considered that there are several jack-up operations until the turbine is fully installed. Each operation leaves footprints that interact with a monopile foundation. Therefore, the superposition of footprints needs to be considered as well.

A novel framework for modeling the vegetation and atmosphere effect on the behaviour of infrastructure embankments

Un nouveau cadre pour modéliser l'effet de la végétation et de l'atmosphère sur le comportement des remblais d'infrastructures

V. Pujević*
Department of Geotechnical Engineering/Faculty of Civil Engineering/University of Belgrade, Serbia
L. Zdravković
Department of Civil and Environmental Engineering/Faculty of Engineering/Imperial College, London, UK
**vpujevic@grf.bg.ac.rs*

ABSTRACT: The soil-vegetation-atmosphere interaction is a dynamic process, which governs the continuous change of soil hydrological conditions. These changes directly affect the seasonal and long-term performance of infrastructure cut and embankment slopes. It has been established that the combined effect of vegetation and precipitation induces seasonal cycles of shrinkage and swelling, which give rise to serviceability issues. Previous numerical studies regarding the effect of the soil-vegetation-atmosphere system interaction on the behaviour of infrastructure embankments, were unable to quantitatively reproduce the observed hydraulic behaviour. They were either based on pure hydraulic approach or in case of fully coupled analyses were employing saturated mechanical models. The framework presented in this paper is based on the fully coupled flow-deformation analysis, combined with unsaturated soil mechanics theory and sophisticated climatic boundary conditions, implemented within the ICFEP numerical code. The instrumented railway embankment located in the UK, suffering from poor track ride quality related to the presence of vegetation on the slopes, is used as a case study for this investigation.

RÉSUMÉ: L'interaction sol-végétation-atmosphère est un processus dynamique qui régit le changement continu des conditions hydrologiques du sol. Ces changements affectent directement la performance saisonnière et à long terme des talus des infrastructures et des talus. Il a été établi que l'effet combiné de la végétation et des précipitations induit des cycles saisonniers de retrait et de gonflement, qui posent des problèmes d'entretien. Les études numériques antérieures concernant l'effet de l'interaction du système sol-végétation-atmosphère sur le comportement des remblais d'infrastructures n'ont pas permis de reproduire quantitativement le comportement hydraulique observé. Soit elles étaient basées sur une approche hydraulique pure, soit, dans le cas d'analyses entièrement couplées, elles utilisaient des modèles mécaniques saturés. Le cadre présenté dans cet article est basé sur l'analyse écoulement-déformation entièrement couplée, combinée à la théorie de la mécanique des sols non saturés et à des conditions aux limites climatiques sophistiquées, mises en œuvre dans le code numérique ICFEP. Le remblai ferroviaire instrumenté situé au Royaume-Uni, souffrant d'une mauvaise qualité de roulement liée à la présence de végétation sur les pentes, est utilisé comme étude de cas pour cette enquête.

Keywords: Soil-vegetation-atmosphere interaction; coupled analysis; unsaturated constitutive model; RWUM; precipitation.

1 INTRODUCTION

The interaction between the soil, atmosphere and vegetation drives continuous movement of water in and out from the ground, affecting the distribution of subsurface water. The ability of vegetation to remove water from the soil varies seasonally, with peaks during summer drier months, and lows during the winter months, when evapotranspiration processes are diminished or ceased. These opposite processes cause cycles of drying and wetting, and associated pore water pressure variations within the soil, which in turn produce seasonal cyclic changes of effective stresses. Therefore, in embankments constructed of clay having a high-volume change potential, these are accompanied by corresponding cycles of soil shrinkage and swelling (Smethurst et al., 2015).

Due to the irregular distribution of vegetation along the embankment length as well as variations in vegetation species, sizes and densities related to water

demands, together with intrinsic heterogeneity of the clay fill, alternating volumetric deformations are nonuniform, both in longitudinal and lateral direction, thereby inducing excessive differential movements of the track and consequently poor ride quality. These are characterized as serviceability limit states (SLS) and are most frequent during late summer/early autumn, when the effects of desiccation on high-plasticity clay fills are most significant.

Magnolia Road Project is an example of an embankment that was suffering from poor track ride quality and a high rate of maintenance due to movements associated with the presence of vegetation on the slopes of the embankment (Arup Geotechnics, 2007), and is used as a case study for the evaluation of modelling framework presented in this paper.

Predicting soil-vegetation-atmosphere interaction is not straightforward, due to the complexity of both the boundary conditions involved and the hydro-mechanical behaviour of soils, which is coupled, highly nonlinear and inherently unsaturated in case of embankments. Current paper presents an advanced approach incorporating fully coupled unsaturated flow-deformation finite element analyses.

2 MAGNOLIA ROAD CASE STUDY

The instrumented embankment is located on the Shenfield–Southend Victoria railway line near Hawkwell, Essex, UK (OS grid reference TQ856923). Highly vegetated slopes at this section of the rail track, and associated excessive cyclic shrink-swell movements, negatively affected the serviceability through frequent speed restrictions and maintenance requirements.

The embankment was constructed around 1887. Along the instrumented section, its height and width are around 5.5 m and 35 m respectively. The slope of the embankment is typically around 20° steepening to around 30° at the shoulder of the embankment. This 'coat-hanger' shape, shown in Figure 1, is clear indicator that high-water demand trees were present for the prolonged period of time. The embankment consists of intermediate to high plasticity clay fill of London Clay origin covered with a layer of ash and ballast. The techniques used for embankment construction back in the 19th century involved simple tipping in one layer to the full height with practically no mechanical compaction (Skempton, 1996), forming distinctive structure often referred to as dumped clay fills. The conceptual model for the dumped clay fill, as proposed by (O'Brien et al., 2004), consists of clods of parent material that govern the compressibility and shear modulus of the soil, and the matrix which controls the permeability and shear strength.

At the start of the monitoring period in March 2006, the embankment was densely vegetated with mature and semi-mature oak and ash trees. According to (NHBC standards, 2007) oak is being classified as high water demand tree, wail ash is more of a moderate type. Beyond the embankment to the north lies predominantly agricultural land with grass vegetation.

In March 2007, the vegetation was removed over the shoulder of the embankment leaving only the vegetation near the toe. Further tree clearance occurred in March 2010, along the full length of the embankment.

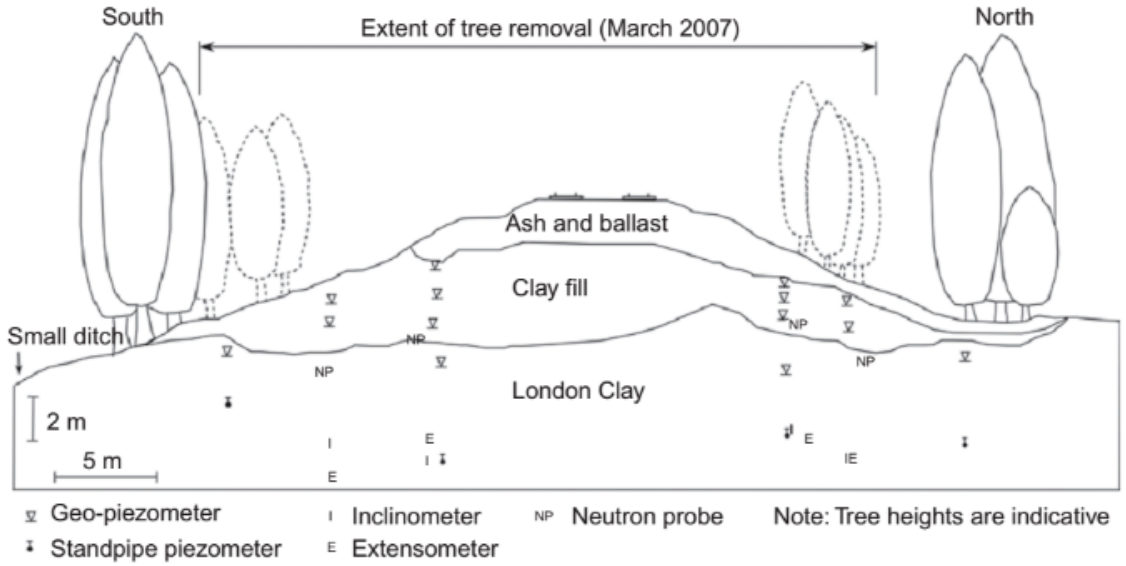

Figure 1. Cross-section view of Hawkwell embankment indicating the extent of first tree removal and location of instrumentation.

Geotechnical Interpretative Report and monitoring data were made available by (Arup Geotechnics, 2007; Geotechnical Observations, 2013). Monitoring data was available from spring 2006 until March 2011. Instrumentation was installed predominantly at two sections (Figure 1.) and consisted of: standpipe piezometers; GeO flushable piezometers (Ridley et al., 2003); neutron probe access tubes; inclinometers; extensometers; tipping bucket rain gauge.

3 NUMERICAL MODEL

Fully coupled flow-deformation analysis, combined with unsaturated constitutive model and sophisticated climatic boundary conditions, implemented within the ICFEP numerical code (Potts & Zdravković, 1999) were used to evaluate the ability of this numerical modelling approach to quantitatively reproduce the observed behaviour of the Hawkwell embankment, both prior and after vegetation removal.

The part of the finite element mesh of the northern half of the embankment and foundation soil used in plain strain analysis of the Hawkwell embankment is shown in Figure 2.

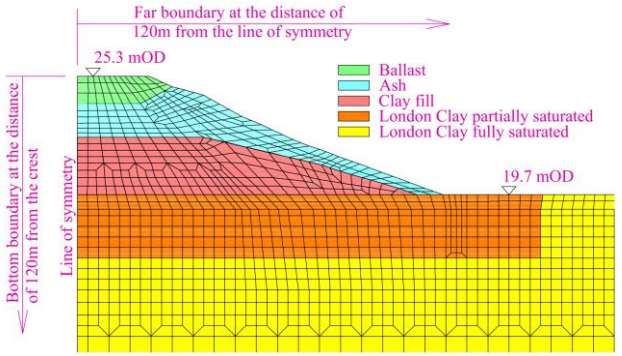

Figure 2. Zoomed in view of finite element mesh.

3.1 Hydraulic behaviour

The hydrological soil properties used in the analyses are shown in Table 1. The saturated permeability of the clay fill was adopted from the permeability testing data presented in the work of (O'Brien et al., 2004). The difference in permeability of dumped clay fill (derived from London Clay) and natural London Clay, is attributed to specific internal structure of the dumped clay fill, characterized by relatively high permeability matrix that acts as preferred flow path.

In the current analysis non-hysteretic soil water retention curve (SWRC) available in ICFEP (Melgarejo, 2004).

The gradient of the SWRC is crucial in a coupled analysis, because it affects the flow of water generated by the changes in water content. Considering that laboratory measurements of clay fill SWRC for the Hawkwell embankment were not available, the retention curve for the analysis was calibrated against in situ measurements of volumetric water content and corresponding pore water suctions.

Table 1. Hydraulic properties used in the analysis.

	Clay fill	London Clay	Ash	Balast
Isotropic/Anisotropic	Isotropic	Isotropic	Isotropic	
Saturated coefficient of permeability K_0 [m/s]	$2x10^{-9}$	$5x10^{-10}$	$4x10^{-5}$	
Nonlinear permeability model	none	logarithmic	none	Free draining
a	/	0.007	/	
Unsaturated hydraulic constitutive model	Van Genuchten type	none	none	
s_{air} *(kPa)*	20			
a	0.0125	/	/	
n	1.5			
m	0.33			

3.2 Mechanical behaviour

With regard to mechanical behaviour ash and ballast were assumed to behave as saturated materials and were therefore modelled with a linear elasto-plastic Mohr-Coulomb constitutive model. The in-situ London Clay foundation soil was also treated as saturated, except the shallow part just beneath the embankment, which is in accordance with the borehole loggings.

Table 2. Material properties used in the analysis.

	Balast	Ash[(1)]	London Clay[(2)]
Bulk unit weight γ [kN/m^3]	18,0	11,0	18,8
Shear strength parameters φ [°], c [kPa]	φ' = 40°, c' = 0 kPa	φ' = 35°, c' = 2 kPa	φ' = 20.0°, c' = 2 kPa
Angle of dilation ψ [°]	0	0	0

[(2)]London Clay properties from (O'Brien, Ellis & Russell, 2004)
*Small-strain stiffness parameters used

Table 3. Parameters of the small strain stiffness model.

Shear	A	B	C [%]	α	γ	$E_{d,min}$	$E_{d,max}$	G_{min}
	970	890	0.001	1.47	0.7	0.00173	0.173	3333.3
Bulk	R	S	T	δ	μ	$\varepsilon_{v,min}$	$\varepsilon_{v,max}$	K_{min}
	772.5	712.5	0.001	2.069	0.42	0.005	0.15	4000

Pre-peak behaviour of in-situ London Clay was formulated in terms of small strain stiffness model developed by (Jardine *et al.*, 1986) and implemented into ICFEP. The model parameters are calibrated to match shear stiffness curve measured for the London clay at Terminal 5, Heathrow Airport (Hight et al., 2003), and are given in Table 3.

The Barcelona Basic type model, modified by (Georgiadis, 2003) was used to simulate the

mechanical behaviour of clay fill. The version of BBM model implemented into finite element code ICFEP requires a minimum of 23 parameters to be defined. The significantly greater number of model parameters compared to original BBM is primarily linked to the extended (Lagioia et al., 1996) expression. The calibration exercise was based on the data published in the work of (Monroy, 2005) and are provided in Table 4.

Table 4. Modified BBM model parameters values.

Model 81 parameter	Value	Description	Model 81 parameter	Value	Description
α_g	0.4	Plastic Potential function parameters	κ_s	0.07	Elastic coefficient of compressibility for suction changes
μ_g	0.9		λ_s	0.3	Coefficient of compressibility for suction changes
M_g	0.89	Slope of the critical state line in the q–p space for triaxial compression	v_1	2.75	Specific volume at unit pressure for fully saturated conditions
α_f	0.4		χ	1	Factors the coefficient κ_s
μ_f	0.9	Yield surface parameters	ω	0	Controls the effect of S_r on the coefficient κ_s
M_f	0.89		s_{air} (kPa)	20	Air-entry suction value
α_c	1.98	Characteristic stress ratio	s_0 (kPa)	1.0E+6	Yield suction
$\lambda(0)$	0.152	Coefficient of compressibility for fully saturated conditions	p_{atm} (kPa)	100	Atmospheric pressure
κ	0.02	Elastic Coefficient of compressibility (along elastic paths)	OCR	10	Overconsolidation ratio
r	0.45	Maximum soil stiffness parameter	K_{min} (kPa)	2000	Minimum bulk modulus
β	0.011	Soil stiffness increase parameter	μ	0.35	Poisson's ratio
k	SWRC	Cohesion increase parameter *r*			

3.3 Boundary conditions

The analysis stages were systematically assembled in order to replicate as closely as possible previous stress and strain history of Hawkwell embankment. The sequence of finite element analyses is illustrated in Table 5.

Table 5. Sequence of analyses.

Increment number	Description of analysis stage	Duration
0	Setting of the initial conditions	-
0	Deactivation of the elements representing the embankment	-
1-17	Construction of the embankment	6 months
18-29	Increments not used – reserved for some trial analysis steps	-
30-605	Initialisation	4 years
606-749	Seasonal flustuation stage – first year of monitoring period	1 year
750-1325	Vegetation clearance	4 years

The purpose of the initialisation stage was to cover as realistically as possible 120 years of embankment existence prior to the start of monitoring, but at the same time without overly compromising the analysis duration (Tsiampousi et al., 2017).

The bottom boundary of the mesh was assumed to be rigid, and that pore water pressures remain unchanged from the initial state (Δp_f=0). For the line of symmetry and the far boundary, the displacements were fixed at zero in the horizontal direction and free in the vertical direction. The vertical boundaries of the mesh were assumed to be impermeable (no flow boundaries). The pore water pressure profile before the embankment construction was assumed to be hydrostatic, with the groundwater table located at 1m depth, resulting in a suction of 9.81 kPa at the surface.

Precipitation is simulated via dual condition is developed by (Smith, 2003) and implemented in ICFEP, which operates either as an infiltration (specified constant flow) condition, or as a constant prescribed pressure (variable flow) condition, thereby providing automatic and continuous division of the surface reached rainwater into infiltration, run-off and ponding. The position of precipitation BCs is schematically illustrated in Figure 3. The rainfall data used in the current analysis corresponds to the Shoeburyness weather station rainfall measurements for a period 2006-2011, Figure 7.

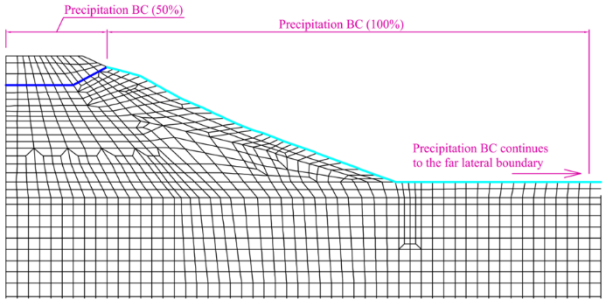

Figure 3. Contours of precipitation boundary condition.

Vegetation is simulated through non-linear root water uptake model developed by (Nyambayo & Potts, 2010). The model parameters include potential evapotranspiration, maximum root depth and reduction function. The potential evapotranspiration data for deciduous trees correspond to ones calculated using the FAO Penman-Monteith method, Figure 5. The extent over which vegetation was applied is shown in the Figure 4.

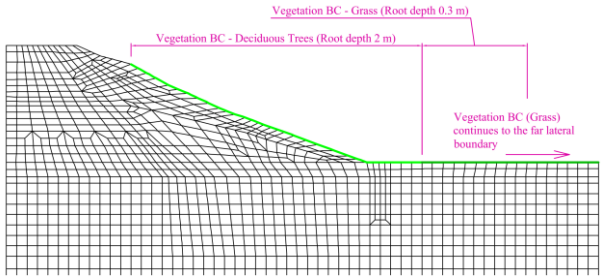

Figure 4. Contours of vegetation boundary condition.

In the present analysis the felling of large deciduous trees was modelled by reducing the root depth to 0.3 m and potential evapotranspiration rates to match the root system characteristics of the small and sparse vegetation (10% of mature trees). Trees were removed from the entire embankment slope, with the exception of zone just beyond the toe.

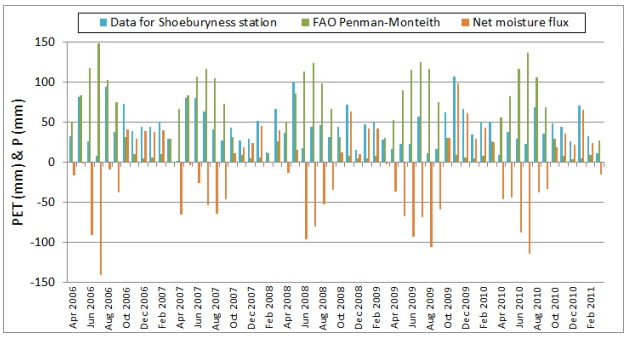

Figure 5. Potential evapotranspiration, precipitation and net rates.

3.4 Results

In the Figure 6. the comparison between the results of numerical simulation and field pore water pressure data for a midpoint of clay fill layer are presented. The obtained results, unlike some previous studies on (Briggs et al., 2016), show very good agreement with piezometers readings.

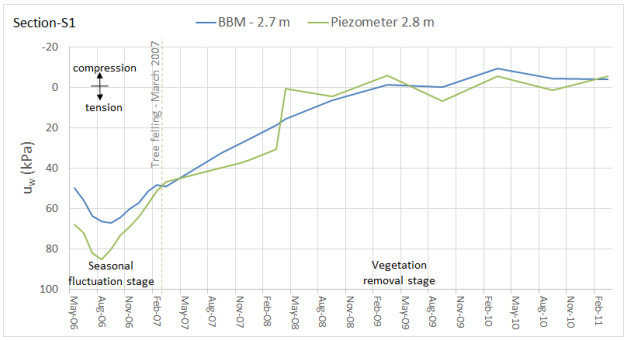

Figure 6. Comparison of numerical results and in-situ measurements of pore water pressures.

The comparison of estimated and recorded evolution of vertical displacements of a point close to the surface of section S2 is illustrated in Figure 7.

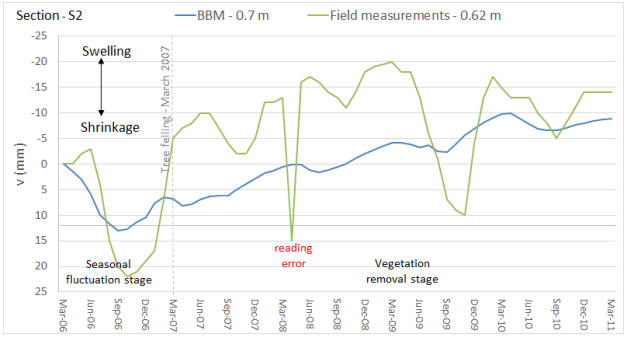

Figure 7. Comparison of numerical results and in-situ measurements of vertical displacements.

It can be seen that the numerical model somewhat underestimates the magnitudes of vertical movements. The reason for discrepancy lies in the fact that the adopted value of compressibility coefficient κ_s, that links volumetric deformation to suction changes, is based on tests on reconstituted and compacted London Clay and not the dumped clay fill.

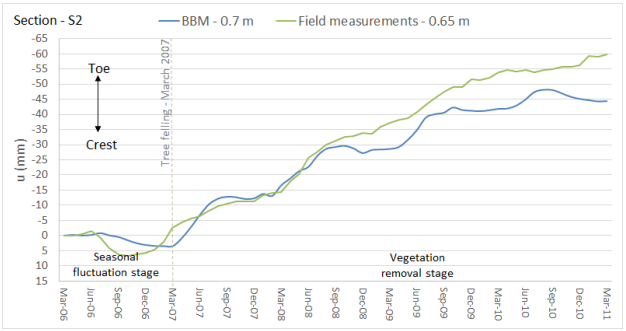

Figure 8. Comparison of numerical results and in-situ measurements of horizontal displacements.

The comparison of numerical simulations and inclinometer loggings of horizontal movements is presented in Figure 8. Both qualitatively and quantitatively, analysis predictions very accurately comply with filed observations.

4 CONCLUSIONS

The results of the presented numerical simulation prove that presented approach based on fully coupled numerical analyses combined with appropriate water retention curve, hydraulic conductivity function and advanced partially saturated constitutive model offers considerable advantages in reproducing reality. These findings will improve vegetation management, in particular the design of tree clearance schemes, and will build confidence in predictions regarding the effects of climate change.

Hydraulic properties of general-shape monodisperse granular materials: An insight from pore-network perspective

Propriétés hydrauliques de matériaux granulaires monodisperses de forme générale: Un aperçu du point de vue du réseau de pores

ABSTRACT: The understanding of the hydraulic properties of granular materials is of fundamental importance in geotechnical engineering. These macroscopic properties are fundamentally influenced by their micro-structure. However, the understanding of the link between the microstructure and the permeability is still limited, especially for granular assemblies of irregular shapes. This study bridges the gap using a framework that incorporates Discrete Element Method (DEM) simulation, image processing, and pore-network analysis. Five assemblies of natural sand grains with different sphericity and roundness are generated in DEM based on images of real geomaterials. The 3D geometries of the assemblies are processed in OpenPNM to build their pore networks, with pores represented as nodes and pore throats represented as edges that are weighted by local hydraulic conductance. Based on complex network theory, pore network features are extracted and analysed for insight into the intrinsic links between particle shape and hydraulic properties such as permeability and tortuosity. The result shows the hydraulic properties such as permeability, tortuosity and pore structures including pore size, throat size, and weighted closeness centrality of the pore network are intrinsically influenced by the particle shape.

RÉSUMÉ: La compréhension des propriétés hydrauliques des matériaux granulaires est fondamentale dans l'ingénierie géotechnique. Ces propriétés macroscopiques sont fondamentalement influencées par leur micro-structure. Cependant, la compréhension du lien entre la microstructure et la conductivité hydraulique est encore limitée, en particulier pour les assemblages granulaires de différentes formes de grains. Cette étude comble cette lacune en utilisant un cadre qui incorpore la simulation par la Méthode des Éléments Discrets (MED), le traitement d'image et l'analyse du réseau de pores. Cinq assemblages de grains de sable naturels avec différentes sphéricités et rondeurs sont générés en MED à partir d'images de véritables géomatériaux. Les géométries 3D des assemblages sont traitées dans OpenPNM pour construire leurs réseaux de pores, les pores étant représentés comme des nœuds et les gorges entre les pores comme des arêtes pondérées par la conductance hydraulique locale. Sur la base de la théorie des réseaux complexes, les caractéristiques du réseau de pores sont extraites et analysées pour comprendre les liens intrinsèques entre la forme des particules et les propriétés hydrauliques telles que la perméabilité et la tortuosité. Le résultat montre que les structures de pores, y compris la taille des pores, la taille de la gorge et la centralité de proximité pondérée du réseau de pores, sont influencées par la forme des particules.

Keywords: Granular material; hydraulic properties; pore network; complex network theory; particle shape.

1 INTRODUCTION

The hydraulic properties of porous media are of great importance in engineering applications such as dam design, geothermal engineering (Bidarmaghz et al., 2021), CO2 geo-storage (Fei et al., 2015), and radioactive waste disposal (Brauer, 1981). Such properties are fundamentally influenced by the microstructures within the porous media(Van der Linden, 2019). The influence of particle shape on the hydraulic behaviours has been investigated through numerical simulations (Garcia et al., 2009; Zhao & O'Sullivan, 2022) and laboratory tests (Wei et al., 2021). However, the characterisation and links between the pore structures, grain shapes, and the hydraulic properties are largely unknown.

In this study, the micro-geometries of natural sand particles are obtained from CT scanning based on an established framework (Fei et al., 2021) and used to build non-spherical particle assemblies using Discrete Element Methods (DEM) (Galindo-Torres, 2013). Pore network models are constructed using Open-PNM, with maximal inscribed spheres representing the pores and cylinders representing the throats (J. T. Gostick, 2017). Complex network theory (Van der Linden et al., 2018) are utilized to analyse the intrinsic

links between the microstructures and the hydraulic properties, which is one of the first studies of its kind.

2 METHODOLOGY

2.1 Discrete element assemblies

To investigate the influence of particle shape on the microstructure and the resulting hydraulic properties, five particle shapes from CT-scanned natural sand are selected as the input for the framework proposed by this study (Table 1). Sphericity was adopted as shape descriptors to quantify the irregularity of particle shapes. In this study, only the contribution of particle shape to the microstructures of the assemblies was considered. All the particles are normalised to the same equivalent diameter of 3mm to create monodisperse assemblies.

Table 1. Particles with different sphericity.

ID	G1	G2	G3	G4	G5
Sphericity	0.895	0.863	0.790	0.719	0.588
Shape					

The monodisperse granular assemblies are generated based general-shape DEM within the open-source code Mechsys (Galindo-Torres, 2013). DEM particles are generated in a rigid box with a dimension of X×Y×Z=60×36×36mm. The irregular particles are initially placed in 6×6 horizontal matrices with random orientations and then drop to the bottom of the box driven by gravitational forces (Figure 1 (a)).

Subsequently, the generated assemblies are compressed (Figure 1 (b)) by a rigid plate from the top at a (relatively slow) speed of 0.01mm/s until reaching the target initial porosity n =0.4. Next, particles in the assembly were fixed to form a rigid assembly after particles stabilised.

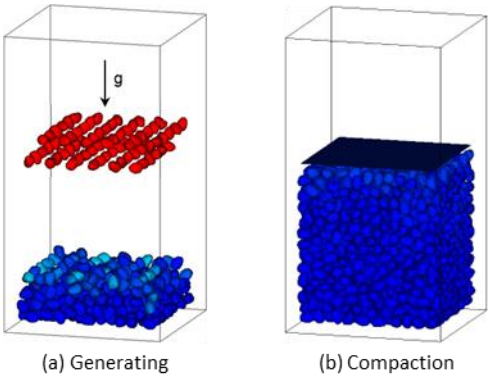

Figure 1.General-shape granular assemblies (a) DEM particle generation; (b) assembly compaction.

2.2 Pore-network construction

The pore network generator, Open-PNM, requires sequential images as inputs. Firstly, the granular assemblies generated in DEM were exported as STL meshes to obtain the geometry of the void space within the assemblies. Next, Boolean operations are conducted in Blender by subtracting the assembly meshes with a solid cube, which creates a pore geometry cube in the form of STL meshes (Figure 2(a)). The pore geometry cube was further sliced in Blender by horizontal planes along the vertical direction with evenly distributed intervals, which creates a stack of pore images (Figure 2 (b)) for the subsequent pore network construction.

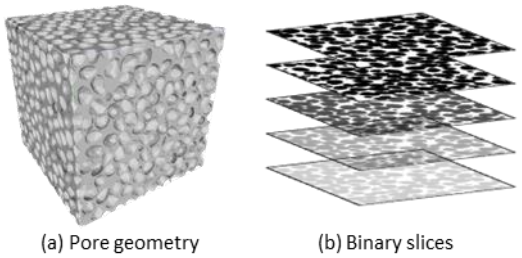

Figure 2. Pore information extraction (a) pore space geometry; (b) pore binary slicing.

To build the pore network models, the binary images (Figure 3 (a)) are processed with Open-PNM in Python. The SNOW algorithm (J. Gostick et al., 2016; J. Gostick, 2017) was applied to segment and recognize the pores (Figure 3 (b)).

To construct the pore network model, pores are represented by their maximum inscribed spheres, while the throats connecting the pores are represented by cylinders (Figure 3 (c)). By implementing these representations, the three-dimensional pore networks including the distribution and connectivity information are thus extracted from the granular assemblies (Figure 3 (d)).

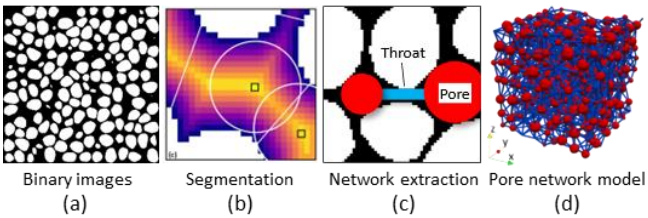

Figure 3. Construction of pore networks.

3 RESULTS

3.1 Pore and pore throat size distributions

To investigate the influence of particle shapes on the pore network structures, the probability distributions

of pore and throat sizes within assemblies of different particle shapes are statistically calculated (Figure 4). Particle shape has been observed to have a significant influence on the statistical distributions of the equivalent diameter of both the pores and throats. Rounded particles, such as G1, generally exhibited higher probability at larger equivalent diameters for both pores (0.8mm) and throats (1.7mm), compared with platy particles, such as G5.

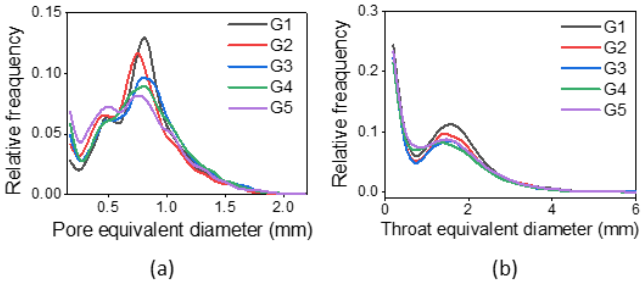

Figure 4. Pore networks size distribution:(a) pore size distribution; (b) throat size distribution.

3.2 Pore throat orientation

To further understand the impact of particle shape on pore network orientations, the edges in the networks are considered as vectors and are thus projected onto the horizontal (XY) and vertical (XZ) planes (Figure 5 (a)). The probability distribution of the orientations from the projected vectors are calculated, and here only the results for G1 and G5 are compared for simplicity. The particle shape has induced a larger difference on the XZ plane (Figure 5 (b)) compared with that on the horizontal XY plane (Figure 5 (b)). The platy particle G5 has induced structural anisotropy in pore networks, with pores having better connectivity along the horizontal direction compared to the vertical direction. Such phenomenon reals the particle shape has a significant influence on the orentation of pore networks.

3.3 Network features

Complex networks theory was uses to characterise the pore network structures. A network consists of multiple nodes connected by edges. In certain circumstances, the weights are assigned to the edges to describe the strength or importance of the connection. In this study, the pores are treated as nodes and the throats as edges. The edges are weighted by the local hydraulic conductance (Van der Linden et al., 2018) calculated from the equivalent cylindrical pores and all the connecting throats.

Network features are calculated following complex network theory, to quantify the pore networks. The *closeness centrality* measures the proximity of a node to other nodes, which has been proved to have a strong corelation with the hydraulic properties of sphere assemblies (Van der Linden et al., 2018), and thus was employed to characterise the pore network structures.

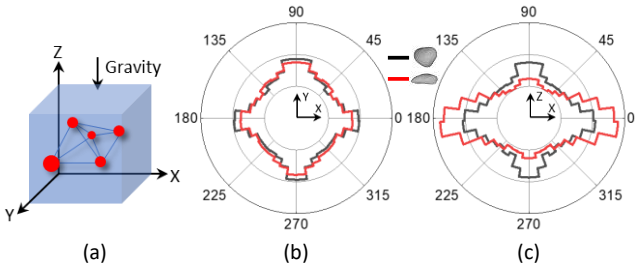

Figure 5. Pore network orientation (a) schematic of pore network projection; (b) frequency on XY plane; (c) frequency on XZ plane.

The node closeness centrality for each pore and their probability distribution are calclulated (Figure 6 (a)), which exhibits minor varation induced by particle shape. To link the pore networks with the macroscopic hydraulic properties, *weighted closeness centrality* was calculated from the local hydraulica conductance weighted pore network model (Figure 6 (b)). It is observed that the particle shape has a significant impact on the weighted closeness centrality distribution. Rounded particles, like G1, generally have higher weighted closeness centrality compared with platy particles such as G4 and G5.

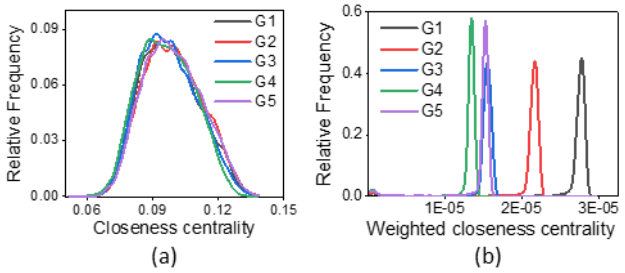

Figure 6. Probability distribution of pore network features: (a) closeness centrality (b) weighted closeness centrality from local hydraulic conductance.

3.4 Hydraulic properties

The influence of particle shape on the hydrolic properties are further investigated. Permeability along the horizontal and vertical directions was directly derived from the local hydraulic conductance within pore networks (Figure 7 (a)). Tortuosity, which quantifies the extent of distortion in flow paths along the macroscopic flow direction, was calculated from the effective diffusion path length devided by the straight-line distance along specific direction (Figure 7 (b)). Particle shape influences the permeability and tortuosity in both directions. Anisotropy was observed in permeability and tortuosity along both the horizontal and vertical directions. The platy particles

such as G5 have induced more significant anisotropy in both hydraulic properties.

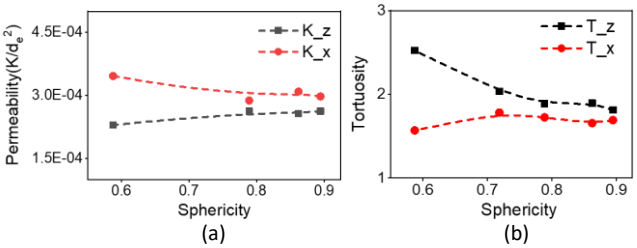

Figure 7. Influence of particle shape on hydraulic properties (a) permeability (b) tortuosity.

4 CONCLUSIONS

Based on DEM simulation, images processing, and pore network analysis, this study reveals the influence of particle shapes on the pore network and hydraulic properties of monodisperse granular assemblies.

The pore structures of granular assemblies are intrinsically influenced by the shapes of the constituent particles. Assemblies composed of more rounded particles generally exhibit larger pore and throat sizes.

The structural and hydraulic anisotropy induced particle shape are observed, which was more intensive for more platy particles such as G5.

Weighted edge closeness centrality could reflect the influence of particle shape on pore structures and hydraulic properties.

Future studies could expand the investigation to include a broader range of particle shapes, sizes and more detailed network features for pore network insight.

ABSTRACT: This study investigates the effectiveness of bentonite-amended flyash (BAF) liners as barriers against infiltration in municipal solid waste (MSW) landfills. Laboratory experiments were conducted to evaluate the compaction properties and hydraulic conductivity (HC) of the BAF liners with varying mix proportions. Flyash, a byproduct of coal-fired power plants, amended with bentonite was utilized as a cost-effective alternative to conventional clay liners. Bentonite, a highly expandable clay mineral, was incorporated to enhance hydraulic performance. Standard Proctor compaction tests were performed to determine optimal compaction properties of different BAF mixes. Further, BAF specimens with different mix proportions were prepared by compacting at maximum dry density (MDD), and optimum moisture content (OMC). HC tests were performed on the compacted samples using a flexible-wall (triaxial) permeameter apparatus following ASTM standards. Compaction test results revealed that a mix ratio of 80:20 (Flyash: Bentonite) resulted in highest MDD and lowest OMC. Results also revealed a significant reduction in HC upon the addition of bentonite to the BAF liner. As the bentonite content increased, the HC decreased, indicating improved barrier properties. The optimal performance was achieved with a bentonite content of 20-30%, resulting in good compaction properties (high MDD and low OMC), and a HC below the regulatory limit of 10^{-7} cm/s, rendering the mix proportion optimal for barrier application. Overall, this study highlights the potential of BAF liners as efficient and cost-effective barrier systems for MSW landfills. The significant reduction in HC because of bentonite amendment, and excellent heavy metal and nutrient adsorption capabilities of flyash renders BAF effective for application as a barrier material in landfills.

RÉSUMÉ: Cette étude examine l'efficacité des revêtements de cendres volantes modifiées par de la bentonite (BAF) comme barrières contre l'infiltration de lixiviat dans les décharges de déchets solides municipaux (MSW). Des expériences en laboratoire ont été menées pour évaluer les propriétés de compactage et la conductivité hydraulique des revêtements BAF avec différentes proportions de mélange. Les cendres volantes, un sous-produit des centrales électriques au charbon, modifiées avec de la bentonite, ont été utilisées comme alternative rentable aux revêtements en argile conventionnels. De la bentonite, un minéral argileux hautement expansible, a été incorporée pour améliorer les performances hydrauliques. Des tests de compactage standard Proctor ont été effectués pour déterminer les propriétés de compactage optimales de différents mélanges BAF. De plus, des échantillons de BAF avec différentes proportions de mélange ont été préparés par compactage à une densité sèche maximale (MDD) et à une teneur en humidité optimale (OMC). Des tests de conductivité hydraulique ont été effectués sur les échantillons compactés à l'aide d'un appareil à perméamètre à paroi flexible (triaxial) conformément aux normes ASTM. Les résultats des tests de compactage ont révélé qu'un rapport de mélange de 80:20 (Flyash: Bentonite) entraînait un MDD le plus élevé et une OMC la plus faible. Les résultats ont également révélé une réduction significative de la conductivité hydraulique lors de l'ajout de bentonite au revêtement BAF. À mesure que la teneur en bentonite augmentait, la conductivité hydraulique diminuait, ce qui indique des propriétés de barrière améliorées. Les performances optimales ont été obtenues avec une teneur en bentonite de 20 à 30%, ce qui se traduit par de bonnes propriétés de compactage (MDD élevé et faible OMC) et une conductivité hydraulique inférieure à la limite réglementaire de 10 à 7 cm/s, rendant la proportion de mélange optimale pour application de barrière. Dans l'ensemble, cette étude met en évidence le potentiel des revêtements BAF en tant que systèmes de barrière efficaces et rentables pour les décharges de DSM. La réduction significative de la conductivité hydraulique due à l'amendement bentonite et aux excellentes capacités d'adsorption des métaux lourds et des nutriments par les cendres volantes rendent le BAF efficace pour atténuer la migration des lixiviats et minimiser les risques de contamination de l'environnement.

Keywords: Bentonite-amended flyash; hydraulic conductivity; leachate containment; landfill liners.

1 INTRODUCTION

Landfilling, with its aim of safeguarding the environment from potential harm due to waste disposal, addresses the critical challenge of managing the municipal solid waste (MSW). MSW, if not properly contained, poses severe risk of contaminating surface water, groundwater, soil, and air, thereby directly or indirectly affecting human health (Freeman, 1989; USEPA, 1989; Qasim and Chiang, 1994). A typical engineered landfill consists of three essential components: the top soil cover system, waste layer, and a bottom liner system (Sharma and Reddy, 2004). The bottom liner layer plays a crucial role in restricting the infiltration of leachate to groundwater. Acting as pivotal barriers, liners play an important role in effectively preventing the migration of harmful leachate substances into underground aqueducts and aquifers (Sharma and Reddy, 2004). The soil liner layer, functioning as a barrier generally consists of compacted fine-grained soil, which must adhere to specific criteria, including HC ($<10^{-7}$ cm/s), sufficient strength (Unconfined compressive strength (UCS) - 200 kPa), the absence of shrinkage/desiccation cracks, the absence of lumps/clods in compacted clay, and an adequate thickness of compacted clay (>100 cm), as outlined by Central Pollution Control Board (CPCB, 2001), and United States Environmental Protection Agency (USEPA, 1989).

Constructing liners for landfills becomes a formidable task when obtaining large quantities of low-permeable materials near the site proves challenging. In instances where suitable clayey materials are not locally available, project costs can escalate significantly due to the necessity of importing materials from external sources (Mishra and Ravindra, 2015). In addition, the high swelling characteristic of bentonite and some other low permeable clays often results in the development of desiccation cracks after several wetting and drying cycles (Gahlot et al., 2022). Nevertheless, leveraging the superior rheological and adsorption properties of bentonite, in combination with other non-plastic materials, offers a promising approach to meet the criteria of strength and permeability for effective liner materials (Daniel and Wu, 1993; Al-Badran et al., 2017; Mukherjee and Mishra, 2020; Raviteja et al., 2024).

Flyash is recognized as a potential material suitable for use as a liner when combined with bentonite or low-permeable clay. The particles of flyash exhibit a spherical shape and comprise solid spheres, cenospheres, irregular-shaped debris, and porous unburnt carbon (Buragohain et al., 2018). Past research has indicated that flyash can be effective in adsorbing a wide range of contaminants making it suitable as a component of landfill liners. However, flyash as a standalone barrier material, owing to its high permeability and non-plasticity, will not satisfy the requirements of a liner system. Hence, it is required to amend flyash with a low-permeable clayey material like bentonite in order to be employed as a barrier material. Hence, the aim of the current study is to evaluate the compaction properties and HC of different proportions of flyash and bentonite to identify the optimal mix of these materials to be employed as a landfill liner material.

2 MATERIALS AND METHODS

2.1 Flyash

In this study, class-F flyash sourced from Charlotte, NC, situated in the South-Eastern part of the USA, is utilized. Table 1 provides an overview of the physio-chemical and geotechnical properties of the flyash in accordance with ASTM standards. According to the Unified Soil Classification System (USCS), the material is classified as ML. The MDD and OMC of the flyash are observed to be 1.3 g/cm^3 and 19.1%, respectively. The saturated HC (SHC) is reported as 8.79×10^{-5} cm/s, indicating the highly porous nature of the material.

Table 1. Geotechnical and physio-chemical properties of bentonite and flyash used in this study.

Property	**Bentonite**	**Flyash**
Specific Gravity	2.49	2.27
Grain Size Distribution		
Coarse fraction	14.4	11
Silt fraction (<0.005 mm), %	30	82
Clay fraction (<0.005 mm), %	70	7
Mean diameter (D_{50}), mm	0.002	0.034
Liquid Limit (LL), %	371.7	-
Plastic Limit (PL), %	42.2	-
Plasticity Index (PI), %	329.4	NP
USCS Classification	CH	ML
Moisture-Density Relationship		
OMC, %	39.0	19.1
MDD, g/cm^3	1.24	1.30
Free Swell, ml/2g	24	-
SHC, cm/s	1.20×10^{-9}	8.79×10^{-5}
pH	9.60	7.57
Oxidation Redox Potential (ORP), mV	70.3	110.0
Electrical Conductivity (EC), µS/cm	1369	1325

2.2 Bentonite

To attain the targeted low HC levels, the utilization of bentonite as a liner material is crucial. Bentonite is composed of clay particles characterized by high plasticity and strong bonding ability. In this research, commercial sodium bentonite VOLCLAY® SOIL SEALANT CP-200, sourced from Colloid Environmental Technologies Company (CETCO), USA, is employed. Table 1 provides an overview of the physio-chemical and geotechnical properties of the bentonite. It is observed that the MDD and OMC of the bentonite are 1.24 g/cm^3 and 39%, respectively. The SHC is noted as 1.2×10^{-9} cm/s, significantly lower than that of flyash.

2.3 Compaction testing

To ensure HC and strength characteristics remain within safe limits for geomaterials employed in liners, it is crucial to identify the appropriate range of compaction parameters, including water content and dry unit weight, as emphasized by Younus and Sreedeep (2012). The desired HC was successfully achieved in both compacted and non-compacted bentonite-flyash mixes at proportions of 40-60% and 70-30%, as reported by Rashid et al. (2021). This underscores the significance of compaction in minimizing the HC of the mixed proportion. In the current research, the compaction properties of various bentonite-flyash mixes, ranging from 0-50%, were investigated. Standard proctor compaction tests as per the procedures stipulated in ASTM D698 (2021) were performed to determine the OMC and MDD of different bentonite-flyash mixtures.

2.4 Hydraulic conductivity testing

The HC of various proportions of bentonite and flyash were then determined at the optimum compaction conditions (OMC and MDD). Pre-compaction, the materials mixed with water, to achieve OMC, were kept in moisture desiccators at room temperature for 24 hours to achieve moisture equilibrium. The materials were then compacted at the predetermined MDD using a Harvard miniature compactor. Tests were conducted using triaxial flexible-wall permeameter at different mix proportions using cylindrical samples with 3.3 cm diameter and 7.1 cm height. Figure 1 shows the test setup for the HC determination. The HC of the compacted samples is determined using constant head method as per the procedure stipulated in ASTM D5084 (2016). The HC of the sample is determined after ensuring full saturation (Skempton's pore pressure coefficient – 0.986).

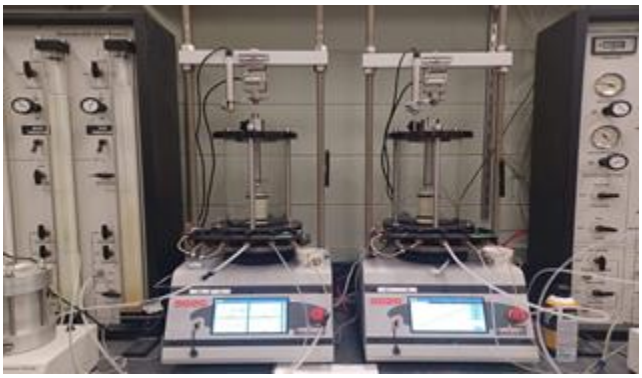

Figure 1. Flexi-wall triaxial setup used for hydraulic conductivity testing.

3 RESULTS AND DISCUSSION

3.1 Compaction testing results

A series of compaction tests were conducted on the BAF mix with proportions of bentonite varying from 5-50%. As shown in Figure 2, it is observed that the MDD has increased from 1.36 g/cm^3 to 1.47 g/cm^3 with an increase in bentonite content from 5 to 20%, and has decreased with further increase in bentonite content. The OMC has decreased from 23.2% to 19.6% with increase in bentonite content up to 20% and increased with further increase in bentonite content.

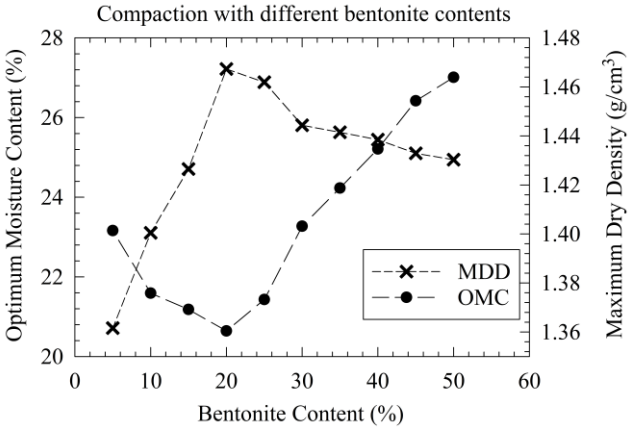

Figure 2. Influence of bentonite content on the maximum dry density (MDD) and optimum moisture content (OMC) of flyash.

It can be noted that the highest value of MDD and lowest OMC was observed at 80% flyash and 20% bentonite mix proportion. The initial increase in MDD values can be attributed to the improved compaction and packing of the soil particles due to the presence of bentonite, leading to greater dry density. Beyond a certain threshold (20%), the continued addition of bentonite may lead to excessive plasticity, hindering effective compaction. Beyond this point, the OMC

may increase, and MDD may decrease as the excess bentonite becomes more difficult to compact effectively.

The scanning electron microscopy (SEM) analysis carried out on the optimum flyash-bentonite mix (80F-20B) is shown in the Figure 3. The large spherical solids are cenospheres and other particles of flyash. Cenospheres are composed primarily of silica, alumina, and iron oxide, which can help in adsorption of inorganic pollutants. The smaller particles adsorbed onto the surface of flyash particles are the particulate matter of bentonite. As observed in the SEM image, the bentonite particles not only bonded with flyash particles, but they also helped in forming flocs of flyash particles. This flocculated structure of BAF particles can be the possible reason for excellent compaction achieved, with highest value of MDD, for 80-20 mix.

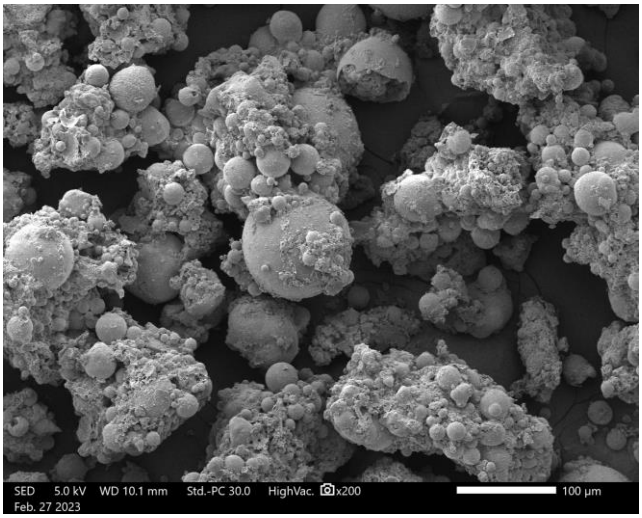

Figure 3. Scanning electron microscopy image of 80% flyash and 20% bentonite mix.

3.2 Hydraulic conductivity testing results

The HC tests were conducted at bentonite proportions varying from 10-50%. The results of the HC tests are presented in Figure 3. It is seen that for the mix proportion containing 0-10% bentonite, the HC is far higher than acceptable value of 10^{-7} cm/s. This is primarily due to the highly porous nature of flyash, which dominates the HC of the mix. The porous structure of flyash facilitates the movement of water, leading to higher HC. However, with further increase in bentonite content the HC has reduced. For a bentonite content of 20% to 30% and more, the HC has reached acceptable levels. The combination of bentonite with flyash aids in reducing HC by establishing a robust bond through pozzolanic reaction and clogging the pore spaces in flyash with swollen bentonite (Rashid et al., 2021).

The results suggest that the specific combination of 70-80% of flyash and 20-30% bentonite, by weight, provides an effective balance between the porous nature of flyash and the low permeability of bentonite. The bentonite content at this ratio sufficiently reduces the overall HC of the mixture, making it suitable for landfill liner applications.

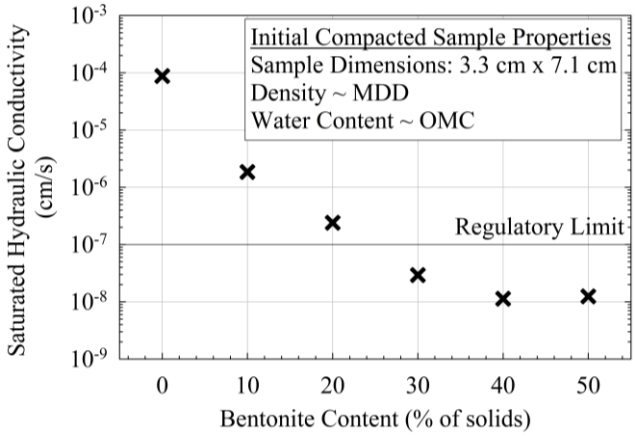

Figure 4. Influence of bentonite content on the hydraulic conductivity of flyash.

Past studies conducted to assess the performance of BAF for liner applications has resulted in similar outcomes. The optimal percentage of flyash that can be mixed with bentonite is determined to be up to 70% to ensure workability and maintain the quality of the liners as observed by Younus and Sreedeep (2012). A study conducted by Murat and Yilmaz (2001) examined the behavior of a mixture of flyash and bentonite, concluding that a combination of flyash with 20% bentonite is suitable as a liner and cover material at waste disposal sites.

4 CONCLUSIONS

Current study investigated the effectiveness of BAF as a low-permeable barrier material for application in covers/liners of MSW landfills. Laboratory experiments evaluated HC under varying conditions. Specimens with different flyash and bentonite mix proportions were prepared and compacted to optimal density. The following observations are made from the study:

- Optimal performance, in terms of compaction properties, of the proposed liner material was achieved with a bentonite content of 20% and 80% of flyash resulting in high MDD of 1.47 g/cm^3.
- Scanning electron microscopy (SEM) analysis of the optimal mix (80F-20B) revealed large

spherical solids as cenospheres of flyash and bentonite particles adhering to flyash.

- The pozzolanic reaction and the formation of a C-S-H gel matrix likely resulted in effective bonding between flyash and bentonite particles, and also resulted in a flocculated structure of particles resulting in effective compaction.
- A significant reduction in HC was observed with increased bentonite content from 0-50%.
- Bentonite content of 20-30% resulted in acceptable levels of HC for barrier applications.

Overall, this study highlights the feasibility of using BAF as efficient and cost-effective barrier material for MSW landfills. Although HC requirements can be satisfied using BAF, further studies regarding compatibility with various contaminants that can be found in landfill leachate are needed for application as a liner. Further, microstructural and chemical component analyses can help in understanding the interactions between bentonite and flyash particles at different mix proportions. In addition, field scale testing is required to assess the performance of the same in the presence of actual leachate containing diverse range of contaminants.

ABSTRACT: Offshore wind turbines are typically fixed to the seabed via open-ended (OE) pile foundations. The risk and cost associated with OE pile installation may be reduced by performing field-scale tests to ensure adequate in-service capacity, as well as gain understanding of installation characteristics for equipment specification. However, to do so is often expensive and in most cases, highly impractical. Instead, 1*g* small-scale model tests can be used, in part, to study mechanistic behaviour which can aid in validating numerical methods which are capable of scaling to field conditions. In this paper, 1*g* pile model tests are undertaken in both sand and soft rock and the differing *in-situ* mechanisms are revealed through novel in-test X-ray techniques with time-resolve enabling a 4D study. The tests presented here are facilitated using a new compact multi-axis loading frame which is operable from within a CT bay.

RÉSUMÉ: Les éoliennes offshore sont généralement fixées au fond marin via des fondations sur pieux à extrémité ouverte (OE). Le risque et le coût associés à l'installation de pieux peuvent être réduits en effectuant des tests à l'échelle du terrain pour garantir une capacité en service adéquate, ainsi qu'en comprenant les caractéristiques d'installation pour les spécifications de l'équipement. Cependant, cela s'avère souvent coûteux et ce n'est pas pratique dans la plupart des cas. Au lieu de cela, les tests sur modèle 1*g* à petite échelle peuvent être utilisés, en partie, pour étudier le comportement mécaniste, ce qui peut aider à valider des méthodes numériques capables de s'adapter aux conditions de terrain. Dans cet article, des tests sur modèles de pieux de 1*g* sont entrepris à la fois dans le sable et dans la roche tendre et les différents mécanismes in situ sont révélés en raison de nouvelles techniques de rayons X en cours de test avec résolution temporelle permettant une étude 4D. Les tests présentés ici sont facilités à l'aide d'un nouveau bâti de chargement multi-axes compact qui peut être utilisé depuis une baie CT.

Keywords: Plugging; pile installation effects; MicroCT.

1 INTRODUCTION

Offshore structures are commonly fixed using open-ended (OE) pile foundations. These, which vary in diameter from less than 1 m to more than 8 m (Buckley et al., 2020), are designed to resist large environmental loads and to do so, require sufficient penetration defined by axial and lateral capacity requirements. Actual installation performance on site can vary, and risks such as pile run and conversely pile refusal can occur, leading to uncertain capacity. For small diameter piles, the risk of refusal is often associated with the occurrence of plugging, for which there is a greater tendency in small diameter piles due to ease of arching. This leads to an increased end bearing component as the plug forms (Fan et al., 2021) and can make reaching installation depth required for adequate lateral and axial capacity challenging. With the above in mind, novel small-scale model tests performed at 1*g* and paired with X-ray imaging are used here to investigate the occurrence of plugging on installation performance in sand and soft rock, the latter notorious for uncertainty in pile installation (Lord et al., 2002). These tests demonstrate how a blend of radiography and computed tomography (CT) can be used to track pile installation and fabric changes, offering new valuable insights which build on prior application of pile tracking through static CT (Doreau-Malioche et al., 2018). Carrying out live X-ray tomography during the installation is challenging and, in this instance, has been achieved by utilising a new multi-axis loading frame developed by Riccio et al. (2024) which is operable from within a CT bay, shown in *Figure 1*.

The tests reported in this study are not aimed to replicate real engineering application due to the limitations of the low-stress level and boundary effects. Rather, they focus on mechanistic, grain scale insight thanks to the micro level (μm) resolution of CT which may help ease the validation of new numerical

simulation techniques, like those used to study pile installation in complex geomaterials (Ciantia, 2022).

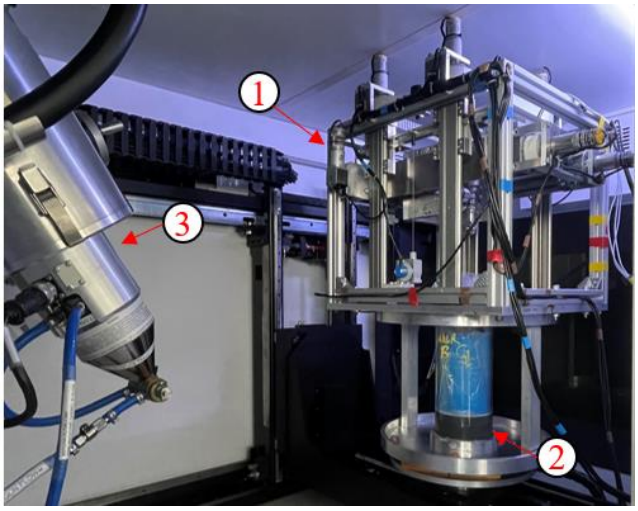

Figure 1. Multi-axis loading frame (1) with sample installed (2) positioned in lab-based X-ray CT scanner (3).

2 MATERIAL AND EXPERIMENT SET UP

2.1 Multi-axis actuator

The model tests were performed using a new multi-axis loading frame (*Figure 1*), which can apply up to 5 kN of vertical load and 400 N laterally. Actuation in the X, Y and Z plane was facilitated by DC motors controlled by a software based PID feedback which enabled both monotonic and cyclic displacement control (Riccio et al., 2024).

2.2 Sample material and preparation

Samples were prepared in a 300 mm tall acrylic chamber with a diameter of 120 mm which was fixed below the multi-axis actuator as shown in *Figure 1*. A well characterised dry sand (HST-95, see e.g., Lauder et al. (2013)) was used and pluviated from an automated hopper into the acrylic tube, achieving a relative density of $D_r = 80$ %. The soft rock sample ($\sigma_c < 2$ MPa, $d_{50} = 86$ µm) consisted of a highly porous sedimentary calcarenite rock which is widely spread along mediterranean coasts and is present at several offshore wind farms (Ciantia et al., 2015; Palix & Lovera, 2020). The cored soft rock sample, 150 mm tall and with a diameter of 100 mm, was fully saturated, notable as its strength reduces with an increasing degree of saturation (Ciantia et al., 2015).

2.3 Experimental procedure

For the soft rock a model pile of diameter Ø11.65 mm and wall thickness of $t_w = 0.74$ mm was used and for the sand a Ø15.37 mm ($t_w = 0.86$ mm). The installation depth was 100 mm in both cases, with a rate of 0.03 mm/s for the calcarenite, in order to preserve fully-drained conditions; and 0.1 mm/s for the dry sand. Following installation, tension pulls were performed on the pile installed in soft rock. During all of the aforementioned stages, live radiography was used to monitor the installation procedure. The CT scan for the soft rock test was performed following installation to study the material fabric around the pile and consisted of 8 frames per position (3141) acquired with an X-ray beam tension of 220 kV and current of 500 µA. The radiography used the same ray settings and projections were obtained every 500 ms.

3 RESULTS

3.1 Force-displacement response

In Figure 2(a) and (b), the installation force-displacement profiles for the sand (a) and the soft rock (b) are shown.

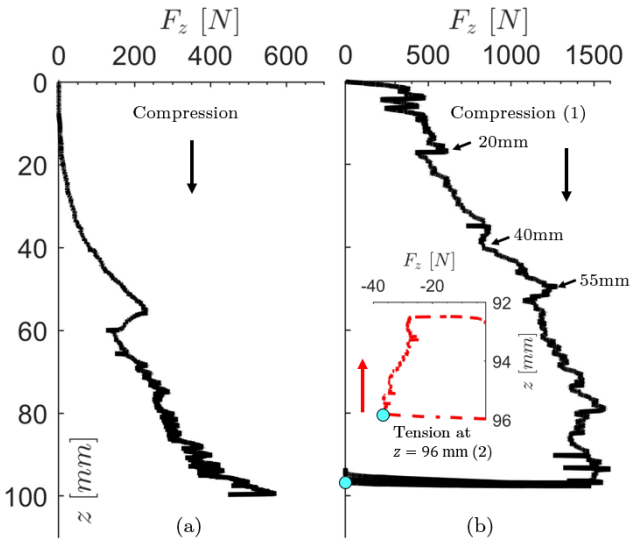

Figure 2. (a) HST-95 sand installation force profile (15.37mm pile) (b) Calcarenite installation (1) tension force profiles (2) (11.65mm pile).

The force-displacement profile of the pile penetrating the sand grew exponentially, indicative of plugging (White et al., 2000). This was likely due to the increasing internal shaft friction caused by dilation, principal stress rotation and soil-arching, sandwiching the lower portion of the plug statically (Liu et al., 2022). Between 50-100 mm the load profile was more volatile with sporadic drops, suggesting a stick-slip

mechanism within the pile plug, which may have been favoured by minor variations in the pluviated material. except for the large dip experienced at 50 mm which was a result in a brief pause in the servo actuation.

For the soft rock, the installation force profile (1) was characterised by a linear trend, with a more jagged response caused by local failures of the brittle intact material immediately below the pile toe, see Figure 2(b). The lack of an exponential force increment implies that the pile remained unplugged. However, the profile exhibited discrete step changes at 20, 40 and 55 mm and the jagged profile gradually smoothened with on-going penetration. It is hypothesised that the profile change indicated that the pile no longer experienced internal shaft stick-slip cycles and brittle failure (unplugged state) and instead transitioned to a ductile punch-like behaviour due to the closure of the pile base. This was supported by the low uplift capacity (2) (< 20 N, which was only 2.5% of the peak compressive penetration load at the same depth), a product of the material's low Poisson's ratio and damage generated around the pile during installation. This has been identified as a cause of low axial capacity of pile foundations in soft rock via large deformation simulations of fully installed close-ended model piles (Ciantia, 2022).

3.2 Post-installation visualisation

Figure 3(a) shows a 2D section through the centre of the pile following installation in the soft rock. The reconstructed image, with a resolution of 120 µm, shows the porosity distribution, obtained by calibration of the grey-values (GV) via the approximate linear relationship between GV and density (Alvarez-Borges et al., 2022). This shows that the pile did indeed plug during installation, leading to a highly densified zone of material ahead of the pile, in which the structure of the intact calcarenite rock collapsed. The bulbous failure zone (R) emphasised in Figure 3(b) extended approximately $2-3D$ ahead of the pile tip. The damage extent, previously observed in close-ended piles, is characteristic of a flat structure punching through rock (Alvarez-Borges et al., 2022; Castellanza et al., 2009). Along the pile walls the extent of damage appeared to increase with penetration depth. At ground level this extended radially by approximately the wall thickness of the pile, increasing to 2-3mm as the pile surpassed the plug initiation zone (exemplified at 2D above the pile tip, see Figure 3(c). This was likely due to the effect of the increased pile displacement which causes marked increases in radial stress, inducing failure of the surrounding material (Fan et al., 2021). The plug structure itself varied along its length as shown in Figure 3(a). At the top of the plug a mixture of intact discs and puttified material could be seen, indicative of the stick-slip mechanism. Toward the pile tip, the material progressively degraded into a dense, destructured state, in-line with the sandwiching mechanism highlighted by Liu et al. (2022).

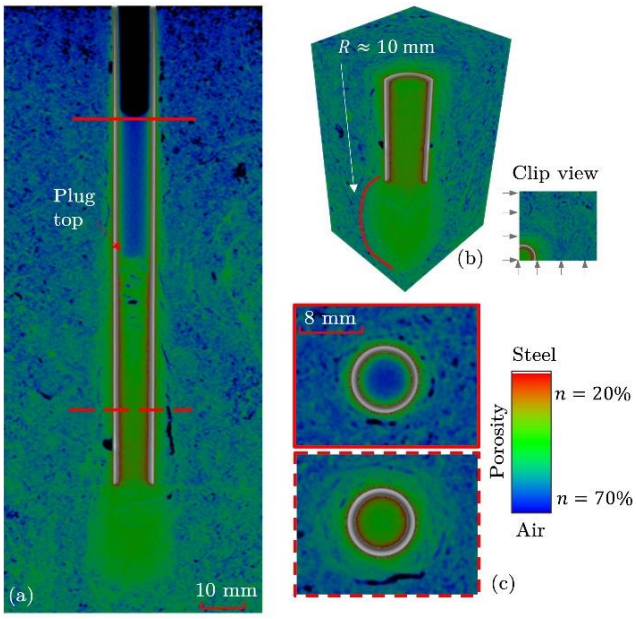

Figure 3. CT image of post installation of OE pile in calcarenite (a) 3D cross-sectional view of pile centre b) damage extent around pile annulus before plugging and after and (c) Damage bulb ahead of tip.

The plugging of this pile was unexpected, opposing a recent study in a similar soft rock (Alvarez-Borges et al., 2022), whereby the OE model pile ($D = 7.94$ mm) penetrated in full coring conditions leaving a small torus damage zone beneath the pile tip. Given that the inner diameter of the pile in this study was greater than that of Alvarez-Borges et al. (2022), a similar coring condition was anticipated. The reasons behind the different penetration mechanism appeared to stem from the variation in average pile roughness (R_a) and material grain size (d_{50}). Alvarez-Borges et al. (2022) used an acrylic pile with an $R_a \approx 0.02$ µm in conjunction with a finer grained chalk sample which had a $d_{50} \approx 5$ µm. In this study, the stainless-steel pile had an $R_a = 1.12$ µm. Combining this with the coarser-grained calcarenite resulted in a three-fold increase in R_a/d_{50}, indicative of a significantly rougher interface. This likely encouraged interlocking of the grains at the pile interface, inducing plugging.

3.3 Live installation visualisation

While it is challenging to use live radiography to assess fabric changes, it enabled real-time visualisation of the plug position for the sand example

throughout the installation, revealing real-time behaviour not attainable from the static CT scan. Figure 4(a) shows the live plug evolution during installation which was identified as the sharpest variation in the average grey-scale intensity along the pile length, e.g., Figure 4(b). This indicated that the pile cored initially and then progressively plugged corroborating with the penetration resistance, see Figure 2(a). As the pile plugged, the sand level surrounding the pile exterior rose significantly due to the increased displacement generated by the pile base closure as was evidenced between 40 and 96 mm of penetration. Although summarised briefly, the potential of live X-ray radiography has been evidenced by the ability to constantly track the pile behaviour and soil during installation.

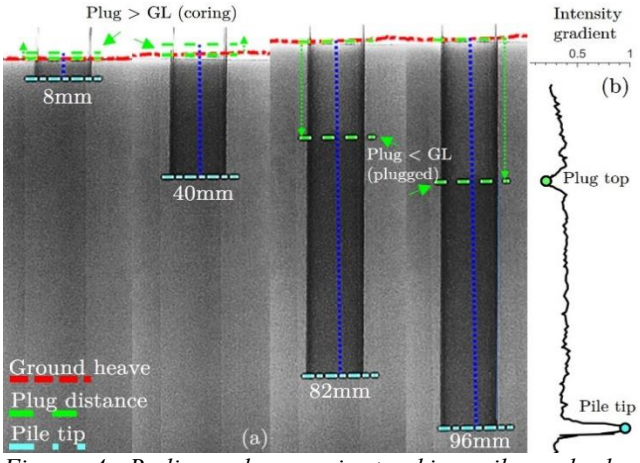

Figure 4. Radiography use in tracking pile and plug displacement during penetration for the sand example.

4 CONCLUSION

This paper has shown how the effect of plugging can alter the soil resistance to jacking. While the focus was on the plugging mechanism exhibited during installation, the CT and radiography techniques employed identified significant other mechanistic behaviour otherwise not revealed during conventional experimental or field scale studies. The new multi-axis loading frame has been highlighted as a valuable tool for researchers wishing to study 3D soil-structure problems in unison with X-ray, offering new insights into in-situ soil/rock-structure interactions.

ABSTRACT: Drilling boreholes for geotechnical purposes such as sampling, in-situ tests and permeability testing are usually performed with the aid of drilling machines. These machines generally use internal combustion motors to provide energy to hydraulic pumps feeding the different actuators needed to push, rotate and hammer the drill bit into the ground. This results in a very noisy and polluted environment for the workers and the surrounding area. With the popularisation of electric vehicles, it's time drilling machines also make the switch to electric power. This paper presents one such prototype machine developed by Fondasol company, with the initially proposed technical specifications and the realised equipment. An autonomy up to one week has been observed on real sites, depending on the project's drilling objective. The use of electric motors allows for a new type of measuring while drilling, as the measurement of electric current and voltage is much more reliable than hydraulic pressure and flow rates. With this electric-based design, additional external sensors are no longer necessary. A first insight into this new type of measurements and its physical meaning is also given and discussed within this paper.

RÉSUMÉ: Les forages à des fins géotechniques comme le carottage, des essais pressiométriques et des essais de perméabilité sont habituellement exécutés à l'aide de machines de forage. Ces machines sont assez lourdes, généralement utilisent des moteurs thermiques pour fournir l'énergie aux pompes hydrauliques qui alimentent les différents vérins nécessaires pour pousser, tourner et marteler l'outil de forage dans le sol. Il en résulte un environnement très bruyant et pollué pour les travailleurs et les alentours. Avec la popularisation des véhicules électriques, il est temps pour les sondeuses de passer à l'énergie électrique aussi. Cette communication présente un prototype d'une telle machine, avec les spécifications proposées initialement et l'équipement réalisé. Une autonomie de plusieurs jours a été observée sur chantiers, selon l'enjeu du projet. L'utilisation de moteurs électriques permet une nouvelle forme d'enregistrement de paramètres instantanés, étant donné que la mesure du courant et de la tension électriques sont beaucoup plus fiables que les mesures de pression hydraulique et débit. Avec cette nouvelle conception, des capteurs externes additionnels ne sont pas nécessaires. Cet article montre un exemple de sondage faite avec cette sondeuse et discute de l'utilisation de ce nouveau type de mesure sa signification physique.

Keywords: Measuring while drilling; electrical drilling machine; sustainable development.

1 CONTEXT

Historically used in the energy resource fields but gaining popularity in the field of geotechnical engineering in the last decades, the method of measuring while drilling (MWD) involves monitoring and recording drilling parameters during the drilling process (Rodgers et al, 2020). In this method, a drill bit destroys the terrain as it advances downward, pushed and spun by hydraulic motors while a fluid cools down the equipment and removes loose debris from the hole (Reiffsteck, 2010).

The drilling may have multiple objectives: creating holes for sampling, in-situ tests like pressuremeter tests, installing piezometers, verifying the efficacy of soil treatments or simply gaining knowledge about the subsoil. It has the advantage of being a rapid essay giving continuous information, much like the cone penetration test, while allowing an identification of the soil (Fortunati & Pellegrino, 1998; Cardu et al, 2013).

The drill rigs used in creating these holes may vary in size and overall power but share similar architecture: they all have a mast on which translate the drilling head. The length of the mast and the characteristics of the drilling head may differ according to the project's objectives (Reiffsteck, 2010).

In addition to the translation motor, the drilling head is equipped with a rotation motor and eventually a hammer that transmit rotating forces to the drill bit underground through the drill string. Both elements are usually hydraulic. The mast has the functions of guiding and driving the drilling head vertically, pushing the drill bit into the soil. This movement is also achieved by a hydraulic system (Reiffsteck, 2010).

There are other hydraulic systems in the rig as well, such as the stabilizing cylinders, the mandible and the cylinder that folds down the mast to put the machine in displacement mode. All these systems, as well as the pump for drilling fluid, are typically powered by a hydraulic motor (ICE) (Nishi et al., 1998; Reiffsteck, 2010).

According to Reiffsteck (2010), one of the risks associated with this method is the accidental release of hydrocarbons (oils or fuel) into the soil from the various hydraulic systems or the motor, which could contaminate the water table. The combustion motor also produces polluting gases and a lot of noise which can be detrimental to the workers' health and the surrounding area, even more so when used in closed environments.

To remedy these issues and improve on the method's energy efficiency, Fondasol has developed an electric drill rig that is presented in this paper. The use of electric motors also allows a different way of measuring drilling parameters, which is also discussed in the article.

2 OBJECTIVES OF THE CLEA PROTOTYPE

The new CLEA drill rig proposes to change soil investigations by using electric motors instead of mechanic/hydraulic actuators fed by an internal combustion engine.

This allows more efficient drilling, as electric motors are more energy efficient than hydraulic systems, while producing less noise and air pollution. The drilling parameters can also be measured more reliably, as it is easier to continuously monitor electrical currents and voltages than fluid pressure or flow rate.

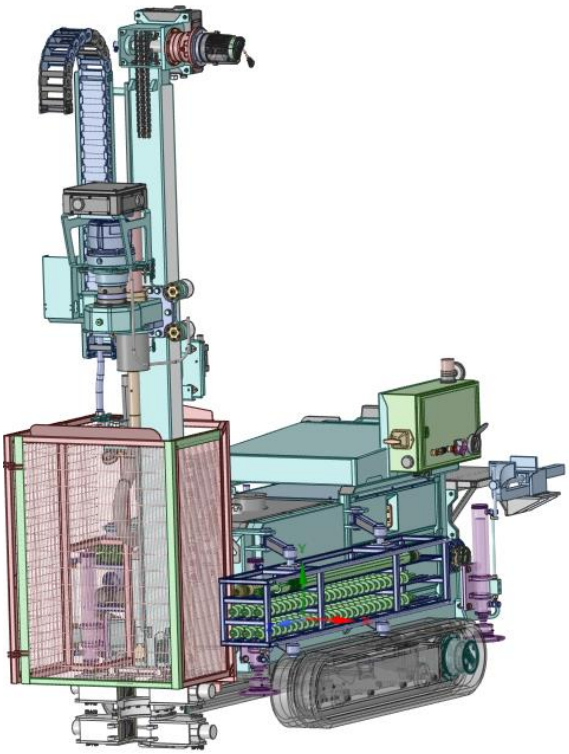

Figure 1. Electric drill rig prototype by Fondasol.

3 DRILL RIG SPECIFICATIONS

The prototype can achieve vertical speed of 900 m/h or 1500 mm/min with a maximum force of 21 kN. This movement is powered by an electric motor. The electric rotation motor allows a rotation speed of 350 rpm and a torque of 1500 Nm.

These specifications were chosen to approximate those of a conventional 32 kW hydraulic drill rig: vertical speed of 900 m/h, down force of 20 kN, rotation speed of 300 rpm and 1500 Nm of torque.

The battery bank used for the prototype is in the form of a detachable wagon and an autonomy of well over a week has been observed in the field (8 to 12% of battery used per day).

However, at this stage of development the prototype is not completely electric, it was built on the chassis of a conventional rig and still uses ICE powered hydraulic systems to operate the stabilizing cylinders and to unfold the mast. The engine is also used to power the continuous tracks while in displacement mode. A new 100% electric prototype is being built at the moment on a custom chassis with integrated power banks.

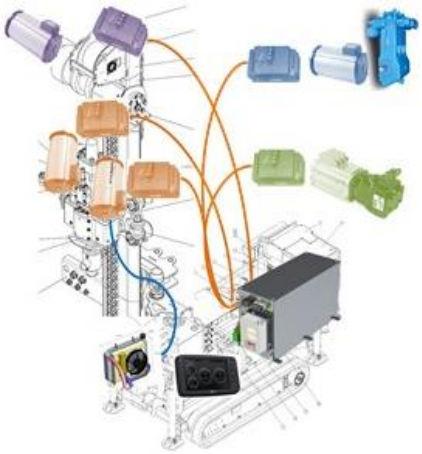

Figure 2. Scheme of all electric motors in the prototype.

4 ELECTRICAL MWD MEASUREMENT

The use of electric motors allows the monitoring of drilling parameters through the current and voltage. These electrical parameters are directly proportional to torque and rotation speed, respectively. This advantageously replaces the pressure transducers and the optical/magnetic sensors used to measure rotation speed typically used in conventional hydraulic rigs that only indirectly measure each parameter. The pressure transducers also have the disadvantage of not measuring the forces truly delivered to the drill bit as they are placed beside the pumps and cannot account for energy losses in the system (Peronne et al., 2021).

Unlike the typical measurements, the CLEA directly measures the current delivered to each motor, which is directly proportional to the torque applied on the drill bit. Instead of logging the values measured as a function of depth (typically each 2 cm), the prototype registers all the parameters as a function of time resulting in a much more detailed dataset.

The collected data can be displayed both as the conventional physical parameters in their respective units (MPa, Nm) of measurement and in terms of energy spent or power in kW delivered to the motors. Calculating the power spent by each motor also has the advantage of providing the total energy spent during the survey, which can be used to confirm the battery indicator and visualize which motor spent the most energy at a given moment.

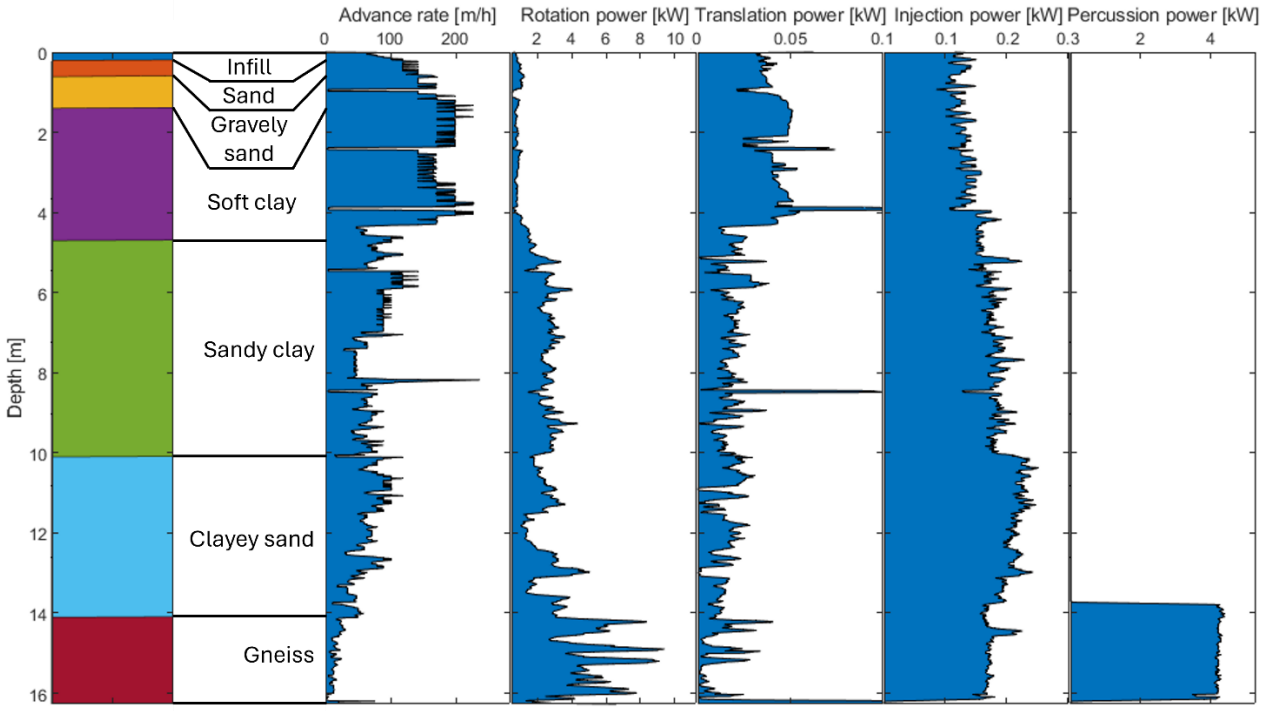

Figure 3. Example of MWD logs for electrical rig.

As shown on Figure 3, the motor responsible for vertically translating the drilling assembly (related to the down thrust parameter) consumes the least power, while the motor that rotates the rods and the hammer consume equivalent amounts of energy. Changes in soil layers are clearly visible, as indicated by the reduction in penetration rate and rise in rotation power at about 4.0 m. It can also be seen that the hammer was only used to excavate through the layer of gneiss below 14 m accompanied by a rise in rotation power. The layers of sandy clay and clayey sand above the gneiss can be differentiated by the change in injection power and larger variations in rotation power. These logs suggest that parameters based on electrical

consumption can be used to determine lithology, much like the hydraulic parameters typically recorded.

5 CONCLUSIONS

This paper has presented the architecture of a new model of drill rig that uses electrical motor instead of hydraulic ones fed by an internal combustion engine. The prototype tested in situ has performed better than expected, with autonomy for over a week of surveying without recharging, all the while being more silent and not generating greenhouse gas emissions. The data collected by logging the current and voltage used by the various motors has been shown to be as detailed or more so than the data registered while using pressure transducers in a conventional drill rig. The data can be displayed as the conventional physical parameters or in terms of power spent by each motor and can be interpreted in the same manner as regular MWD logging.

ABSTRACT: Shallow geothermal energy systems are evolving as an alternative source of energy for building space heating and cooling with notable contributions to carbon emission reduction. In this context, proper soil thermal characterization is crucial for determining the potential of these systems' use and their energy efficiency evaluation. This paper presents the results of the assessment of the physical and thermal characterization of samples retrieved in the city of Aveiro, Portugal. The thermal tests were performed in transient conditions using a needle probe and plane sensor device and the respective results were compared. The study provides some insights regarding Aveiro soil's thermal characteristics which will be further used in building energy simulation of campus buildings integrating shallow geothermal energy systems towards sustainable energy planning and development.

RÉSUMÉ: Les systèmes d'énergie géothermique peu profonde sont en train de devenir une source d'énergie alternative pour le chauffage et la climatisation des bâtiments, avec des contributions notables à la réduction des émissions de carbone. Dans le contexte de la caractérisation thermique des sols, la caractérisation est cruciale pour déterminer le potentiel d'utilisation de ces systèmes et l'évaluation de l'efficacité énergétique. L'article présente l'évaluation de la caractérisation physique et thermique d'échantillons prélevés dans la ville d'Aveiro, au Portugal. Les essais thermiques ont été effectués dans des conditions transitoires à l'aide d'une sonde à aiguille et d'un capteur plan et les résultats respectifs ont été comparés. L'étude fournit quelques informations sur les caractéristiques thermiques du sol d'Aveiro, qui seront ensuite utilisées dans la simulation énergétique des bâtiments du campus intégrant des systèmes d'énergie géothermique peu profonds pour la planification et le développement de l'énergie durable.

Keywords: Shallow geothermal energy; soil thermal conductivity; thermal probes; sustainability.

1 INTRODUCTION

For the space heating and cooling of buildings, low enthalpy ground source systems have been shown as a promising and sustainable source of renewable energy. To harness shallow geothermal energy, it is crucial to assess and determine the thermal parameters of soils as they determine the heat exchange performance between the ground and the buildings to be acclimatized (Del Pozo et al., 2021). Heat transfer processes in soils can occur, through the physical processes: conduction, convection or radiation. However, for these systems, conduction is the dominant process (Vieira et al., 2019). Thermal conductivity quantifies the ability of materials to conduct thermal energy, it is the soil´s most important factor in determining the primary circuit performance of shallow geothermal heat exchangers (Roka et al., 2023). Volumetric heat capacity indicates the amount of heat energy required to raise the temperature of a unit volume of a substance by one degree Celsius or one Kelvin. It's an important parameter when considering the thermal behavior of soil, including its ability to store or release heat (e.g. Kodesová et al., 2013). A proper knowledge of the thermal properties of soil is essential to design the geothermal system as they influence heat extraction from the soil and heat rejection to the soil as well as the performance and efficiency of the geothermal system (Vieira et al., 2017). Several factors influence the soil's thermal

conductivity and heat capacity in particular their index properties such as soil particle distribution, water content, bulk and particle density, degree of saturation, and void ratio (Zeh et al., 2021). Among these, the factors that most influence soil thermal properties are the water content (degree of saturation) and porosity. The mineralogical composition of the soil also has a significant influence on its thermal behavior.

To design an energy simulation model of the campus buildings of Aveiro University with the integration of shallow geothermal systems using whole-building energy simulation software CitySim Pro the knowledge of the heat extraction potential from the soil is crucial. The assessment of information on the thermal properties of Aveiro soils will help to fulfil this purpose.

2 LABORATORY EXPERIMENTS

2.1 Theoretical background: needle and surface probes

The needle sensor is a Transient Line Source (TLS) device for the determination of the thermal conductivity of soil in non-steady state conditions in an infinite medium (e.g. Lockmuller et al., 2003). This technique uses a line heat source, the temperature changes in soil over time are recorded when the heat of a known amount is applied to the sample soil. Carslaw and Jaeger, (1959) give the relation of temperature response at any time t (s) accordingly:

$$T = \frac{q}{4\pi\lambda}\int_x^\infty \frac{e^{-u}}{u}du \quad (1)$$

where q (W.m^{-2}) is the power input per unit area, T (K) is the temperature at any radial distance r(m) from the needle, x is $\frac{r^2}{4\alpha t}$, α (m^2.s^{-1}) is the thermal diffusivity and the thermal conductivity of soil λ (W.m^{-1}.K^{-1}).

In the TLS method, a thin needle heat source is inserted into the soil sample, simulating a linear heat source of infinitesimal radius in a semi-infinite medium. The heat flow within the soil sample follows a radial pattern. The rate of heat propagation in the soil sample is contingent on its thermal conductivity. For soils with high conductivity, the propagation time is notably shorter. Conversely, in soils with lower conductivity, the propagation time is prolonged. This distinction in propagation times provides valuable insights into the thermal characteristics of different soil types, contributing to a more comprehensive understanding of their behavior in response to heat.

When the t (s) is too large, Eq. (1) becomes:

$$T = \frac{q}{4\pi\lambda}\left(ln\frac{4\alpha t}{r^2} - \gamma\right) \quad (2)$$

Where γ represents Euler‘s constant. For a specified medium in a time-space t_1 (s) and t_2 (s) with the heat flux q (W.m^{-2}), equation 3 provides the thermal conductivity. The derived λ (W·m^{-1}·K^{-1}) value should fall within a 5% deviation from the mean value of each test (ASTM, D5334-14).

$$\Delta T = T_2 - T_1 = \frac{q}{4\pi\lambda}.ln\left(\frac{t_2}{t_1}\right) \quad (3)$$

Thermal conductivity is related to thermal diffusivity, material density and specific heat capacity. Equation 2 illustrates the relationship,

$$\lambda = \alpha.\rho.c \quad (4)$$

where ρ (kg.m^{-3}) signifies the soil density, α (m^2.s^{-1}) is thermal diffusivity, and c (J.kg^{-1}.K^{-1}) denotes specific heat capacity.

The international standards ASTM D5334-14 and IEEE 442 provide standard information regarding λ (W.m^{-1}.K^{-1}) measurement techniques for TLS. Thermal conductivity can also be measured by the surface probe or transient plane source (TPS). However, this probe is specially designed for hard soil. The surface probe sensor features elements that function both as a heat source and a temperature sensor. Comprising a robust electrical conducting pattern crafted from thick nickel foil embedded within an insulating Kapton layer, the device exhibits a dual role. The application of consistent heat through electrical power induces changes in the sensor's resistance, denoted as R_t (Ω) which is directly correlated with the corresponding increase in temperature T (K). The time-dependent resistance, R (Ω), is mathematically expressed by equation 5. Comprehensive details regarding the calculations and the specifics of the equation can be referenced in (Gustafsson, 1991).

$$R_t = R_0(1 + \phi.\Delta T_t) \quad (5)$$

where R_0 (Ω) is the initial resistance of the hot disk present in the surface probe, ϕ is the temperature coefficient of resistance (TCR) for the probe and $\Delta T_T=(T_T-T_0)$ is the temperature increase in the sensor concerning the time variable t (s). Also,

$$t = \sqrt{\left(\frac{t_0}{\theta}\right)} \text{ and } \theta = \left(\frac{\alpha^2}{\alpha}\right) \quad (6)$$

where t_o(s) is the time from the start of the transient heating, a signifies a constant that is a measure of the overall size of the resistive pattern (half the side of the hot square or the radius of the hot disk) and θ denotes the characteristic time as in equation 6 (Gustafsson, 1991).

When assuming the sample is infinitely large and has no influence from the boundaries, and the geometry of the disk consists of an n concentric ring with a radius of the outermost ring r (m) and ΔT_T can be expressed with the below equation 7,

$$\Delta T_T = \frac{P_o}{\sqrt[3]{\pi}.r\lambda}.D_T \quad (7)$$

where P_0(W) is the total output power of the probe and D_T is a dimensionless time function and can be written in equation 7 (Gustafsson, 1991).

$$D_T=(n(n+1))^{-2}.\int_0^T \frac{d\sigma}{\sigma 2}.(\sum_{h=1}^{n} h(\sum_{k=1}^{n} k.\ Exp((-h^2+k^2)/4\sigma^2n^2).l_0(h.k/2\sigma^2n^2))) \quad (8)$$

where L_0 is the modified Basel function, h(m) is the thickness of the disk, n is the number of concentric rings in the disk and σ is an integration variable. So, λ (W.m^{-1}.K^{-1}) can be obtained by fitting the experimental data to the straight line given by equation 7, and equation 6 gives thermal diffusivity.

2.2 Sampling and sample preparation

Samples were extracted at a construction site near the University of Aveiro using a tube sampler of 70mm diameter and 140mm length. The samples were extracted from excavation cuts from depths of 1m to 3.5m. After the extraction, they were wrapped with thin plastic to preserve initial moisture and carefully transported to the National Laboratory of Civil Engineering (LNEC) Soil Mechanics laboratory and stored in a temperature and moisture-controlled room. Disturbed samples were also taken from the same place as the intact ones to perform physical characterization tests namely grain size distribution, initial water content, Atterberg limits and particle density. As mentioned, some physical parameters of soil have a paramount effect on the λ (W.m^{-1}.K^{-1}). Figure 1 displays a map indicating the sampling locations. At this stage, three samples were tested. The respective results will be used in the multiscale building energy simulation. The three samples can be seen in Figure 2.

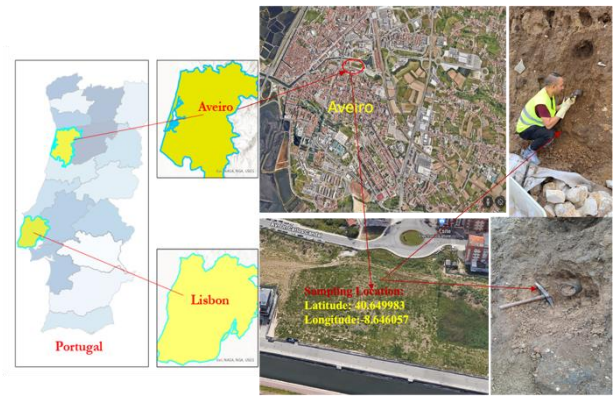

Figure 1. Location map of sampling site in Aveiro.

2.3 Equipment description

For the thermal characterization of samples, equipment comprising a measurement platform, TLS-100vCp and TLS-100 needle sensors and TPS-

Figure 2. Soil samples and their thermal tests.

4 asymmetric (single-sided) sensors were used. Both TLS have a total 100mm needle length. According to ASTM D5334-14, the specimens should be 200±30mm long and 50mm in diameter (ASTM, D5334-14). The user manual of MP-2 mentions that the minimum sample size should be 100mm long and 50mm in diameter. TPS-4 has a sensor diameter of 12.8mm and at least a 35mm diameter sample is recommended for the test recommended by the MP-2 manual (MP-2, 2022). Table 1 presents the spectrum of thermal conductivity measurements and the corresponding accuracy achieved by three distinct sensors, alongside the adhered standards.

2.4 Experimental description

Firstly, the sensor TPS-4 was calibrated by using Pyrex verification sample (λ=1.110W·m^{-1}·K^{-1}) and afterwards both needle sensors with a Polymer verification sample (λ=0.330 W.m^{-1}.K^{-1}) at room temperature 25^{0}C. Additionally, Figure 3 provides a visual representation of the MP-2 device alongside the three sensors.

Table 1. Measurement range of sensors (MP-2, 2022).

Sensor's type	Range of λ ($W \cdot m^{-1} \cdot K^{-1}$)	Accuracy	Standard followed
TPS-4	0.03-5	±5%	ASTM D5334 & IEEE 442-1981
TLS-100	0.1-5	±5%	ASTM D5334-14 & ISO 22007-2
TLS-100vCp	0.02-5	±5%	ASTM D5334-14

Figure 3. MP-2 device with three sensors.

After the calibration, some tests were carried out in a reference soil (Fontainebleau sand). Aljundi et. al., (2019) have previously measured the thermal conductivity of Fontainebleau sand under different densities and saturation degrees. The λ ($W \cdot m^{-1} \cdot K^{-1}$) value obtained at density 1715 $kg.m^{-3}$ at fully dry condition is 0.344 $W \cdot m^{-1} \cdot K^{-1}$ and fully saturated condition is 2.84 $W \cdot m^{-1} \cdot K^{-1}$. A density of 1690$kg.m^{3}$, which was missing in that study, in fully dry and fully saturated conditions was prepared and the obtained values of λ ($W \cdot m^{-1} \cdot K^{-1}$) are presented in Table 2.

Firstly, the samples were tested by using TPS-4 followed by the two-needle sensors. The top surface of the sample was levelled carefully and a weight of one kilogram was placed above the sensor in order to achieve good contact between the plane sensor and the soil sample as shown in Figure 2. Furthermore, while using the needle probes a thermal paste was used to ensure better contact with the surrounding soil. S6062 and S6063 were soft enough to insert the needle probe whereas for S6061 a hole was made with a metallic rod smaller in diameter than the needle. Special care was taken to insert the needles so as not to damage them.

A series of five measurements were performed for each sample with three sensors. The interval between each measurement should be at least 15 to 20 minutes in order to achieve a thermal equilibrium according to the manual of MP-2, though a minimum of 30 minutes was given to provide enough time for better accuracy in the results.

3 RESULTS AND DISCUSSION

Table 3 showcases information about the specific gravity of the soil particles ρ_s, moisture content w (%), void ratio e, degree of saturation S_r (%), liquid limit L_L (%), plastic limit P_L (%), particle size distribution and soil classifications of the tested samples. The particle size distribution of the three Aveiro samples is shown in Figure 4. It can be observed that S6061 has lesser fine particles with major parts of sand and gravel, whereas S6062 and S6063 have a very similar granulometric composition with more than 60% finer particles and were classified as low plasticity clays.

For the thermal tests, the calibration results with the verification sample fell below ±5% of the known value. Table 4 presents a summary of the results of the thermal tests conducted. Each value corresponds to the average of five determinations. For all cases, the repeatability R(%) obtained was excellent (with differences between measurements lower than 5%). Regarding the thermal conductivity measurements in Fontainebleau sand, as expected the value in fully saturated conditions is much higher (about 8 times more) than that in fully dry conditions. When sand is saturated with water, the air in the pore spaces is displaced. Since water has a higher thermal conductivity than air, the replacement of air with water increases the soil thermal conductivity.

In turn, in Figure 5, the values of the thermal conductivity estimated by the three probes for the different samples are shown. Globally it can be observed that the values measured with the surface probe TPS-4 are almost always inferior to the ones obtained with TLS-100 probes.

Additionally, it is noteworthy that the average difference in thermal conductivity measurements between the TLS-100 and TPS-4 sensors remained below 2% for samples 6062 and S6063. However, in the case of sample S6061, this difference exceeded 12%. The significant disparities in results between the plane source TPS-4 and TLS-100 were particularly evident in the sample with more percentage of sand and gravel. This observation may be attributed to the challenge of achieving 100% contact between the sensor and the sand and gravel, potentially allowing air to enter the gap and influencing the measurements.

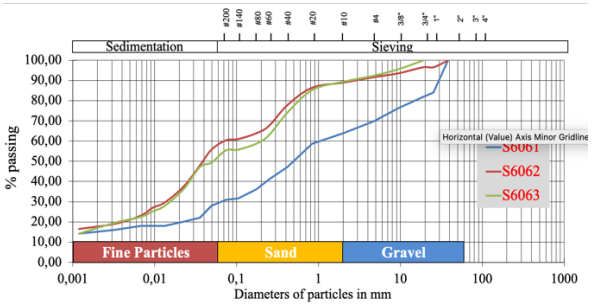

Figure 4. Particle size distribution curves.

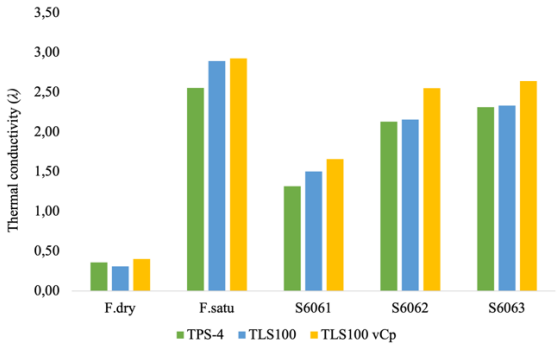

Figure 5. Test results comparison of three sensors.

Regarding measurements conducted with the two needle probes, it is notable that values obtained with probe TLS100-vCp, which incorporates heat capacity measurements, consistently exhibit higher values. On average, the differences relative to the mean are approximately 10%. The thermal conductivity of the samples is influenced by the degree of saturation. Samples S6062 (S_r=91.22%) and S6063 (S_r=92.02%) have higher thermal conductivity values than sample S6061 (S_r=67.22%). However, the relationship is complex and depends on various factors, including mineral composition, and temperature conditions. The measured values of α ($m^2.s^{-1}$) for samples are in the range of $1.0x10^{-6}$ to $3.0x10^{-6}$ $m^2.s^{-1}$. According to Hillel, (1982) the thermal diffusivity of moist soil ranges from $1.0\ x10^{-6}$ to $3.0x10^{-6}$ $m^2.s^{-1}$. Additionally, Abu-Hamdeh, (2003) obtained a volumetric heat capacity value of $1.09\text{-}3.04x10^6$ $J{\cdot}m^{-3}{\cdot}K^{-1}$ and the measured value of C_p ($J{\cdot}m^{-3}{\cdot}K^{-1}$) in this research is $1.053\text{-}2.012x10^6$ $J{\cdot}m^{-3}{\cdot}K^{-1}$ for moist soil.

Table 2 provides information on maximum density ($kg{\cdot}m^{-3}$) and their respective void ratios e^{max}, e^{min}, and e^{cal} for Fontainebleau sand.

Table 2. Maximum, minimum and calculated densities and void ratio of Fontainebleau sand.

Sample	ρ_{max} ($kg.m^{-3}$)	ρ_{min} ($kg.m^{-3}$)	ρ_{cal} ($kg.m^{-3}$)	e^{max}	e^{min}	e^{cal}
Fontainebleau sand	1750	1440	1690	0.855	0.521	0.579

Table 3. Physical properties of the Aveiro samples.

4 FINAL REMARKS

In this work, laboratory-measured values of the thermal properties of Aveiro soils using different thermal probes were presented. Values of the physical properties of these soils were also provided, along with data recorded on a reference soil. All measurements were conducted under non-steady-state heat flow conditions. Overall, the obtained values are typical values of the tested soil types, and very good repeatability was obtained. It was observed that the thermal conductivity values measured with the surface probe were consistently lower than those measured with the needle probes. This difference may be attributed to heat losses, contact issues, or the analytical approximations underlying this determination.

On the other hand, it is also not clear why there is a difference in measurements between the two needle probes with the probe that also allows obtaining thermal diffusivity values giving consistently higher values. According to the manufacturer, the conductivity values, in this case, are estimated based on an iterative calculation performed during the test based on the line source solution expression, which enables the simultaneous evaluation of λ ($W.m^{-1}.K^{-1}$) and α ($m^2.s^{-1}$) but not on a direct determination of λ ($W.m^{-1}.K^{-1}$). Further investigations, encompassing numerical replication of evaluation of λ ($W.m^{-1}.K^{-1}$)

Table 4. Thermal characteristics of the Aveiro soil samples by MP-2 platform with three sensors.

Samples	Thermal sensors	Thermal properties

Environmental life cycle assessment of ground reinforcement using rigid inclusions

Analyse du cycle de vie du renforcement de sol par inclusions rigides

ABSTRACT: There are increasing societal and political concerns about the consequences of human activities on climate change and other environmental issues. In that sense, methodologies such as Life Cycle Assessment (LCA) are being developed to evaluate technical systems based on their function, considering the whole life cycle in a multi-criteria approach. Applied to the construction sector since the 1990s, particularly to buildings and other civil engineering structures, little has been done so far on geotechnical works specifically. This contribution seeks to present an application of LCA to soil reinforcement solutions in the framework of the ASIRI+ National Project. The objectives of the assessment are, first, to quantify the environmental impacts potentially generated when implementing rigid inclusions as ground improvement techniques, and second, to compare them with the impacts of other possible solutions. The study highlights the contribution of materials such as cement, lime and steel to the overall impacts, and particularly climate change, the importance of optimizing their use when designing and implementing solutions, and the need for contextualized data for such materials. It also stresses the importance of extending the limits of the assessed system to include foundations, and not to strictly focus on rigid inclusions.

RÉSUMÉ: Les préoccupations sociétales et politiques concernant les conséquences environnementales des activités humaines vont croissantes. De ce fait, les méthodologies telles que l'Analyse du Cycle de Vie (ACV) sont développées pour évaluer les systèmes techniques sur la base de leur fonction, en considérant l'ensemble du cycle de vie, dans une approche multicritère. Appliquée au secteur de la construction depuis les années 1990, peu d'études portent spécifiquement sur les ouvrages géotechniques. Cette contribution vise à présenter une application de l'ACV à des solutions de renforcement de sol, investiguées dans le cadre du Projet National ASIRI+. Les objectifs de l'analyse sont, tout d'abord, de quantifier les impacts environnementaux potentiels générés lors de la mise en œuvre des inclusions rigides comme technique de renforcement de sol, et ensuite de les comparer avec les impacts d'autres solutions envisageables. L'étude souligne la forte contribution de matériaux tels que le ciment, la chaux et l'acier aux impacts totaux, et la nécessité de données contextualisées pour ces matériaux. Elle montre également la nécessité d'étendre les limites du système étudié pour inclure les fondations, et non pas regarder strictement les inclusions rigides.

Keywords: Life cycle assessment (LCA); soil reinforcement; rigid inclusion; ASIRI+.

1 INTRODUCTION

Governmental bodies, companies and the public are increasingly concerned about the consequences of human activities on climate change and other environmental issues (depletion of resources, biodiversity loss, or degradation of human health). To translate these concerns into action, it is necessary to understand what are the impacts of such activities, how to reduce them, and/or to identify alternatives delivering the same service, with better environmental performances. In that sense, methodologies such as environmental Life Cycle Assessment (LCA) are being developed to evaluate technical systems based on their function, considering the whole life cycle (from extraction of material to end of life) in a multi-criteria approach (Jolliet et al., 2017). Applied to the construction sector since the 1990s, particularly to buildings (Peuportier et al., 1997) and other civil engineering structures (Horvath 2006; de Bortoli et al 2020), little has been done on geotechnical works specifically, until recently (Basu et al., 2013; Raymond et al., 2021).

This contribution presents an application of LCA to soil reinforcement solutions using rigid inclusions, analysed in the framework of the ASIRI+ French National Project. Its objectives are, first, to quantify

the environmental impacts potentially generated when implementing rigid inclusions as ground improvement techniques, and second, to compare them with the impacts of other solutions.

2 METHODOLOGY

2.1 Goal and scope definition

The approach adopted in this paper follows the guidelines described in ISO 14040 standards (ISO 2006) for the application of LCA (Saadé and Jolliet 2024). It consists first in defining a functional unit (FU), representing the function of the modelled system (goal and scope definition) and serving as the reference unit for the quantification of material flows and environmental impacts. For different modelled scenarios, flows of matter and energy emitted to and extracted from the environment are quantified per FU (life cycle inventory). Based on these flows, potential impacts are evaluated in different environmental categories or areas of protection (climate, human health, ecosystems…) in the life cycle impact assessment phase. During these different phases, results are being discussed and limitations described (interpretation).

2.2 Case study

The case study considered corresponds to the foundation system of the bus station attached to the multimodal transport centre of the City of Nice, France (Chen 2022), located in a moderated sismic hazard area (zone 4) according to the French regulation.

Table 1. Soil characteristics.

Level	γ [kN/m³]	p_l [MPa]	E_M [MPa]	α [-]
+6,5 to -10,5	20	0,3	5,0	½
-10,5 to 14,5	21	2,5	23,0	¼
Under 14,5	20	0,3	5,0	½

The foundation of the bus station covers a surface of 5800 m², on of B2 class soil according to the Natural Riks Prevention Plan (Table 1). The solution implemented for the foundation is a concrete slab on a soil reinforced by rigid inclusions and ductile cast iron piles. An alternative solution considered consists of a concrete slab on soil reinforced by concrete and ductile cast iron piles. Data for both solutions are provided by the company Keller Fondations Spéciales.

2.2.1 Functional unit

The functional unit is defined as the "foundation of the bus station operational for a duration of service of 50 years for the soil characteristics given in Table 1".

2.2.2 System boundaries

The system boundaries are given in Figure 1. They include the extraction of resources and the processes required for the production of materials (concrete, mortar, cast iron, reinforcing steel…), transport of materials, the use of engines on the construction site, demolition and recycling. Transportation of engines and workers are not taken into account.

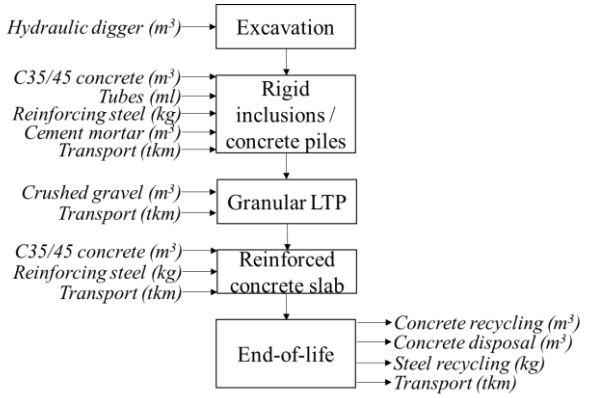

Figure 1. System boundaries.

2.2.3 Scenario definition

The two previously described scenarios are considered.

Table 2. Material quantities per scenario.

Material	Scenario 1	Scenario 2
Armed RI		
Concrete	749 m³	-
Tubes	34600 kg	-
Concrete piles		
Concrete	-	695 m³
Reinforcing steel	-	34760 kg
Ductile cast iron piles		
Tubes	16950 kg	16950 kg
Cement mortar	53 m³	53 m³
Platform	2320 m³	1740 m³
Slab		
Concrete	2030 m³	2900 m³
Reinforcing steel	111650 kg	261000 kg

The first scenario (actually implemented and proposed by the contractor) consists of a C35/45 reinforced concrete slab (0,35 m thick) + granular load transfer platform LTP (0,4 m thick) + armed rigid inclusions and ductile cast iron piles (functioning as rigid inclusions). Rigid inclusions are constituted of a

XA2 C35/45 concrete and armed with a 114 mm diameter tube; 6,2 mm thick. Ductile cast iron piles consist of tubes with a diameter of 118 mm and 9 mm thick. They are covered with a coating of cement mortar to avoid corrosion. The steel ratio in the slab is 55 kg/m^3.

The second scenario (basic solution proposed by the project manager) consists of a C35/45 reinforced concrete slab (0,5 m) + granular load transfer platform LTP (0,3 m) + concrete piles (below the structure loads) and ductile cast iron piles (functioning as rigid inclusions). In this case, the steel ratio in the slab is about 90 kg/m^3.

2.2.4 Data and assumptions, LCI database and LCIA method

Foreground data regarding the material quantities have been collected from the Keller company (Table 2). For concrete, the transport distances considered to the concrete plan are 30 km for aggregates, 49 km for cement (Portland), 232 km for blast furnace slag, 1230 km for additives. The distance between the concrete plan and the construction site is estimated at 15 km. Steel and granular material for the LTP are transported over a distance estimated at 100 km and 50 km respectively.

Background data are provided by the ecoinvent database (Frischknecht et al., 2007). The impacts are calculated using the set of indicators provided by the EN15804 standard (AFNOR 2014).

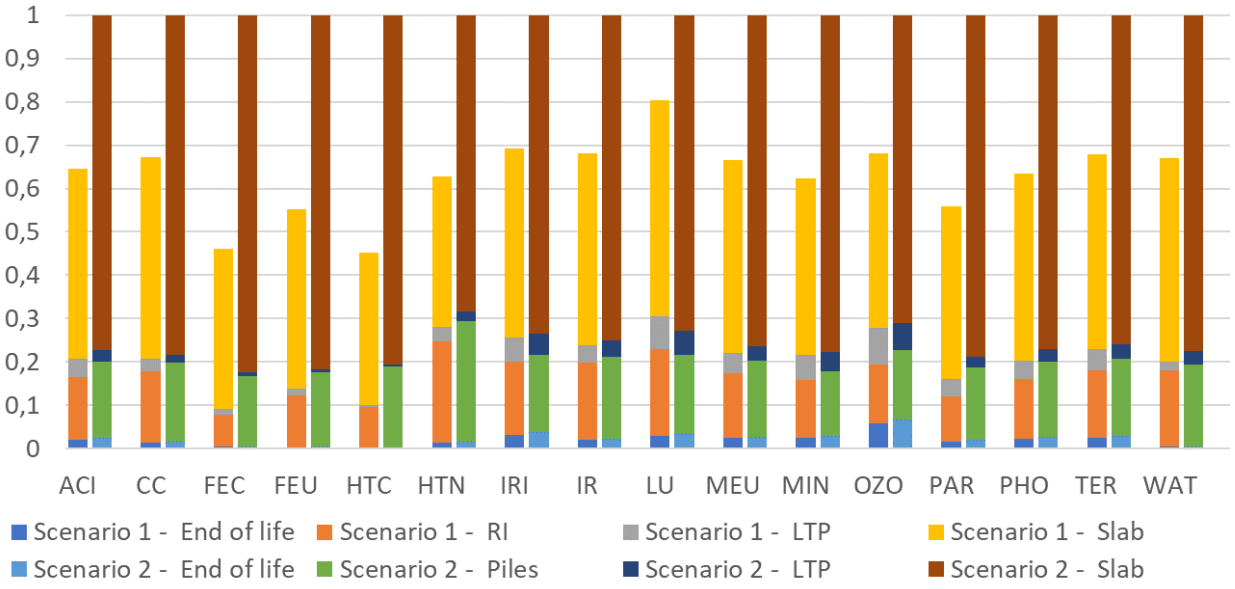

Figure 2. Comparison between the two scenarios, relative to the maximum impact score per environmental category. ACI: Acidification; CC: Climate change; FEC:Freshwater ecotoxicity; FEU: Freshwater eutrophication; HTC: Human toxicity, cancer effects; HTN: Human toxicity, non-cancer effects; IRI: Ionizing radiation E (interim); IR: Ionizing radiation HH; LU: Land use; MEU: Marine eutrophication; MIN: Mineral, fossil & ren resource depletion; OZO: Ozone depletion; PAR: Particulate matter; PHO: Photochemical ozone formation; TER: Terrestrial eutrophication; WAT: Water resource depletion.

3 RESULTS

3.1 Comparison of the two scenarios

Figure 2 compares the impacts of scenarios 1 and 2 considering the contribution of the different sub-processes of the system. Taking into account the foundation system (slab + load transfer platform + soil reinforcement solution), scenario 2 appears to have the largest impact for all categories. Most of its impact comes from the concrete slab, which explains between 70 and 80% of the overall impact, according to the environmental category. For example, respectively 45% and 35% of the climate change score are related to the production of concrete and reinforcing steel used in the slab. 20 to 30% of the impacts are related to the production and transport of the soil reinforcement solution. The granular mattress represents a few percentages of the total impact. The contribution of materials transport to the overall impact is also limited compared to materials production (Figure 3).

The impacts of scenario 1 are also dominated by the reinforced concrete slab, but in a relatively lesser extent. The relative contribution of the soil reinforcement solution is in the same order of magnitude (between 20 and 30% of the total impact depending on the environmental category). The better

environmental performance of the first scenario is explained by the lower amount of concrete and reinforcing steel used for the slab, but is still dominated by production of materials (concrete, reinforcing steel, cast iron) as illustrated by Figure 3.

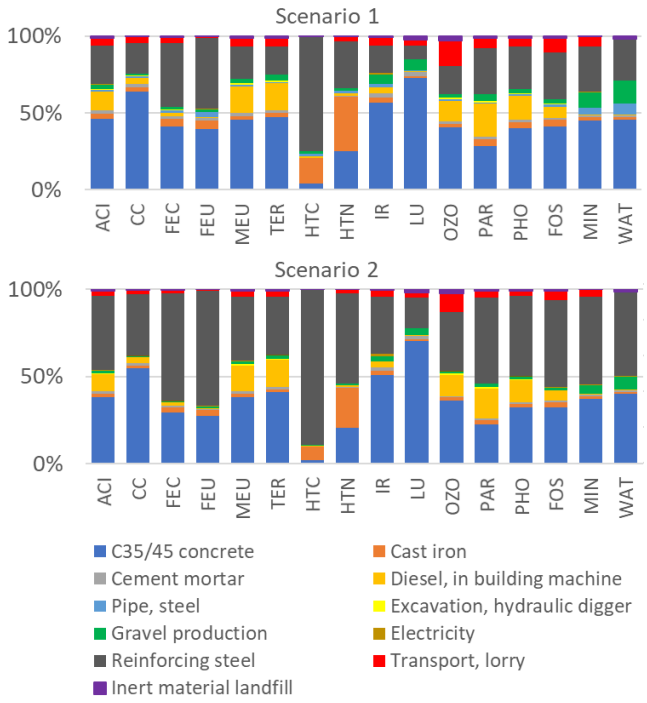

Figure 3. Scenario 1: Contribution analysis.

4 CONCLUSIONS

The study shows that materials such as cement and steel are major contributors to the overall impacts, and particularly climate change. It is therefore important to optimize their use when designing and implementing soil improvement solutions. It also stresses the need for contextualized data for such materials. The study also highlights the importance of extending the limits of the assessed system to include foundations, and not to strictly focus on soil reinforcement solutions, here rigid inclusions.

ACKNOWLEDGEMENTS

The results presented in this paper were part of the ASIRI+ National Project. The authors are grateful for the data provided by the company Keller Fondations Spéciales.

Centrifuge modelling of hollow heated piles in saturated sand

Modélisation centrifuge de pieux creux chauffés dans du sable saturé

ABSTRACT: Thermal piles are a sustainable foundation solution which support structural load whilst generating geothermal energy. Current design practice has been developed for conventional solid concrete thermal piles. This paper focusses on the use of a new innovative hollow thermal pile, the HIPER pile, developed in collaboration with Keltbray Piling. This pile is significantly more thermally efficient; leading to greater temperature gradients than could be expected with conventional thermal piles. A total of four centrifuge model tests at 50g in sand have been conducted to investigate the effects of heating and cooling cycles on pile behaviour under constant load. During testing the pile head movement, pile temperature, and soil temperature were recorded. Relationships between pile movement and thermal cycles are presented.

RÉSUMÉ: Les pieux thermiques sont une solution de fondation durable qui supporte la charge structurelle tout en générant de l'énergie géothermique. Les pratiques de conception actuelles ont été développées pour les pieux thermiques en béton massif conventionnels. Cet article se concentre sur l'utilisation d'un nouveau pieu thermique creux innovant, le pieu HIPER, développé en collaboration avec Keltbray Piling. Ce pieu est nettement plus efficace thermiquement; conduisant à des gradients de température plus importants que ceux auxquels on pourrait s'attendre avec des pieux thermiques conventionnels. Au total, quatre essais sur modèle de centrifugeuse à 50 g dans du sable ont été réalisés pour étudier les effets des cycles de chauffage et de refroidissement sur le comportement des pieux sous charge constante. Au cours des tests, le mouvement de la tête du pieu, la température du pieu et la température du sol ont été enregistrés. Les relations entre le mouvement des pieux et les cycles thermiques sont présentées.

Keywords: Centrifuge modelling; thermal piles; temperature effects.

1 INTRODUCTION

The drive towards efficiency and sustainability within the construction industry has led to an increased demand and use of energy geostructures (Laloui & Di Donna, 2013). One such structure is the thermal pile. Thermal piles use geothermal energy thereby reducing the need to use conventional energy sources, whilst also providing structural support.

Current design practice for thermal piles in the UK is presented by the Ground Source Heat Pump Association (2018). Such piles are assumed to be solid concrete. However, the HIPER (Hollow, Impression, Precast, Energy, Reusable) pile differs significantly from a solid concrete thermal pile both in geometry and thermal efficiency and the expectation is that the behaviour of this pile will not be adequately represented by the current guidance. In order to gain a better understanding of the behaviour of these piles and the effect thermal cycles have on them a short series of centrifuge tests have been undertaken.

McNamara et al. (2014) described a field study for a novel type of hollow, cast-in-situ pile, noting that this type of pile may be suited for use as a thermal pile. Adopting a large diameter hollow pile offers the prospect of energy generation from standard length bored piles that carry structural load rather than very deep dedicated energy collectors. In addition, such piles can provide high efficiency heat transfer because they are water filled with only a narrow concrete annulus, typically 200mm.

A limited number of field tests have been undertaken in order to investigate the thermal performance of HIPER piles (Ground Engineering, 2022). The available information from these tests has provided promising data on heat efficiency as noted earlier. However, the lack of control of boundary effects can lead to variability in the results of such tests making them difficult to interpret with confidence, particularly when investigating the effect of temperature cycles on pile performance.

In order to obtain reliable data from an equivalent physical event, centrifuge testing can be used to model reduced-scale piles under controlled conditions, allowing isolation of specific variables of interest. The tests reported sought to investigate the effect of thermal cycles on pile settlement and establish how these compare to typical data in the literature.

2 PREVIOUS WORK

Previous work on centrifuge modelling of heat transfer in soil (Savvidou, 1988) states that for coarse grained soils heat transfer is primarily by free convection through the pore fluid, assuming the soil is saturated. Savvidou (1988) reviewed scaling laws for heat transfer by convection and concluded that the heat transfer would occur N^2 times faster in the model than in the prototype.

Ng et al (2020) undertook a modelling of models exercise to investigate scaling effects on loaded thermal piles subjected to temperature cycles. They found that there were no scaling effects for tests in sands with a D/d_{50} greater than 92, where D is the diameter of the pile and d_{50} is the mean particle size. In the tests reported by Ng et al. (2020), 7 cycles of change in temperature of 20°C, resulted in an overall pile head settlement of 1.3%D. There have been a number of other centrifuge test results reported in the literature but these relate to dry sands and silts, for example Wang et al (2017) and Goode and McCartney (2015) where the heat transfer mechanism will be different, or tests to examine the effect of temperature on pile capacity rather than settlement, for example Ng et al. (2015).

3 OBJECTIVES

The objective was to carry out centrifuge tests at 50g using the 40g-tonne centrifuge at City, University of London, to examine the influence of cycles of temperature on the displacement of a pile under constant axial load. The length of the temperature cycles and the height of the water table were varied.

The piles were placed in a bed of dense 0.7 – 1.25 mm alluvial sand. The temperature was cycled between 17-18°C and 43-45°C for 4 cycles of 30 minutes and then 4 cycles of 60 minutes. The piles had a relatively low length to diameter ratio and were filled with water leading to a good exchange of temperature between the pile and soil; characteristics typical of those expected of a HIPER pile.

4 APPARATUS

The tests were conducted in a 375mm deep cylindrical stainless steel tub with a diameter of 420mm (Figure 1).

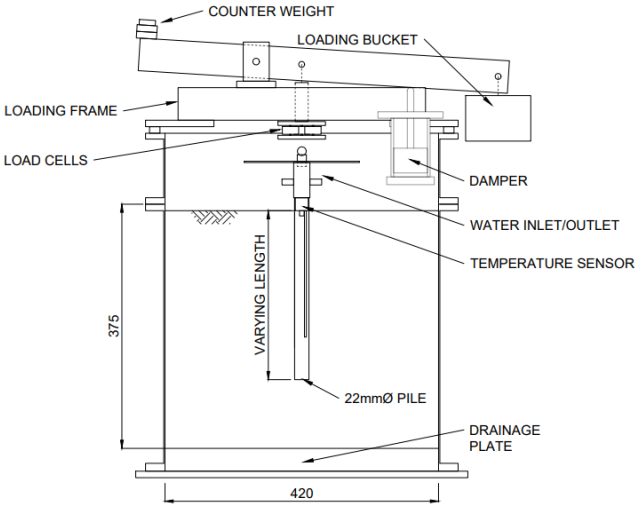

Figure 1. Model pile and loading frame set up.

The pile was modelled using 22mm outside diameter (1.10m diameter prototype) cylindrical copper tubes, coated in 0.7 – 1.25 mm alluvial sand ensuring good and consistent interface friction. This was the same sand that was used to create the soil bed. The pile cap was made from a Perspex body which housed inlet/outlet tubes for water to flow through the pile as well as a temperature sensor (Figure 2). An aluminium plate on top of the pile cap allowed LVDTs to measure vertical pile displacement.

The constant load apparatus comprised a loading beam with a water bucket at one end and a set of counterweights at the other. During the test, the loading bucket was filled with water corresponding to the desired axial load and that load was applied to the pile head. The load was measured by a load plate consisting of three load cells sandwiched between two aluminium plates ensuring that the load cells were not subjected to bending. Load was applied through a steel ball bearing at the top of the Perspex body ensuring pure axial load. To avoid a sudden movement of the bucket, and therefore an impact on the pile head, a damping mechanism was introduced.

Figure 2. Model pile embedded in sand.

5 MODEL PREPARATION AND TESTING PROCEDURE

Correct placement of the pile and soil temperature sensors was achieved with an installation guide. The pile and temperature sensors remained attached to the guide until the required height of soil was reached.

The sand was carefully placed into the tub, around the pile and soil temperature sensors, in layers of approximately 10mm, with compaction taking place after each layer of sand was placed. Pore pressure transducers were inserted through openings in the walls of the tub. A smoothing tool was used to level out the surface of the soil.

Once the top of the soil model was levelled, the installation guide was removed and the loading frame, with the load cells and LVDTs was carefully fixed onto the tub. The model was then placed on the centrifuge swing for connections to be made. A standpipe was connected to the model to establish and maintain the required water table for each test and the model was accelerated to 50g. When the water table was established the pile was loaded by filling the bucket with water to achieve the desired load. Thereafter, heating and cooling cycles began.

The pile embedment depth, water table levels, and factors of safety (FOS) for the two tests presented are summarised in Table 1.

Table 1. Summary of test variables.

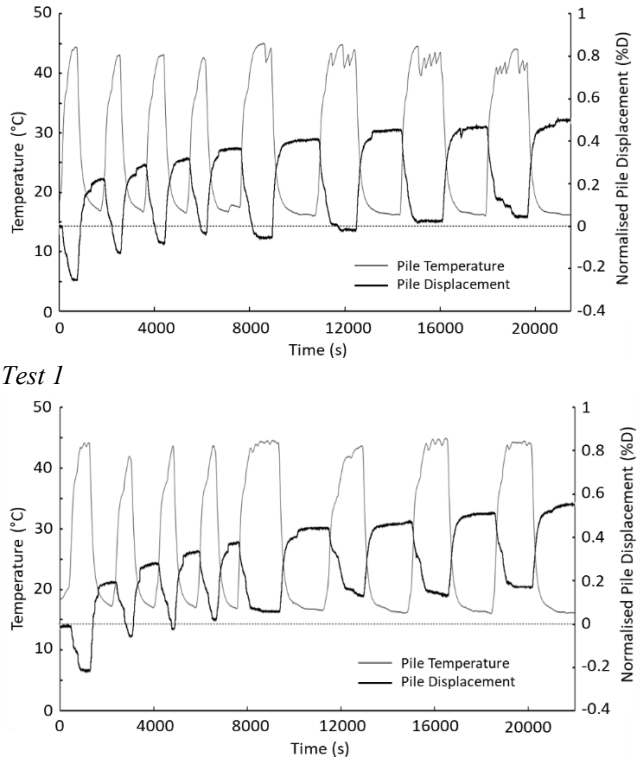
Test ID	Pile embedment depth (mm)	Water table in mm below ground level	FOS
Test 1	265	129	2.6
Test 2		31	1.7

6 RESULTS

For Tests 1 and 2, the pile embedment depth was 265mm at model scale, equivalent to 13.25m at prototype scale. As noted above the first four cycles of temperature each took 30 minutes, which is equivalent to 52 days of heat transfer at prototype scale; owing to the N^2 scaling factor for heat transfer (Savvidou 1988). The second four cycles were 104 days at prototype scale. The normalised pile displacements during heating and cooling stages are shown in Figure 3.

The initial temperature of the piles was between 17 and 18°C and this was governed by the mains supply temperature. The piles were then heated to 43°C by circulating hot water through the pile, applying a temperature change of approximately 26°C between heating and cooling cycles. A slight variation in both maximum and minimum temperatures of the pile was observed owing to heat loss during cycling.

Pile heave of just under 0.3%D was observed during the first heating phase for Test 1, followed by a settlement of approximately 0.5%D during the first cooling phase. During subsequent heating and cooling cycles, ratcheting settlement of the pile was observed, with a final settlement of 0.5%D, but at this stage the net settlement at the end of a temperature cycle had reduced to 0.03%D. There was a smooth non-linear reduction in net settlement per cycle which was not affected by the length of the temperature cycle. In this test the water table was approximately half way down the pile and below the temperature sensors.



Test 1

Test 2

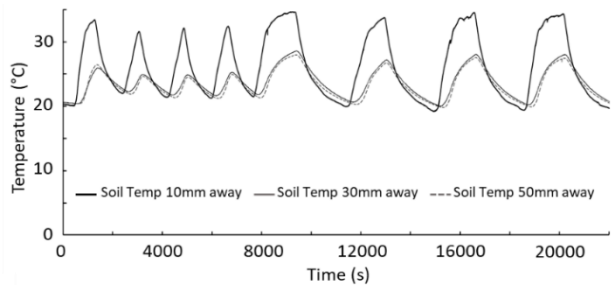
Figure 3. Normalised pile displacements during temperature cycles. Negative pile displacement is heave.

In Test 2 the water table was near ground surface, and pile displacement was reduced; just over 0.2%D of heave occurred when the pile was initially heated, followed by 0.45%D of settlement during the first

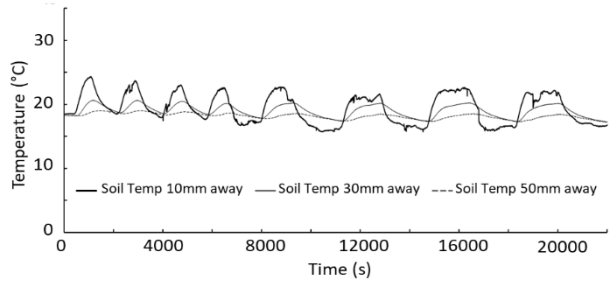
cooling phase. During subsequent heating and cooling cycles the net settlement increased more significantly than in Test 1 with a final settlement after 8 cycles of 0.53%D. The net settlement for the final cycle was approximately 0.03%D. In this test it appears that the cycle duration influenced the net settlement in each cycle, as there was an increase in net settlement during the first long cycle; although it is possible that this may be a function of slight disparities in the temperature cycles.

7 DISCUSSION

There was heave at the pile cap upon initial heating, followed by settlement as the pile and surrounding soil cooled and contracted. Settlement always exceeded heave but by gradually lesser amounts. The factor of safety for Test 2 was lower than that for Test 1 because the water table was near the surface and this should lead to significantly greater settlements during this test. However, the increase in settlement was marginal and this may be explained by examining the change in temperature in the soil surrounding the pile. Figure 4 shows the temperature measured at sensors placed 10, 30 and 50 mm away from the pile.



Test 1



Test 2

Figure 4. Temperature variation away from the pile.

It is clear from this figure that temperature dissipates more rapidly with distance from the pile when the sand is saturated. This might be expected as the primary mechanism of heat transfer in a coarse-grained soil is convection due to motion of the pore fluid (Savvidou, 1988). In the unsaturated/dry sand at the top of the pile in Test 1 this mechanism of heat transfer will not occur and the soil surrounding the pile will be subjected to more dramatic changes in temperature leading to greater heave and settlement than might occur in a saturated sand at an equivalent factor of safety. This may also cause a pile in saturated sand to be less thermally efficient, but this is not something that could be easily established from these tests. The temperature changes are consistent with those seen by Ng et al. (2020) for thermal piles in saturated sands. Wang et al. (2017) testing piles in dry sand recorded greater temperature changes at similar distances from the pile, but in Test 1 half of the pile is in saturated soil. The overall pile head settlement after 7 cycles of temperature observed by Ng et al. (2020) was greater than in Test 2, but the pile length to diameter ratio in those tests was 19, whereas in the tests reported here it is only 12 representing a realistic geometry for a HIPER pile. A longer pile should generate greater displacement at the pile head when heated and cooled.

8 CONCLUSIONS

A short series of centrifuge testing of piles in sand has confirmed that heat transfer through saturated sand by convection within the pore fluid reduces temperature changes in the soil surrounding the pile. This in turn reduces temperature induced settlements under axial load. In comparison with similar tests on piles with higher length to diameter ratios these wider and shorter hollow piles seem to develop less net settlement, even at quite low factors of safety.

The series of tests was limited in number and further work is necessary to explore the effect of varying the water table for constant factor of safety piles.

ABSTRACT: Arbuscular mycorrhizal (AM) fungi play a pivotal role in promoting plant growth by enhancing root biomass, cellulose content, and biomechanical properties of plant roots. The present study investigates the potential of AM fungi in conjunction with Bermuda grass (Cynodon dactylon L.) to optimize soil bioengineering methods. These environmentally friendly approaches effectively mitigate soil erosion by facilitating root adhesion to the soil matrix and reinforcing both mechanical and hydraulic properties by root biomechanical properties. The study focuses on assessing the impact of AM fungi on distinct growth and decay periods induced by controlled burning and herbicide treatments. Various parameters, including root biomass, cellulose content, and mechanical properties such as root tensile strength and root young's modulus, are measured at different temporal intervals. The findings elucidate that the presence of AM fungi significantly augments plant root biomass and root tensile strength relative to the absence of AM fungi. However, during the decay period, the influence of AM fungi on root tensile strength can increase, but it is not statistically significant. Nonetheless, these properties are notably higher in the presence of AM fungi compared to their absence, suggesting that AM fungi enhance these traits predominantly during the growth phase. The outcomes of this study underscore the profound positive effects of AM fungi on plant root properties and provide valuable insights into their potential implementation in soil bioengineering.

RÉSUMÉ: Les champignons mycorhiziens arbusculaires (AM) jouent un rôle central dans la promotion de la croissance des plantes en améliorant la biomasse des racines, la teneur en cellulose et les propriétés biomécaniques des racines des plantes. La présente étude examine le potentiel des champignons AM en conjonction avec l'herbe des Bermudes (Cynodon dactylon L.) pour optimiser les méthodes de bio-ingénierie des sols. Ces approches respectueuses de l'environnement atténuent efficacement l'érosion des sols en facilitant l'adhésion des racines à la matrice du sol et en renforçant les propriétés mécaniques et hydrauliques grâce aux propriétés biomécaniques des racines. L'étude se concentre sur l'évaluation de l'impact des champignons AM sur des périodes distinctes de croissance et de décomposition induites par des traitements de brûlage contrôlé et d'herbicides. Divers paramètres, notamment la biomasse racinaire, la teneur en cellulose et les propriétés mécaniques telles que la résistance à la traction des racines et le module de jeunesse des racines, sont mesurés à différents intervalles temporels. Les résultats montrent que la présence de champignons AM augmente considérablement la biomasse des racines des plantes et leur résistance à la traction par rapport à l'absence de champignons AM. Cependant, pendant la période de décomposition, l'influence des champignons AM sur la résistance à la traction des racines peut augmenter, mais elle n'est pas statistiquement significative. Néanmoins, ces propriétés sont nettement plus élevées en présence de champignons AM qu'en absence, ce qui suggère que les champignons AM améliorent ces caractéristiques principalement pendant la phase de croissance. Les résultats de cette étude soulignent les profonds effets positifs des champignons AM sur les propriétés des racines des plantes et fournissent des informations précieuses sur leur mise en œuvre potentielle dans la bio-ingénierie des sols.

Keywords: AM fungi; root biomechanics; growth; decay.

1 INTRODUCTION

In vegetated soil, Plant roots play a pivotal role in conferring stability to shallow slopes and preventing erosion has been underscored in previous studies (Kamchoom and Leung 2018; Ng et al. 2016). A comprehensive understanding of the biomechanical

properties of plant roots is deemed imperative for devising strategies to mitigate soil instability, particularly in regions prone to natural disasters such as landslides and erosion (Apriyono et al. 2022; Stokes et al. 2014). Consistent with this perspective, prior investigations have delved into the biomechanical properties of plant roots, aiming to elucidate their role in mitigating erosion and failures of shallow slopes. However, divergent findings have surfaced in studies exploring the period of plant root decay (Kamchoom et al. 2021; Zhu et al. 2020). It has been observed that during this phase, these biomechanical properties tend to exhibit diminished values, potentially contributing to a detrimental impact on soil stability.

During the process of plant root decay, a symbiotic association with mycorrhizal fungi can exert a significant influence, eliciting positive effects on plant roots (Basyal and Emery 2021). Specifically, Arbuscular Mycorrhizal (AM) fungi facilitate enhanced nutrient absorption by plant roots. Previous studies have indicated that AM fungi may contribute to an increase in cellulose content and even elevate the tensile strength of plant roots. It is important to note that the influence of AM fungi extends to modifications in soil properties (Chen et al. 2019; Solly et al. 2014). These alterations in soil characteristics, in turn, have implications for changes in the properties of plant roots. Nonetheless, the effect of AM fungi subsequent to decay treatment on root biomechanical properties have not been thoroughly investigated.

2 MATERIALS AND METHODS

An investigation was conducted on the roots of Cynodon dactylon, commonly known as Bermuda grass, an herbaceous species. Bermuda grass is frequently employed in soil erosion control due to its ability to develop fibrous root systems in shallow soils (Faucette et al. 2006; Ng et al. 2014). The soil selected for this study is lateritic soil, a type commonly encountered in engineering projects for landscaping purposes in tropical and subtropical regions, such as southern China and Thailand. This soil has been characterized as clayey sand. To ensure its suitability for the research, the collected soil underwent an initial sanitation process at 120 °C for 3 hours, followed by an additional two days of oven-drying at 60°C to inactivate AM fungi in situ. Subsequently, the dry soil was sieved through a 2 mm sieve, and the AM fungi were sourced from a local supplier.

To promote optimal root development, Bermuda grass seeds were germinated in nutrient-rich vermicompost one month prior to transplantation into the soil specimens. AM fungi inoculation was introduced by preparing a mixture comprising 1 kg of soil and 25 g of dry AM fungi inoculum. The soil-AM fungal inoculum underwent compaction within polyvinyl chloride cylinders (90 mm in diameter, 130 mm in depth) using the moist tamping method, resulting in a dry density of 1520 kg/m³. Following the compaction of the soil column, a 15 mm thick layer of vermicompost was applied to the upper surface.

To investigate dynamic changes in root, two distinct experimental groups were established: Soil with AM fungi (denoted as M) and Soil without AM fungi (denoted as NM). Each experimental group comprised 30 samples, meticulously maintained in a controlled glasshouse environment. Within each group, 9 samples were specifically selected for the detailed examination of root growth impact, The grass underwent cultivation for durations of 60, 120, and 180 days, collectively referred to as growth treatments. (For each treatment, a standard reference and two replicates were employed). Following 180 days of grass growth, the remaining 21 specimens underwent two distinct decay treatments: herbicide treatment and burning treatment. In the burning treatment, the entire aboveground biomass, encompassing shoots and leaves, was subjected to a 15-minute incineration using a gas torch, followed by a 3-hour smouldering period to facilitate root decay. 12 specimens were retained in the glasshouse for durations of 30, 60, 120, 180, and 360 days after burning treatment. For the herbicide treatment, two doses of Propanil (N-[3,4-dichlorophenyl] propanamide) were applied as an irrigation solution with a concentration of 36% w/v. Subsequently, 9 specimens underwent detailed assessments of root decay after intervals of 15, 30, and 60 days following the herbicide treatment.

2.1 Measurement of Root biomechanical properties

Each soil specimen containing roots was rinsed gently with running tap water and was subsequently sieved through sieves No.4 and No.10 to obtain root samples. The roots retained on the sieve were carefully collected. The saturated weight of the roots was determined by immersing them in distilled water for a period exceeding 12 hours. For tensile testing in each treatment, approximately 30 roots were chosen, ensuring the selection of root segments without any tortuosity or tissue loss. These root segments were then subjected to a uniaxial tensile test using a universal testing frame, employing a constant extension rate of 0.1 mm/s. Root segments that failed at or near the clamp margins were excluded from analysis. The root young's modulus was subsequently calculated from

stress-strain relationships derived from the tensile strength test.

2.2 Measurement of Cellulose content

The chemical composition of roots, specifically the content of lignin and cellulose, was assessed on the residual portion of each root segment using the method described by Leavitt and Danzer (1993). In general, the procedure entailed the removal of lignin polymers subsequent to the elimination of organic compounds from the root material. This process resulted in the classification of the residual constituent as a compound composed of cellulose.

3 RESULTS

3.1 Effects of AM fungi on root biomechanical properties

During the phase of normal growth, observed in the NM condition (Soil without AM fungi), there was an 18% increase in mean tensile strength from day 60 to 120. In the condition of M (Soil with AM fungi), a modest increase of 4% was noted from day 60 to 120, followed by a more substantial increase of 23% from day 120 to 180 (Figure 1a). Young's modulus demonstrated minimal impact from AM fungal inoculation at 60 and 120 days but exhibited a notable improvement of 35% at 180 days compared to the NM condition (Figure 1b).

During the decay phase, a significant decrease in mean tensile strength was observed, particularly in condition of decay due to herbicide treatment. At 60 days after decay (day 240), the mean tensile strength for NM and M was 14.9 MPa and 19.5 MPa, respectively, for herbicide treatment, and 27.6 MPa and 28.8 MPa, respectively, for burning treatment. After 180 days of burning-induced decay (day 360), AM fungi conditions displayed a clear increase in mean tensile strength, with values of 16.6 MPa for NM and 23.9 MPa for M (Figure 1a), representing a 44% increase. Regarding Young's modulus, after 60 days of decay due to herbicides (day 240), values for NM and M were 146 MPa and 160 MPa, respectively, while for decay due to burning, the values were 252 MPa and 277 MPa, respectively. A comparison of these values indicated that M condition was approximately 11-18% higher than NM condition under both decay phase.

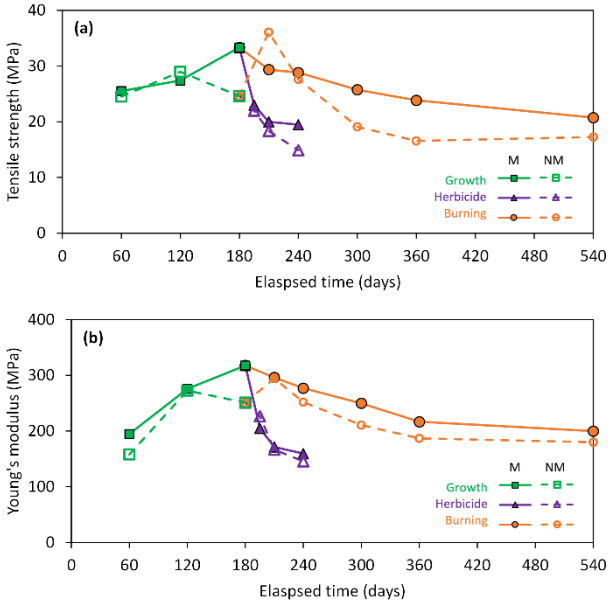

Figure 1. Variation in (a) Tensile strength and (b) Young's modulus of root with and without AM fungi.

3.2 Effects of AM fungi on root biomass and cellulose content

In the M condition, both cellulose content and root biomass exhibited higher values compared to the NM condition at each recorded time point. Throughout the growth period, cellulose content demonstrated an increasing trend. However, between days 120 and 180, a slight decrease was observed in the NM condition (Figure 2a), corresponding with the concurrent reduction in tensile strength and Young's modulus during that phase (Figure 1). During the decay phase, a decline in cellulose content and root biomass was noted, with a more pronounced reduction in the condition of herbicide-induced decay. In the presence of mycorrhizal (M), this decline in cellulose content and root biomass was mitigated, particularly in instances of decay due to herbicide (Figure 2c and d). Notably, in condition of burning treatment, although cellulose content decreased, the rate of decline was slower (Figure 2e). Root biomass also experienced a decrease, but the reduction was less pronounced (Figure 2f). The presence of mycorrhizal further attenuated the rate of decline, particularly when compared to herbicide-induced decay.

4 CONCLUSIONS

This study involved the inoculation of Arbuscular Mycorrhizal (AM) fungi to Bermuda grass, a species recognized for its resilience in revegetation stress. The primary aim was to investigate the influence of AM fungi on root biomechanical properties relevant to soil reinforcement. Preceding decay processes, AM fungi

contributed to an increase in root biomass, providing more initial root materials. In general, roots inoculated with AM fungi exhibited higher cellulose contents compared to without AM fungi. Although a positive correlation between cellulose content and root tensile strength was evident. AM fungi contributed to roots consistently demonstrated significantly higher cellulose content, tensile strength, and Young's modulus than without AM fungi. These observations were particularly pronounced during normal growth and following the burning treatment, except for the herbicide treatment, indicating that herbicide application influenced plant biochemical or physiological processes, accelerating decomposition. Furthermore, certain plant specimens managed to withstand burning while retaining intact root systems. While no significant difference in the in-situ decay rate of roots was observed between with and without AM fungi, the application of AM fungi resulted in noteworthy enhancements in root biomass, cellulose content, tensile strength, and Young's modulus. Our findings suggest that inoculating grass-rooted soils with AM fungi is an effective method for preserving their physical stability.

ABSTRACT: It is essential to highlight that the civil construction industry is a significant contributor to carbon emissions. The aim of this article is to develop a flowchart using the Life Cycle Assessment (LCA) methodology, which has already been employed to calculate the carbon footprint of deep foundations. This flowchart will be specifically tailored to assess the carbon footprint of helix piles used in a building project located in Brasilia, DF. Alongside this, the article will include a literature review of previous research within the foundation sector concerning carbon footprint analysis.

RÉSUMÉ: Il est essentiel de souligner que l'industrie de la construction civile est un contributeur significatif aux émissions de carbone. L'objectif de cet article est de développer un organigramme en utilisant la méthodologie d'Analyse de Cycle de Vie (ACV), qui a déjà été employée pour calculer l'empreinte carbone des fondations profondes. Cet organigramme sera spécifiquement adapté pour évaluer l'empreinte carbone des pieux hélicoïdaux utilisés dans un projet de construction situé à Brasilia, DF. En parallèle, l'article comprendra une revue de la littérature des recherches précédentes dans le secteur des fondations concernant l'analyse de l'empreinte carbone.

Keywords: LCA methodology; helix piles; deep foundations; carbon footprint.

1 INTRODUCTION

Climate change is exerting a significant impact on our environment, making it essential to adopt concrete measures to mitigate its effects. It is well known that energy consumption is the main source of greenhouse gas emissions, encompassing sectors such as transportation, electricity generation, heat generation, buildings, manufacturing, construction, fugitive emissions, and other forms of fuel combustion. For instance, in 2016, heat and electricity generation accounted for 30% of emissions, while transportation contributed 15%, and manufacturing and construction contributed 12% (WRI Brazil, 2020).

In a more specific context, greenhouse gas emissions in Brazil increased by 8.9% in 2016, reaching a total volume of 2.28 billion metric tons of carbon dioxide equivalent (CO_2e), compared to 2.09 billion recorded in 2015 (World Resources Institute Brazil, 2017). These figures position Brazil as the seventh-largest emitter of greenhouse gases globally. To meet the commitments of the Paris Agreement, the country has established ambitious climate targets, incentivizing the implementation of long-term measures to reduce emissions.

In this context, research on carbon footprint plays a crucial role. Carbon footprint, defined in 1990 (Gao et al, 2014), represents the cumulative amount of greenhouse gas emissions (GHG) generated by individuals, companies, or entities, measured in tons of carbon dioxide equivalent (CO_2eq) emitted annually. GHG encompasses a range of gaseous compounds, such as perfluorocarbons, methane, carbon dioxide, nitrous oxide, hexafluoride, sulfur, and hydrofluorocarbons. Effective measures to reduce these carbon emissions include promoting sustainable buildings, which contribute to a healthy environment in the long term, the use of renewable energies, sustainable water consumption (Okeke et al, 2018), as well as the conservation of green spaces and the development of emissions measurement tools in construction (Cheng et al, 2011).

In the field of civil construction, deep foundations, such as helical and drilled piles, play a fundamental role in environmental sustainability. They are often employed in engineering projects that require structural support in challenging soils, such as collapsible soils. However, the construction of these foundations entails significant consumption of resources, energy,

and materials, substantially contributing to the carbon footprint of a project.

Recognizing the importance of adapting deep foundations to make them more sustainable is imperative, as this can contribute to the reduction of greenhouse gas emissions. Strategies include the use of materials with lower carbon intensity, waste and resource consumption minimization, the use of energy-efficient equipment and technologies during the construction of these foundations, and effective management of construction and demolition waste, emphasizing recycling.

Therefore, when considering the construction of deep foundations, especially in challenging soils such as collapsible soils, it is crucial to adopt a sustainable approach that takes into account the environmental impact. Such an approach not only contributes to meeting carbon emission reduction goals but also results in more resilient and durable structures, providing long-term benefits to the environment and society.

Most studies emphasize the importance of assessing emissions during the construction phase of buildings (Keoleian, G et al, 2001; Junnila and Horvath, 2003; Junila et al, 2006). However, it is notable that few of these studies emphasize the construction phase of foundations, which involves the use of large volumes of steel, concrete, and heavy machinery, resulting in significant CO_2 emissions to the environment. According to the Paris Agreement, signed on December 12, 2015, and ratified on November 4, 2016, it became necessary for countries responsible for about 55% of global emissions to commit worldwide. In this context, each country established specific targets, and the European Union, along with 193 other countries, including Brazil, account for more than 90% of greenhouse gas emissions and have adhered to the treaty. The goal of this agreement is to achieve decarbonization targets by 2050 (IPCC, 2018).

Several countries have implemented emission control policies, but in Brazil, the inclusion of a carbon tax in tax reform has not yet been defined. According to a report by WRI Brazil in 2020, this document offers valuable insights into possible paths towards a transition to a low-carbon economy. The report indicates that the country is ready to adopt new economic approaches aligned with the low-carbon economy and highlights the benefits of adopting these policies (WRI Brazil and The New Climate Economy, 2020).

Based on the justifications presented above, the proposed research finds solid grounds for its realization. The gap in studies specifically addressing the construction phase of foundations, along with the need for emission control policies aligned with international commitments, such as the Paris Agreement, and the potential for a low-carbon economy, highlight the relevance of this study. Additionally, the WRI Brazil 2020 report corroborates the country's readiness to adopt sustainable economic approaches, emphasizing the importance of investigating the carbon footprint in helical piles in the region. Therefore, the proposed research is justified as a significant step towards understanding and mitigating CO_2 emissions associated with this phase of construction in Brasília-DF.

2 CARBON FOOTPRINT IN DEEP FOUNDATIONS

The carbon footprint of deep foundations can be significant due to the intensive use of construction materials, transportation of heavy materials and equipment, and the use of large machinery for drilling and excavation. The carbon footprint of these foundations can be reduced by adopting more sustainable construction techniques, such as using low-carbon construction materials and implementing more efficient transportation models. Additionally, the use of renewable energy-powered equipment and the adoption of construction techniques that reduce waste and pollution can also decrease the carbon footprint of deep foundations.

Life Cycle Assessment (LCA) is a methodology used to assess the environmental impacts of processes or products. In the case of deep foundations, LCA considers the environmental impacts of all phases of the foundation construction process, including material extraction, manufacturing, transportation, installation, and disposal. This includes an analysis of the types of materials used in the foundation, the amount of energy and water used during construction, and the emissions of greenhouse gases and other pollutants.

The Life Cycle Assessment (LCA) Matrix for Continuous Flight Auger (CFA) Pile is a tool that allows the assessment of the environmental impacts of this foundation technique. It is divided into life cycle stages of the structure, from raw material extraction to the end of the foundation's service life.

2.1 Definition of the limit for calculating the carbon footprint in continuous flight auger piles in this study

The calculation of the carbon footprint during the Installation phase of continuous flight auger piles will be carried out. In this way, the limit of the carbon footprint in the installation phase of continuous flight auger piles is established in Figures 1 and 2.

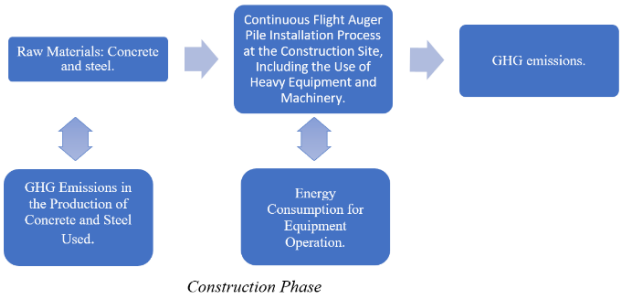

Figure 1. Limit of the carbon footprint in the construction phase of continuous flight auger piles. According with Bilec (2007).

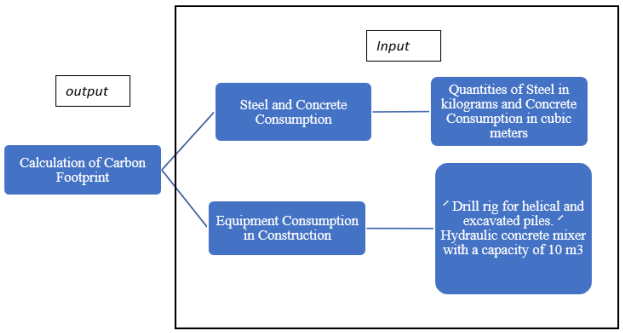

Figure 2. Helical pile limits for settlement calculation, including transport and installation phase. According with Li, et al (2019).

2.2 Calculation of emissions

In this section, we outline the methodology for calculating emissions. Our approach closely mirrors that employed by Zhang and Wang (2016). We will evaluate the carbon emissions associated with the construction of continuous flight auger piles in the collapsible soil of the Federal District. This assessment adopts methodological principles similar to those detailed by Zhang and Wang. The analysis encompasses various aspects, including quantifying carbon emissions linked to concrete transportation necessary for pile foundation, as well as emissions stemming from the production and utilization of critical materials like steel and concrete. Furthermore, we will consider specific carbon emissions generated during the construction phase of the continuous flight auger piles.

By applying this approach, in alignment with Zhang and Wang's work, we aim to ensure a consistent evaluation of the carbon emissions inherent in the implementation of these piles, thereby contributing to a comprehensive analysis of the environmental impact of this construction practice. As per the preceding paragraph, we will utilize Equations 1, 2, 3, 4, and 5, which reflect the methodology proposed by Zhang and Wang.

Manufacturing Emissions of Materials:

$$Cmat = \Sigma Ai \times FEi\ , \quad (1)$$

Emissions from On-Site Construction Activities:

$$Cact = \Sigma Aj \times FEj, \quad (2)$$

Total Carbon Footprint:

$$C_{Total}) = (Cmat + Cact), \quad (3)$$

Emissions from Concrete Transportation:

$$ETC = QCT \times FETC, \quad (4)$$

Total Carbon Footprint R:

$$RC_{Total}) = (Cmat + Cact + ETC), \quad (5)$$

The amount of carbon emissions related to materials (Cmat) is determined by the quantity of material or activity of each type, represented by Ai, multiplied by the specific carbon emission factor for that material or activity, represented by FEi. Similarly, carbon emissions associated with activities performed at the construction site (Cact) are calculated by multiplying the quantity of each type of activity, represented by Aj, by the specific carbon emission factor for that activity, represented by FEj. Therefore, the total carbon footprint (C_Total) is obtained by adding the emissions from material manufacturing (Cmat) to the emissions associated with on-site activities (Cact). Additionally, concrete transportation emissions (ETC) refer to emissions generated during the transportation of concrete from the production site to the construction site of helical piles. These emissions are determined by multiplying the quantity of transported concrete (QCT) by the specific carbon emission factor for concrete transportation (FETC). For a more comprehensive and accurate assessment of environmental impact, concrete transportation emissions are integrated into the calculation of the total carbon footprint (RC_Total), allowing for consideration of all emissions stemming from material manufacturing, on-site activities, and transportation required for helical pile foundation.

2.3 Determination of the carbon emission factor

To calculate carbon emission factors (CE) for various construction materials in civil engineering projects, we use the widely recognized and comprehensive "Carbon and Energy Inventory" (ICE) database, as referenced in Hammond and Jones (2011).

Research approach aligns with Hammond and Jones (2011) and the ICE methodology. We focus on

calculating specific CO_2 emissions for particular reference units, enabling us to determine carbon emission factors. This method offers a detailed analysis of CO_2 emissions throughout material and process life cycles, from extraction to application.

The carbon emission factor, representing CO_2 emissions per unit of activity or product, is determined as follows (Equation 6): Emission Factor = Specific Emissions / Reference Unit.

Emphasizing the importance of using reliable and up-to-date data from recognized sources, such as national emission inventories or scientific databases. In the absence of Brazilian data, reliance will be placed on the ICE database, as also done by Hendler K. J. (2020). ICE provides comprehensive information on carbon emissions related to construction materials and processes. By using ICE, the aim is to obtain accurate data on the carbon emissions of various construction components, facilitating a detailed analysis of deep foundation structures' carbon footprint. Respecting the terms of use of the ICE database, proper attribution to the authors will be provided, and access to the most recent version ensured. Regarding the environmental impact of concrete transportation, the carbon emission factor is crucial. This factor reflects greenhouse gas emissions from concrete transport vehicles. Elements like distance, vehicle type, fuel, and traffic conditions influence these emissions. Sustainable transportation practices are essential to reduce this environmental impact. Data on emission factors will be sourced from Costa (2012) and the greenhouse gas emission inventory guidelines developed by SindusCon (2022). This data will be presented in a table format to enhance understanding and support sustainable decision-making.

Table 1. Portland Cement, Steel and Concrete Emission Factor. Hammond and Jones (2011).

Material	EC ($KgCO_2/Kg$)	EC-GHG ($KgCO_2e/Kg$)
CEM I Portland Cement	0,93	0,95
Virgin bar or rod	2.58	2.74
25/30 MPa	0.106	0.113

Table 2. Emission Factors for Mixer Truck and Drill. Source: Costa (2012) and SindusCon (2022).

Equipment	EC (tCO_2/L)	EC-GHG (tCO_2e/L)

3 DATA COLLECTION

In this section, the main sources of emissions associated with concrete transportation and continuous flight auger pile installation will be presented. Aspects such as the manufacturing of materials, specifically concrete and steel used in the structure, and the energy consumption involved in the concrete transportation processes will be discussed.

3.1 Drill and mixer usage and fuel consumption in construction

Using the values related to these 79 piles, a statistical analysis was conducted, which resulted in the measures of central tendency presented in Table 3. To enable this analysis, the data was properly processed and organized.

Table 3. Statistical Measures for Drilling and Concreting Time at a Construction Site in Brasília, DF.

Statistical measures calculated for drilling and concreting of continuous flight auger piles calculated in minutes			
AM of concreting time	12,9	AM of drilling time	29,3
SD of concreting time	6,4	SD of drilling time	8.9
CV for concreting time	49,6	CV for drilling time	30,2

3.2 Helical pile material quantity

The data related to the materials used in the construction of helical piles, which have depths ranging from 15 to 23 meters and a diameter of 60 centimeters, were utilized. These details were kindly provided by SCCAP, the company responsible for the foundation project, and were directly extracted from the project's foundation plan, and can be found in Table 4.

Table 4. Average Steel and Concrete Consumption per Pile.

Data Type	Average per Pile
Steel Consumption	86,54 kg
Concrete Consumption	6,65 m^3

3.3 Data on concrete transportation to the construction site

The transportation of concrete to the construction site located in the city of Brasília, approximately 7.6 miles away from the production point. A total of 525.1 cubic meters of concrete were used in the concreting of the 79 piles. This is equivalent to 53 truck trips, each with

a concrete-carrying capacity of 10 cubic meters. The distance covered on each trip was approximately 7.6 miles, resulting in a total of 53 trips to complete the concreting process for the 79 piles. The transportation calculation for hydraulic concrete mixer trucks involves 56 trips, each covering approximately 7.6 miles, to transport 79 piles. This results in an average mileage of 5.39 miles per pile.

3.4 Labor data during the construction of helical piles

According to the information provided by the construction company, there were 3 people in the field at the time of pile construction, along with 1 supervising engineer. With this data, is it possible to estimate the carbon footprint related to the labor force.

4 RESULTS

As detailed in the previous sections, this study involved a comprehensive assessment of construction methods, soil analysis, material consumption, transportation, and equipment use. All this information was carefully collected and analysed to calculate the carbon emissions associated with this construction process.

4.1 Calculation of the carbon footprint from equipment usage

According to the emission factor of the machines, as detailed in Table 2, and the time data collected in Section 3, we will perform the calculation in Table 5 to estimate the carbon emissions associated with this equipment during the project execution according to Equation 2 for calculating emissions per activity on the construction site.

Before proceeding with the calculations, it is important to convert the volume of concrete used in each pile from cubic meters to metric tons. To convert 6.65 m^3 to metric tons, I should multiply it by 2.4 t/m^3, which would result in a value of 15.96 t.

Table 5. Calculation of emissions produced by the equipment.

Equipment	Usage Time (hours)	Fuel Consumption per Hour (L/h)	Carbon Emissions per Pile (tCO_2e)
Hydraulic Concrete Mixer	1/6	59,85	31,3215
Drilling Machine	13/30	6,4	8,7083
Total ($KgCO_2e$)			40.029,8

4.2 Carbon footprint calculation for materials used in the installation of Helical

The results of carbon emissions related to these materials will be presented in Table 6, using the emission factors of the materials found in Table 1.

Table 6. Calculation of emissions produced by the steel-reinforced concrete.

Material	Quantity of Material /Pile (kg)	Emission Factor ($KgCO_2e/Kg$)	Carbon Emissions Calculation per Pile $KgCO_2e$
30 MPa Concrete	15960	0.113	1803,48
Civil Steel	86,54	2.74	237,12
Total			2040,6

4.3 Carbon footprint calculation for transportation

To cover 5.39 miles (approximately 8.67 kilometers) with a total weight of about 21.06 metric tons and a fuel consumption rate of 0.0196 L/t.km, you would consume approximately 4.117 liters of fuel. The machine fuel consumption, as reported by SindusCon, is 4,117 liters, with an emission factor of 3.140 tCO_2e per liter. This calculation results in carbon emissions of approximately 12.927 tCO_2e per pile.

4.4 Calculation of the carbon footprint produced by the workforce

According to Li's 2019 study, during a work shift with 30 people at the construction site, a significant carbon dioxide consumption was estimated, as indicated in Table 7, where it was estimated that 460 $kgCO_2$ were produced per shift for 30 people. However, it's important to recognize that conditions and activities may vary between the two contexts. Therefore, the numbers presented here are used as an approximate estimate of carbon emissions related to the workforce in this study.

Table 7. Calculation of emissions produced by the personnel on the construction site.

Source of Consumption	Specification	Carbon Footprint per Shift ($kgCO_2$)
Office	4 people	61,33

4.5 Summary of results

Table 8 shows two key results obtained regarding the carbon footprint of continuous flight auger pile construction.

The total carbon footprint per continuous flight auger pile is calculated by summing the emissions of each component, resulting in 55,058.73 $kgCO_2e$ per continuous flight auger pile.

Table 8. Summary of Carbon Footprint Results.

Aspect Analysed	**Carbon Emissions ($kgCO_2e$/pile)**
Equipment Usage	40.029,00 (73 %)
Materials - Concrete and Civil Steel	2.040,6 (4%)
Concrete Transportation	12.927,00 (23%)
Labor (Li, 2019)	61,33 (0,1 %)
Total Carbon Footprint /pile	55.058,73

5 CONCLUSIONS

Table 8 presents a synthesis of the results obtained from the analysis of the carbon footprint associated with the construction of continuous flight auger piles in a specific project in Brasília, DF. This analysis is crucial for assessing the environmental impact of this construction process and, at the same time, provides valuable insights for the adoption of more sustainable practices in the construction industry. A notable point is the considerable impact of carbon emissions resulting from the use of equipment, especially hydraulic concrete mixers and continuous flight auger rigs, as well as bored piles in the drilling and concreting process. This finding underscores the need to consider more efficient and lower carbon footprint alternatives in the selection and use of equipment during the construction process. Additionally, concrete transportation also represents a significant portion of emissions in pile construction, emphasizing the importance of optimizing transportation logistics, exploring on-site concrete pouring options, and reducing the distance between the concrete plant and the construction site as strategies to minimize transportation-related emissions. It is important to note that most emission factors were derived from the literature and attempt to replicate the reality of the Brazilian industry, although this approach may not be entirely accurate.

ABSTRACT: The redistribution of moisture during uniaxial freezing of the soil at the base of roads in winter is of great importance for its bearing capacity during the spring thaw. In winter, an ice lens forms directly under the road due to the higher thermal conductivity of the pavement layers. And during the spring thaw, the base of the road may become oversaturated, leading to volume changes and damage to the road structure. This article presents a theoretical calculation of moisture accumulation in frozen layers due to water migration in a gaseous state based on monitoring data. A section of the highway near Kosshy town 20 km from the capital of Kazakhstan, was monitored in the winter period of 2021-22 and 2022-23. The water mass transfer in a form of vapour 1.41-1.44·10^{-4} g/h per 1 dm³ of soil at with temperature fluctuations -5-8 °C based on monitoring data of the highway foundations in winter period. The rate of vapour transfer in the frozen soil was 0.467-0.472 m/h and caused the formation of 430-456 g of ice due to the accumulation of water in a gaseous state in every 1 m^3 of soil, which increased the humidity by 40% or more and significantly reduced the bearing road capacity during the spring thaw.

RÉSUMÉ: La redistribution de l'humidité lors du gel uniaxial du sol au pied des routes en hiver est d'une grande importance pour sa capacité portante lors du dégel printanier. En hiver, une lentille de glace se forme directement sous la route en raison de la conductivité thermique plus élevée des couches de chaussée. Et lors du dégel printanier, la base de la route peut devenir sursaturée, entraînant des changements de volume et des dommages à la structure de la route. Cet article présente un calcul théorique de l'accumulation d'humidité dans les couches gelées en raison de la migration de l'eau à l'état gazeux, basé sur des données de surveillance. Un tronçon de l'autoroute près de la ville de Kosshy, à 20 km de la capitale du Kazakhstan, a été surveillé au cours de la période hivernale 2021-22 et 2022-23. Le transfert de masse d'eau sous forme de vapeur est de 1,41-1,44·10^{-4} g/h pour 1 dm³ de sol avec des variations de température de -5-8 °C, d'après les données de surveillance des fondations routières en période hivernale. Le taux de transfert de vapeur dans le sol gelé était de 0,467 à 0,472 m/h et a provoqué la formation de 430 à 456 g de glace en raison de l'accumulation d'eau à l'état gazeux dans chaque m³ de sol, ce qui a augmenté l'humidité de 40% ou plus et a considérablement réduit la capacité portante de la route lors du dégel printanier.

Keywords: Highway construction; temperature-moisture monitoring; freezing of soils; bearing capacity; ice lens formation.

1 INTRODUCTION

Temperature effects and especially moisture content have a huge impact on the strength characteristics of road bases (Teltayev et al., 2022). Due to the continental climate, the impact of temperature changes and transitions through 0°C have a more pronounced impact on the durability of the road structure (Teltayev and Suppes, 2019). The increased thermal conductivity of pavement materials distorts the temperature field under the road, contributing to the accumulation of moisture under the influence of cryosuction forces. The gradual freezing of layers of a road structure in winter initiates the transfer of water in a gaseous state from warm layers to colder ones and, as it freezes, it captures a large suction zone (Sarsembayeva and Zhussupbekov, 2021). The formation of an ice lens under roads leads to a

significant decrease in bearing capacity when melting in the spring.

This study examined temperature and humidity monitoring data during the winter period for 2021-22 and 2022-23 at a section of the highway near Kosshy town, 20 km from the capital of Kazakhstan, Astana. The transfer of water in frozen soils in a gaseous state was considered as the main source of ice lenses formed in the foundation soils of highways in winter.

2 METHOD

The cross-section design of the highway at the experimental site is presented in Figure 1. The temperature and humidity of the highway structure was monitored at a depth of up to 3 m using sensors embedded in metal capsules and recorded by a data logger every hour.

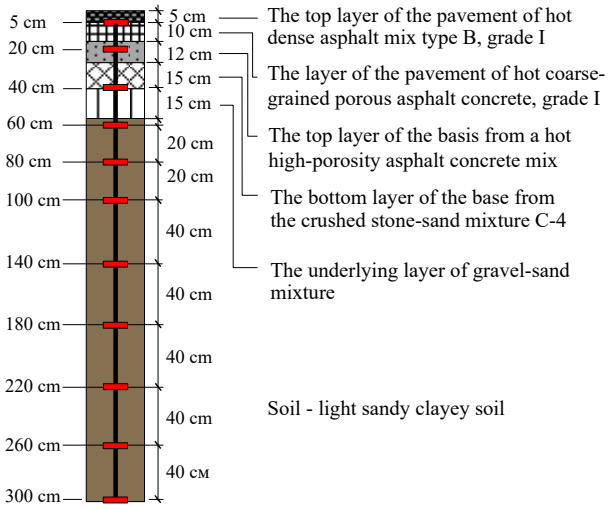

Figure 1. Design of highway structure.

Table 1. Physical and mechanical characteristics of road base soils.

Soil property	Unit	Value
Moisture content	%	20.2
Liquid Limit	%	26.5
Plastic Limit	%	15.1
Plasticity Index	%	11.6
Consistency index		0.5
Bulk density	g/cm³	2.0
Particle density	g/cm³	2.7
Void ratio		0.7
Degree of saturation		0.8
Deformation modulus	MPa	6.5
Cohesion	kPa	23.5
Angle of internal friction	degree	22

The base soil is light sandy clay loams, light brown in colour, hard, with layers of clay at a depth of 2.4 m with a thickness of up to 0.2 m. Soil samples taken from the construction site are water-bearing sediments. The amplitude of groundwater level fluctuations is 1.0-2.0 m from the ground surface, the minimum level is observed in February, the maximum at the end of May. Physical and mechanical characteristics of road base soils are presented in Table 1.

The amount of water transported in a vapour state directly depends on the type of soil and the volume of pores in the soil, the temperature gradient or temperature difference across the depth of the soil, as well as humidity at the transition through 0°C. Calculation of vapour mass using the saturated vapour pressure P_{si} over ice surface is:

$$m_{vapour,t_i} = \frac{\mu \cdot P_{si} \cdot V_{air}}{R \cdot T} \quad (1)$$

where μ - molar mass of vapour, g/mol; P_{si} - saturated vapour pressure over ice surface corresponding to the current temperature, Pa; V_{air} – volume of air in the soil, cm³; R - Universal gas constant, J/(mol·K); T – temperature; Kelvin.

The mass of ice built from the vapour passing over time period t with speed v over the cumulative air channel cross section A_{air} is calculated:

$$m_{ice} = \rho_{vapour} \cdot V_{air\ voids} = \rho_{vapour} \cdot v \cdot t \cdot A_{air} \quad (2)$$

where, m_{ice} - mass of built ice in grams; ρ_{vapour} - is taken as an average density value of the vapour densities at the start and end time point, g/cm³. The detailed calculation method was described in Sarsembayeva et al, 2022a.

3 RESULTS AND DISCUSSION

Figures 2 and 4 present temperature monitoring data in the above layers of the road structure in January 2022 and 2023. And in Figures 3 and 5 the measured moisture content of the pore space in the soil base is presented at a level of 60 cm from the surface of the road surface and below. More detailed results on monitoring temperature and humidity can be found in Sarsembayeva et al. (2022b).

The average air temperature in the winter of January 2022 was –8.12 °C, with maximum air temperatures reaching up to +6.0 °C and minimum values reaching -20.9 °C. In general, this period was characterized by higher average values compared to data from previous years. The greatest temperature fluctuations were confirmed for the upper layers of road pavement with the densest structure. There were 11 short-term transitions through 0°C in air temperature, but the layers of the road base remained in a frozen state and never crossed the 0°C, apparently

due to compensation for the heat transfer of the underlying layers with a lower temperature. Relative stabilization of the foundation soils reached a depth of -180 cm at negative temperatures ranging from -4 - 6°C. The freezing front in January 2022 occurred at a depth of -140 cm and -180 cm, as evidenced by a drop in humidity from 21 and 23%, respectively, to 17% in a frozen state.

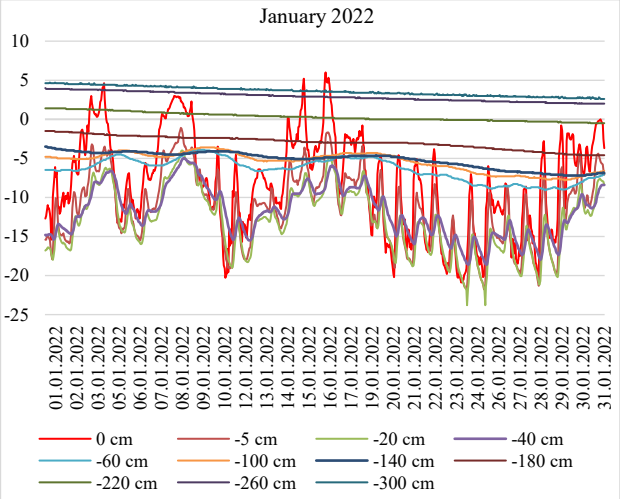

Figure 2. Temperature monitoring in January 2022.

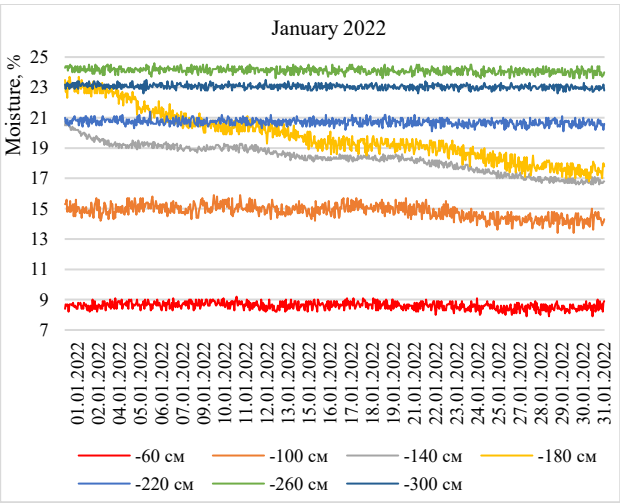

Figure 3. Monitoring of soil humidity in January 2022.

Base soil located at a depth of -60 cm consisting of light sandy clayey soil is a frost susceptible and is in a stably frozen state at a temperature of -5-8 °C. This layer acts as a moisture accumulator during the winter period, and it is there that an ice lens is formed, leading to a weakening of the bearing capacity of the road base during the spring melting period. Therefore, as an example of calculating vapor mass transfer, a soil layer at a level of -60 cm was considered. The water mass transfer in a form of vapor $1.44 \cdot 10^{-4}$ g/h per 1 dm^3 of soil. The rate of passage of vapor towards the freezing front in the soil was 0.467 m/h.

The freezing of the ground base continued for 132 days in the winter period of 2021-22 in Astana with the formation of 456.72 g of ice due to the migration of water in a gaseous state in every 1 m^3 of soil, which increases the moisture content by 40% or more comparing to the pre-freezing period and significantly reduces the bearing road capacity during the spring thaw.

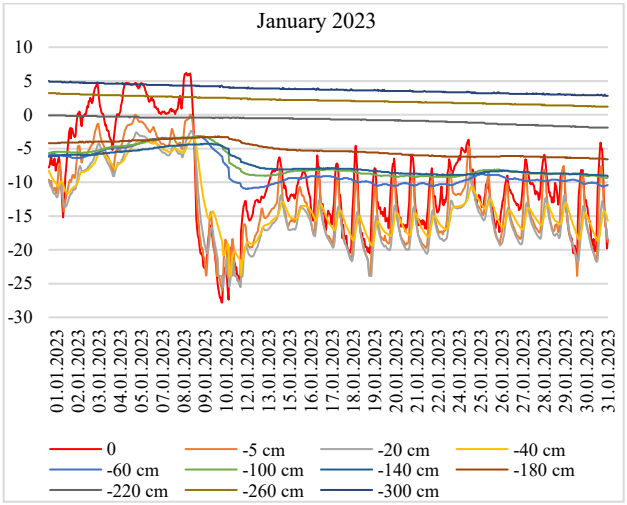

Figure 4. Temperature monitoring in January 2023.

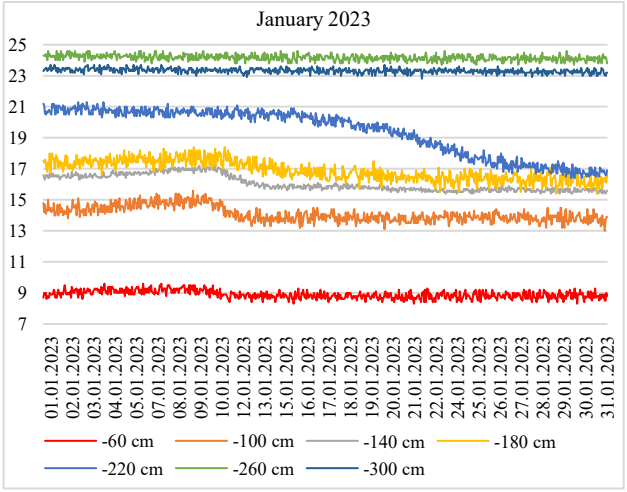

Figure 5. Monitoring of soil humidity in January 2023.

The average temperature for the month of January 2023 was -9.8 °C, with a minimum value of -27.8 °C and a maximum of +6.2 °C. The freezing front against the backdrop of a colder 2023 was deeper than in 2022, at -220 cm from the road surface. In this layer, a drop in humidity was also observed from 21% to 17% as the phase transition of water from liquid to solid state.

The duration of the frozen state of the soil under the highway was 126 days in the winter of 2022-23. The average temperature of the layer -60 cm was -9.49 °C and at a vapor transfer rate of 0.467 m/h, which led to the formation of $1.41 \cdot 10^{-4}$ g/h per 1 dm^3 of soil per day in January 2023. According to the calculations

obtained, during the period of frozen state, 426.38 g of ice per 1 m³ of base soil were accumulated in this soil layer only due to the migration and condensation of water in a gaseous state from warmer layers. An increase in humidity of up to 40% in the event of rapid melting can lead to collapse of the road structure during the spring thaw. In this area there is a restriction on cargo transportation with a large axial load, however, to prevent such risks, it is recommended to lay an additional layer of vapor barrier at a depth of -60 cm, which will also serve as thermal insulation by maintaining low humidity in the pore space of the soil.

4 CONCLUSIONS

1. Soil bases of highways, as well as layers of road pavement, remain in a stably frozen state during short-term temperature of air increases up to +6.0 °C due to sub compensation of heat (heat transfer) of the underlying layers and have a sufficient margin of safety.

2. With short-term increases in air temperature, only 25 cm from the top of the pavement are affected, which corresponds to the top layer of the base made of a hot, highly porous asphalt concrete mixture.

3. Daily temperature fluctuations in the top covering of hot dense asphalt concrete mixture average 2-5 °C with air temperature fluctuations of 6-12 °C.

4. The freezing of the layers is accompanied by a sharp drop in the humidity of the pore space from 21-23 to 11-14%, when part of the water in the gaseous state sublimates and forms a negative cryosuction pressure in these layers.

5. The base soil, located at a depth of -60 cm, consisting of light sandy clayey soil, is a frost susceptible layer and is in a stably frozen state at a temperature of -5-8 °C.

6. The water mass transfer in a form of vapour 1.41-1.44·10^{-4} g/h per 1 dm^3 of soil at with temperature fluctuations -5-8 °C based on monitoring of the highway foundations in winter period over the past 2 years. The rate of passage of vapour towards the freezing front in the soil was 0.467-0.472 m/h.

7. The freezing of the ground base continued for 126-132 days in winter periods of 2021-2023 and 2022-2023 in Astana city with the formation of 430-456 g of ice due to the accumulation of water in a gaseous state in every 1 m^3 of soil, which increased the humidity by 40% or more and significantly reduced the bearing road capacity during the spring thaw.

6. As a solution to the problem of water migration in the form of vapour, it is proposed to lay an additional layer of vapour barrier over the soil base at a depth of -60 cm.

ABSTRACT: In previous studies, the authors have demonstrated an irreversible change in void ratio with suction change of sand-bentonite mixtures after saturation, while that prior to saturation is reversible. However, it has not been clarified how the compression characteristics differ between sand-bentonite mixtures with and without pre-saturation. Therefore, in this study, one-dimensional compression tests were conducted to investigate this. As a result of the compression tests, both types of materials had nonlinear curvature of the compression line, revealing that the compression index of pre-saturated specimens increase. Furthermore, in this study a reproduction analysis of the test results using the SYS Cam - clay model which can consider the effect of soil skeleton structure was performed and good reproducibility could be obtained.

RÉSUMÉ: Dans des études antérieures, les auteurs ont démontré que le changement de l'indice de vide avec le changement de succion des mélanges sable-bentonite lorsque saturation est irréversible, tandis que celui sans saturation est réversible. Cependant, il n'a pas été clarifié en quoi les caractéristiques de compression diffèrent entre les mélanges sable-bentonite avec et sans pré-saturation. Par conséquent, dans cette étude, des tests de compression unidimensionnels ont été réalisés pour le clarifier. À la suite des tests de compression, les deux types de matériaux présentaient une courbure non linéaire de la ligne de compression, révélant que l'indice de compression de l'éprouvette pré-saturée devenait plus grand. En outre, dans cette étude, une analyse de reproduction des résultats des tests à l'aide du modèle SYS Cam-Clay qui peut prendre en compte l'effet de la structure du squelette du sol a été réalisée et il a été constaté qu'une bonne reproductibilité pouvait être obtenue.

Keywords: Sand-bentonite mixtures; suction; compression characteristic; unsaturated soil; elastoplastic.

1 INTRODUCTION

The compaction curve obtained from consolidate on tests for saturated bentonite shows nonlinear curvature and previous studies have discussed this factor. It is shown that for sand-bentonite mixtures there are two zones with different compression lines, with bentonite characteristics at low pressures and sand characteristics at high pressures (Mollins et al., 1996). Regarding the modeling of nonlinear compression lines, there are models that couple an elastoplastic model and water retention (Bosch et al., 2021), but no formulation has been proposed only an elastoplastic constitutive model behaviour. On the other hand, the area above the normal consolidation line is assumed to have be a high structure region and there are elastoplastic models that are expressed in terms of the super loading surface (Asaoka et al., 2002). This model is called SYS Cam - clay model. It is considered that the super loading surface can be used to describe the nonlinear curvature of the compression line. In this study, consolidation tests were performed using saturated and unsaturated sand-bentonite samples to determine the compaction properties. Furthermore, we reproduced the consolidation test using the SYS Cam-clay model, examined the applicability of the model, and examined its applicability to the behavior of compressed bentonite.

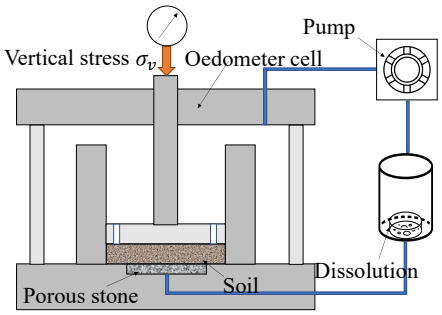

Figure 1. Schematic of the suction-controlled oedometer device using osmotic solution.

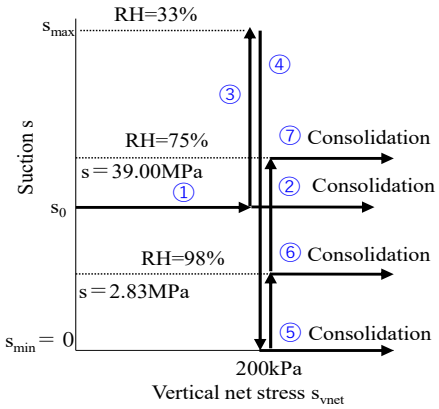

Figure 2. Test procedure.

2 MATERIAL AND EXPERIMENTAL PROCEDURES

The material used in this study is a mixture of sodium bentonite (Kunigel V1, initial water content $w_0 =$ 8.77 %) and silica sand, with a dry mass ratio of bentonite/silica sand of 7:3. The silica sand is a mixture of No. 5 and No. 7 sand in a weight ratio of 1:1. After adjusting the water content of the mixed specimens to 17 %, they were statically compacted using a high pressure hydraulic press (5 MPa) to produce specimens with a dry density of 1.600 Mg/m^3, a diameter of 60 mm and a height of 10 mm. The test apparatus is a swelling measurement device incorporating a rigid mould inside a pressure-resistant acrylic cylinder, which can also measure swelling forces and deformation by suction change under constant vertical stress loading. The test apparatus is shown in Figure 1. A porous stone is attached to the bottom plate supporting the rigid mould of the test apparatus, and the air flow in the porous stone is connected to the humidity control system through tubes connected to the bottom plate. In addition, a porous stone is attached to the pressure plate having tubular openings in contact with the upper surface of the specimen and is connected to the humidity control system through the perforations. Suction is controlled by the vapour pressure method and humidity is controlled by saturated saline solution.

Two types of specimens (with or without saturation history) were used in this study. The test procedure for this test is shown in Figure 2. First, the specimens were set in a rigid mould and subjected to a vertical stress of 200 kPa to ensure that the compressive deformation reached equilibrium. For unsaturated specimens without saturation history, the consolidation tests are carried out by increasing the vertical stress after the compression deformation has reached equilibrium. For specimens with saturation history, after the compression deformation has reached equilibrium, humidity controlled (RH 33 %) air is circulated through the porous stone at the base and the amount of shrinkage deformation resulting from increased suction is measured. After equilibrium is confirmed, the specimen is saturated by distilled water soaking through the porous stone below, while maintaining the vertical stress loading. For the specimens under saturated conditions, consolidation tests are carried out. In case of unsaturated specimens with two imposed saturation history and a specific suction that the above-mentioned compression tests were performed.

3 EXPERIMENTAL RESULTS

The compression test results for the unsaturated specimen without saturation history compared with consolidation test result for the saturated specimen are shown in Figure 3, and the consolidation test results for the saturated specimen compared with unsaturated specimen with saturation history are shown in Figure 4. For the unsaturated specimen without saturation history, the compression curve becomes straight above 2000 kPa, and for the specimen with saturation, including the saturated specimens, the compression curve becomes a straight line above 800 kPa. Therefore, the dashed line shown in Firure 3 is assumed to be the normal consolidation line in the region above this value. Comparing the unsaturated specimen without saturation history, the unsaturated specimen showed less compressibility and the saturated specimens showed greater compressibility. The slope of the NCL also increases with saturation. Therefore, the structures develop according to suction decreases. The elasto-plastic model presented by Alonso et al. (1990) also considers a model in which the compressive index decreases with decreasing suction, which is consistent with the results of this study.

For the specimens with saturation history, the compression lines tended to converge to the same

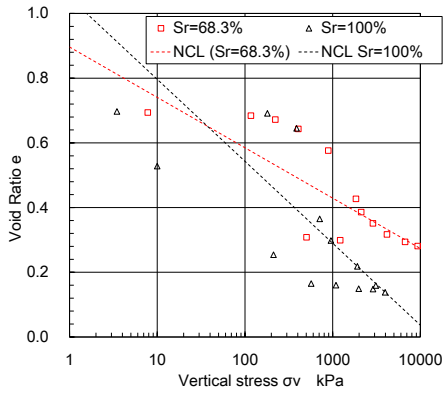

Figure 3. Compression test results of unsaturated specimen without saturation history compared with saturated specimen.

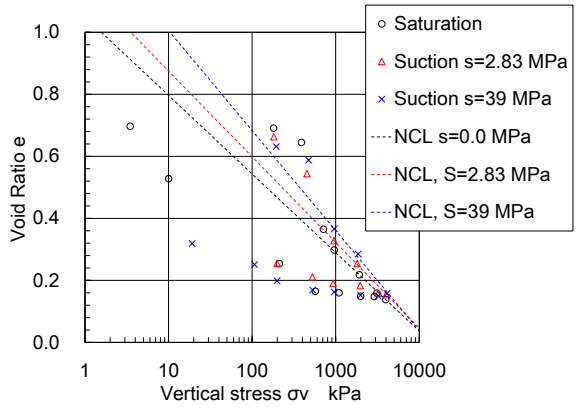

Figure 4. Consolidation results of unsaturated specimens with saturation history compared with saturated specimen.

slope regardless of suction. In terms of the structure, it tended to decrease with decreasing suction. The difference between the samples with or without saturation history is due to the evolutionary differences in the structure and the slope of the compression line under high pressure converge to same line.

4 OVERVIEW OF SYS CAM-CLAY MODEL

With regard to the behaviour of unsaturated or saturated sand-bentonite, the SYS Cam-clay model (Asaoka et al., 2002) was applied. This model was developed based on the Cam-clay model by adding the concept of "structure", "overconsolidation" and "anisotropy" as a soil skeleton structure of soils, and the changes of soil skeleton structure with ongoing plastic deformation was modeled as evolutionary rules. This model can describe the typical mechanical behavior of sand and clay using same theoretical framework, depending on the different speed of the evolutionary rules. In this study, further attempts are applied to this model to sand-bentonite mixture and confirm the effects of saturated/unsaturated condition and the saturation history on the soil skeleton structure, especially focusing on the degree of structure $1/R^*$. Here, structure refers to the bulkiness of soil (a state which can possess a larger void ratio under the same effective stress), and soil with a highly developed structure can take a stress state above the normal consolidation line. Furthermore, since structural deterioration acts as plastic compression, large volumetric compression occurs during structural deterioration. See Asaoka et al, (2002) for the detail.

5 MODELLING RESULTS

In this study, Abaqus was used as the solver and the SYS Cam-clay model was applied for analysis. The analysis method used unit elements and covered the stages from loading to the end of unloading, ignoring pore water. The parameters of the SYS Cam-clay, the initial void ratio e_0, compression index λ and swelling index κ are values obtained from experimental results. The Poisson's ratio is fixed at $\nu = 0.10$ in all cases. As a result of this study, the analysis results for the unsaturated specimen without saturation history

	Without saturation	With saturation S=0.001 MPa
λ	0.068	0.11
κ	0.01	0.04
$1/R$	150.0	105.00
$1/R_i$	7.0	5.0

Figure 5. Comparison between consolidation test results and reproducible analysis (specimen without saturation history).

	S=0.001 MPa	S=2.83 MPa	S=39.0 MPa
λ	0.11	0.12	0.14
κ	0.04	0.034	0.03
$1/R^*_0$	105.0	30.0	8.0
$1/R_0$	5.0	5.0	4.88

Figure 6. Comparison between consolidation test results and reproducible analysis (specimen with saturation history).

compared with saturated specimen is obtained as shown in Figure 5, while the analysis results for the specimens with saturation history are compared with saturated specimen in Figure 6. The analysis results show a good agreement for the compression lines. Comparing the unsaturated and saturated specimens by Figure 5, the compressive index λ is larger for the saturated specimen, meaning that the compressive index λ increases as suction decreases. Focusing on the degree of structure $1/R^*$, it can be seen that the structure is more highly developed in unsaturated specimens than in saturated specimens. In addition to a larger compression index λ, unsaturated specimens have the characteristic of producing large volumetric compression by the collapse of the structure with ongoing increase of vertical stress. Under large vertical stress condition, the structure becomes degraded, regardless of whether it is saturated or unsaturated, and possesses a stress state on the normal consolidation line. On the other hand, the compression index λ of the specimens with saturation history was almost equal. Focusing on the degree of structure $1/R^*$, it can be seen that the lower the suction, the more significantly the structure is developed. This trend is opposite to that in Figure 5, which has no prior saturation history. From a comparison between Figure 5 and Figure 6, it was found that the presence or absence of a pre-saturation history has a great influence on the subsequent compression properties, especially on the structural development associated with the suction action. The analysis results indicate that the SYS Cam-clay model can be adapted to describe the non-linear compressive behaviour of saturated and unsaturated sand-bentonite specimens with or without saturation history.

6 CONCLUSION

The compressive behaviour of saturated and unsaturated sand-bentonite mixture was obtained by using a suction-controllable consolidation test apparatus with the vapour pressure method. As a result of the study, compression behaviour with non-linearity was obtained for both saturated and unsaturated specimens, and the compression behaviour differed depending on whether the specimens are with or without saturation history. Comparing the compression behaviour of the unsaturated and saturated specimens, the compressibility tended to be small and increased with approaching a saturation. The slope of the NCL also increases due to saturation. For the specimens with saturation history, the compression lines tended to converge to the same slope regardless of suction. In terms of the structure, it decreases with decreasing suction. Furthermore, the SYS Cam-clay model was used to perform the analysis, which showed that the compression behaviour could be reproduced by using the upper load surface. The SYS Cam-cay model can be used to describe the non-linear compression behaviour of saturated and unsaturated sand-bentonite, however a state-specific evolution law is required for the parameters such as the degree of skeletal structure for the specimen with or without saturation history.

Effect of rainwater infiltration from pavement surface on base course bearing capacity

Effet de l'infiltration de l'eau de pluie à la surface de la chaussée sur la portance de la couche de base

ABSTRACT: Japan has a huge stock of road pavements, exceeding 1.2 million km. However, road pavements require constant maintenance and repair work because they gradually progress in deterioration due to various factors immediately after the operation. In particular, the deterioration of base course bearing capacity due to rainwater infiltration through cracks from the asphalt layer is said to have a significant impact on the durability of road pavements. However, it is difficult to observe and investigate the deterioration in the base course while it is in service, and there are only a few cases where detailed investigation and analysis have been attempted. This study reports the results of CBR tests on the effects of water content ratio at the time of sample preparation and rainwater infiltration time on the bearing capacity reduction behaviour of base course using two types of pavement materials.

RÉSUMÉ: Le Japon dispose d'un énorme stock de chaussées routières, dépassant 1,2 million de km. Cependant, les chaussées nécessitent des travaux d'entretien et de réparation constants car elles se détériorent progressivement sous l'effet de divers facteurs immédiatement après leur mise en service. En particulier, la détérioration de la portance de la couche de base due à l'infiltration de l'eau de pluie à travers les fissures de la couche d'asphalte est considérée comme ayant un impact significatif sur la durabilité des chaussées routières. Cependant, il est difficile d'observer et d'étudier la détérioration de la couche de base pendant qu'elle est en service, et il n'y a que quelques cas où une étude et une analyse détaillées ont été tentées. Cette étude rapporte les résultats d'essais CBR sur les effets du rapport de la teneur en eau au moment de la préparation de l'échantillon et du temps d'infiltration de l'eau de pluie sur le comportement de réduction de la capacité portante de la couche de base en utilisant deux types de matériaux de chaussée. Je suggère d'inclure des conclusions plus détaillées si possible.

Keywords: Bearing capacity; base course; rainwater infiltration; CBR tests.

1 INTRODUCTION

Japan's road pavement stock exceeds 1.2 million km. In the future, it will be important to establish maintenance management methods for road pavements. However, in recent years, Japan has been facing a declining birth-rate and an aging population, and road maintenance and management costs are facing a very difficult situation. In the future, road managers will be required to perform maintenance management with high economic and technical effectiveness. Road pavements are structures that gradually deteriorate by the passage of years in service. In particular, the loss of base course bearing capacity due to rainwater infiltration through cracks in the asphalt layer is known to significantly affect the durability of road pavements [1].

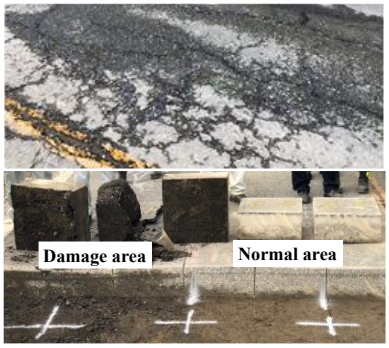

Figure 1. Early deterioration of asphalt pavement.

The process of base course bearing capacity reduction is as follows: (1) cracks occur in the asphalt layer due to age-related deterioration (Figure 1), (2) rainwater infiltrates through the cracks, (3) the fine

grains in the base course are released by the pumping phenomenon when large traffic loads act on the pavement under rainwater infiltration, and (4) Pavement bearing capacity decreases due to the change in the pore structure caused by the change in the grain size of the base course material and rainwater infiltration (Figure 1). This decrease of base course bearing capacity is a major factor in the early deterioration of road pavements. When deterioration progresses rapidly, the base course needs to be replaced. However, replacement of the base course material is rarely implemented due to traffic obstructions caused by construction regulations, construction period problems, and high repair costs. In the future, appropriate maintenance and repair technology will be required before premature deterioration of pavements progresses. However, it is difficult to understand the details of base course damage of pavements with early-stage deterioration, and very few research have attempted to investigate and analyse the damage. The water content ratio of the geomaterial at the time of base course material placement and density control after compaction are considered to have a significant effect on the base course bearing capacity [2]. Therefore, it is considered effective to obtain an experimental understanding of the mechanism of base course deterioration due to rainwater infiltration to investigate the early stage of pavement deterioration. This study reports the results of CBR tests on the effects of water content ratio at the time of sample preparation and rainwater infiltration time on the bearing capacity reduction behaviour of base course using two types of pavement materials.

2 TEST PROCEDURE

2.1 Experimental samples

Two types of pavement materials were used in this study: M-25, which was mixed and prepared from No. 4-7 crushed stone, sand, and stone dust, and RM-25, which was recycled concrete material purchased from a construction materials company. Table 1 shows the physical properties of the two materials. Figure 2 shows the particle size distribution curves of the samples before and after compaction. Figure 3 shows the compaction curve. Particularly, for RM25, particle crushing by compaction occurred, indicating that it was affected by the water content ratio. This is considered to be due to the effect of the cement content attached to the aggregate of RM-25, which was crushed by compaction.

2.2 Testing conditions

The E-b method was used in accordance with the Soil Compaction Test Method by compacting (JIS A 1210). Here, the E-b method for soil compaction is used a meld inner diameter of 15 cm (volume: 2209 cm3) and a rammer of 4.5 kg dropped from a height of 45 cm without repeated use of a soil sample with adjusted water content. In addition, the number of times of compaction was reduced to 82 times for each sample at the optimum water content ratio in order to achieve a uniform dry density of Dc=99% for each specimen. In the case of RM-25, Dc=99% was set to 1.70 x 0.99 = 1.68 Mg/m^3 at about 3% before and after the optimum water content ratio in consideration of the implementation of the project. In the same way, M-25 was set to 2.28 × 0.99 = 2.26 Mg/m^3, where Dc=99%. Table 2 shows the experimental conditions. The water content ratio of M-25 was set to 1.6 (dry side), 2.8 (optimum water content), and 3.6 (wet side) % at Dc=99%. In the case of RM-25, three different water content ratios w = 9.9 (dry side), 13.5 (optimum), and 17.4 (wet side) % at Dc=99% were used in the study.

In order to investigate the change in base course bearing capacity due to rainwater infiltration, water was sprayed from the top of the specimen after the specimen was prepared. The amount of water sprayed was set so that the water content ratio of each specimen increased by w=4.0%.

The CBR penetration tests were conducted immediately after all the sprayed water had infiltrated from the top of the specimen (t=0h) and after 6 hours(t=6h) and 24 hours (t=24h). Table 3 shows the time required to complete infiltration under each condition. The CBR penetration test was conducted after removing the water from the top of the specimen because the water did not infiltrate even after 96h in the wet side of RM-25 with 150 ml of water sprayed.

Table 1. Physical properties of base course materials.

sample	M-25	RM-25
Appearance		
Soil particle density ρ_s(Mg/m^3)	3.056	2.642
Uniformity coefficient U_c	35.10	58.37
Coefficient of curvature U_c'	2.81	1.33
Abrasion loss R(%)	14.30	30.70
Water absorption (%)	0.40	9.02

Sample	Specific water content w(%)	Compacted times	Amount of water sprinkled	Dry density ρ_d(Mg/m^3)	Standby time
M-25	1.6 (Dry) 2.8 (Optimum) 3.6 (Wet)	92times (E-b) 82times (Optimum)	0 ml 200 ml	2.26 (Dc=99%)	0 h 6 h 24 h
RM-25	9.9 (Dry) 13.5 (Optimum) 17.4 (Wet)	92times (E-b) 82times (Optimum)	0 ml 150 ml	1.68 (Dc=99%)	

Table 3. Time to the end of infiltration.

Specific water content	Sample (Amount of water sprinkled)	
	M-25 (200ml)	RM-25 (150ml)
Dry	3min	40min
Optimum	3min	1.5h
Wet	3min	96h

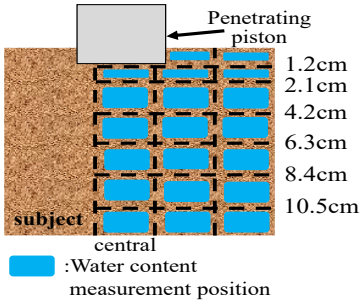

Figure 4. Location of water content measurement.

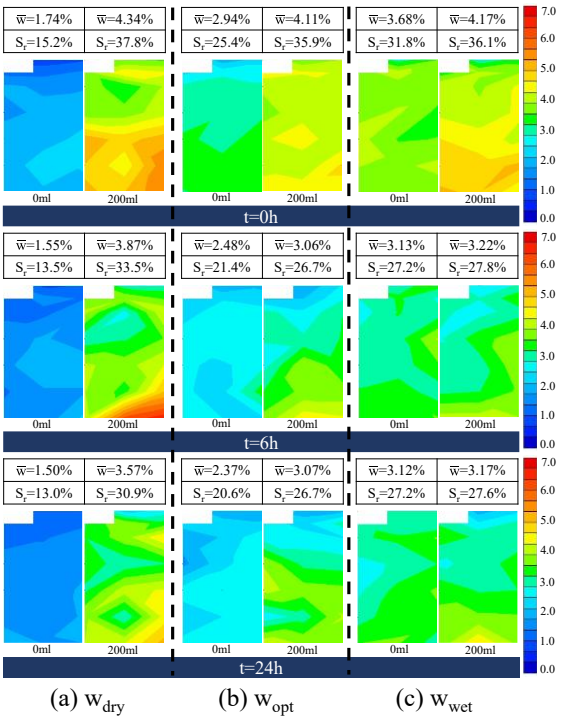
In this study, water content was measured at the locations shown in Figure 4 immediately after the CBR penetration test in order to evaluate the behaviour of bearing capacity reduction due to rainwater infiltration from the state of pore water inside the specimens. Measurements were taken at a total of 20 locations, 7 in the vertical direction and 3 in the horizontal direction, without the penetration position.

3 RESULTS AND DISCUSSIONS

Figures 5 and 6 show the distribution of water content inside the specimens after the CBR test for M-25 and RM-25 at (a) the dry side, (b) the optimum water content, and (c) the wet side, for each elapsed time after water sprayed. The average water content and saturation of the entire specimen are also shown. Figure 7 and Figure 8 show the CBR test results for M-25 and RM-25. Here, the results of experiments conducted by the authors using Decomposed granite soil under the same conditions are also shown in each figure.

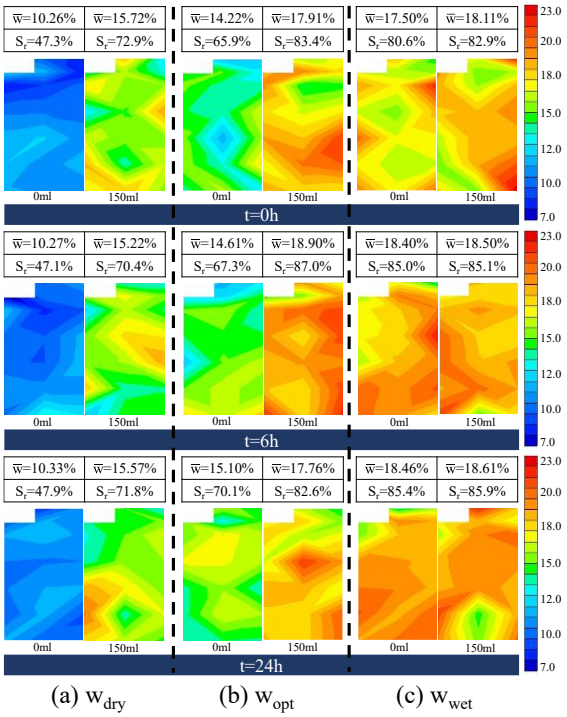
3.1 Dry side

Just after water sprayed, both specimens showed a significant decrease in bearing capacity with water sprayed, similar to the results for Decomposed granite soil. This is considered to be due to the decrease in suction caused by the increase in saturation due to water infiltration. As time elapsed after water sprayed,



(a) w_{dry} (b) w_{opt} (c) w_{wet}

Figure 5. Distribution of water content in the specimen (M-25).



(a) w_{dry} (b) w_{opt} (c) w_{wet}

Figure 6. Distribution of water content in the specimen (RM-25).

the bearing capacity of M-25 increases compared to that of the bearing capacity just after infiltration (Figure 7(a)), similar to that of Decomposed granite soil. On the other hand, the bearing capacity of RM-25 decrease (Figure 8(a)). This is caused by the good permeability of M-25 and the decrease in water content in the upper part of the specimen with elapsed time, and the high water absorption of aggregate in RM-25 and the high water content maintained in the upper part of the specimen.

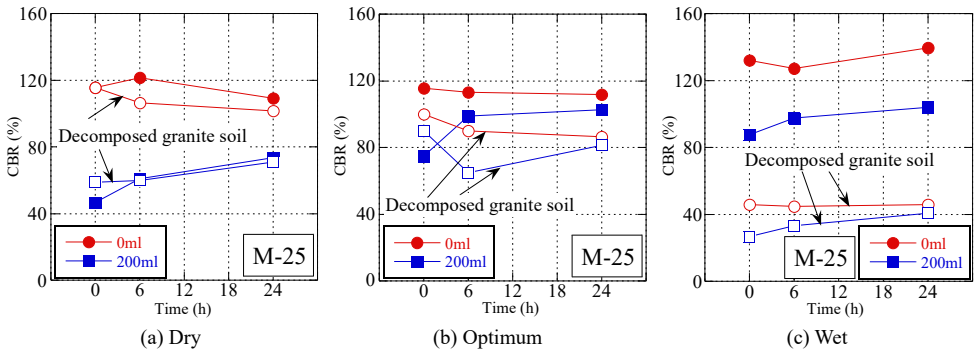
3.2 Optimum water content ratio

In both samples, the rate of decrease in bearing capacity due to water sprayed is smaller than that of the dry side. In addition, the bearing capacity of M-25 increased with the elapsed time immediately after water infiltration and approached the bearing capacity without water sprayed (Figure 7(b)), as is the case for the dry side. This is due to the assumption that the water content in the specimen approached the optimum water content with the elapsed time, as shown in the water content distribution in Figure 5(b), and that the specimen was not easily affected by the water flowing down the specimen. In comparison, the bearing capacity of RM-25 decreased after 6 hours and did not change thereafter (Figure-8(b)), as was observed for the dry side. This is considered to be due to the fact that water runoff does not occur after 6 hours and the upper part of the specimen was kept at a high water content ratio due to water absorption by the aggregate.

3.3 Wet side

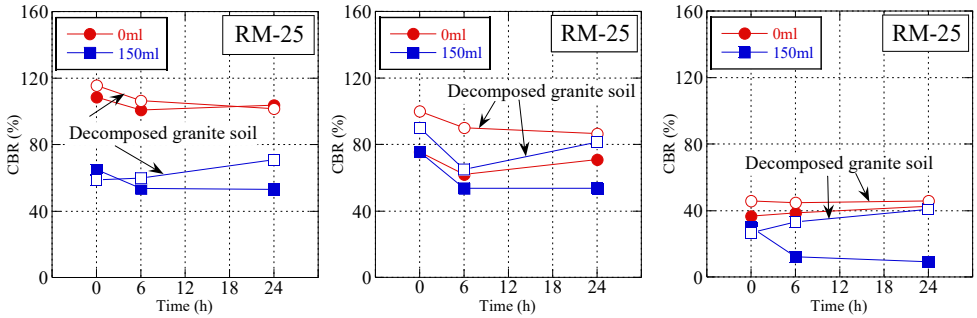
M-25 shows high bearing capacity as well as other initial water content ratios, and the effect of water sprayed on the bearing capacity is similar to that of the optimum water content ratio. With the elapsed time, the bearing capacity gradually increases and recovers compared to that immediately after water sprayed (Figure-7(c)). This is caused by the distribution of the water content ratio returning to almost the same level as that before water sprayed over time, in spite of the wetted side.

On the other hand, the bearing capacity of RM-25 before water sprayed is the smallest among the other water content ratios, showing the same level of bearing water content ratios, showing the same level of bearing capacity as decomposed granite soil. This suggests that RM-25 was crushed by compaction as shown in Figure-2, causing a significant decrease in bearing capacity due to the increased water retention of the aggregate. This effect also caused a slight decrease in bearing capacity after 6 hours, after which no change was observed (Figure-8(c)). This is considered to be due to the gradually infiltrating water sprayed into the specimen, which increased the degree of saturation.



(a) Dry (b) Optimum (c) Wet

Figure 7. CBR test results (M-25).



(a) Dry (b) Optimum (c) Wet

Figure 8. CBR test results (RM-25).

4 CONCLUSIONS

1) The water content of the base course at compaction has a significant effect on the strength reduction after rainwater infiltration.
2) The change of water content in the base course with the passage of time after rainwater infiltration has a significant effect on the bearing capacity behavior of the base course.

ABSTRACT: The increasing development of renewable energy (e.g. on and offshore wind) has increased the demand on existing electricity transmission networks in the UK. However, the remoteness of the transmission network, particularly in Scotland, makes upgrade and renewal, both economically and environmentally challenging, with often highly restrictive access constraints. Steel grillages are an alternative non-concrete foundation that can be loaded immediately post-backfill and transported to remote locations using low-ground pressure vehicles or helicopters. This paper investigates the optimisation of steel grillages for overhead line foundations such that the uplift load-displacement response is comparable to solid foundations (i.e. a concrete pad). Initial 1g uplift tests have shown that the optimal grille-spacing-to-width ratio (s/w) for a comparable ultimate uplift capacity to a solid plate lies within $1 < s/w < 2$.

RÉSUMÉ: Le développement croissant des énergies renouvelables (par exemple, les éoliennes terrestres et en mer) a augmenté la demande sur les réseaux de transmission d'électricité existants au Royaume-Uni. Cependant, l'éloignement du réseau de transmission, en particulier en Écosse, rend les travaux de modernisation et de renouvellement à la fois économiquement et environnementalement difficiles, avec des contraintes d'accès souvent très restrictives. Les grillages en acier sont une alternative aux fondations en béton qui peuvent être chargées immédiatement après le remblai et transportées vers des lieux reculés en utilisant des véhicules à basse pression au sol ou des hélicoptères. Cet article examine l'optimisation des grillages en acier pour les fondations de lignes aériennes de manière à ce que la réponse au déplacement sous charge de soulèvement soit comparable à celle des fondations solides (c'est-à-dire une dalle en béton). Les premiers tests de soulèvement à 1g ont montré que le rapport optimal entre l'espacement des grilles et la largeur (s/w) pour une capacité ultime de soulèvement comparable à une plaque solide se situe dans l'intervalle $1 < s/w < 2$.

Keywords: Grillage foundations; uplift; physical modelling; transmission infrastructure.

1 INTRODUCTION

The widespread and increasing development of both on- and offshore renewable energy in Scotland requires connection to the electrical transmission network. However, the existing network has insufficient capacity to meet future developments and new localised transmission infrastructure or upgrades are required. The current foundation design practice for new (or upgraded) overhead lines (OHLs) adopts material-heavy concrete spread foundations (e.g. concrete pads or pyramids). While these solutions have shown to be effective, they are not always practical when employed in remote and challenging terrain where limited or no access exists and often require the economically and environmentally costly operation of haul roads. Thus, recent interest in non-concrete alternatives has grown, such as those that can be heliborne or transported and installed using low-ground pressure vehicles, speeding up construction time and negating concrete's 28-day curing time before backfilling and loading. One alternative non-concrete solution is steel grillages, consisting of multiple standard steel sections (e.g. I-beams and angle sections) bolted together (Papailiou, 2017). Steel grillage foundations have been utilised extensively for steel lattice towers but fell out of fashion in the 1980s, coinciding with the

development of drilled concrete cast in-situ piles (Kulhawy *et al.*, 1983). Unfortunately, this led to a loss of knowledge and experience of these foundation types in the UK, specifically concerning their required configurations for resisting uplift forces. This paper investigates the optimum grille spacing of grillages subjected to uplift in granular soils through a series of scaled 1g uplift tests to address this knowledge gap.

1.1 Current UK design approach

The frustum method is a commonly adopted approach for determining the uplift capacity of shallow foundations for OHLs (National Grid, 2018). However, it is unclear whether the frustum method applies to grillages. Further guidance exists in BS EN 50341-1 (2012), stating that the net area of the grillage may be assumed, given that the spacing between grilles (s) does not exceed ⅓ the width (w) of the grilles and thorough backfill compaction is achieved. In addition to the uplift capacity, National Grid (2018) sets a serviceability criteria of 25 mm maximum vertical displacement.

The method assumes the resistance (Q_{FM}) is the sum of the weight of the foundation (W_f) and the weight of soil above the foundation confined within an inverted frustum (W_s) extending upwards at angle θ from the base of the foundation (Eq. 1-3):

$$Q_{FM} = W_f + W_s \quad (1)$$

$$W_s = \tfrac{1}{3}H\gamma(B^2 + B \cdot B_s + B_s^2) \quad (2)$$

$$B_s = \mathrm{B} + 2\mathrm{H}\tan\theta \quad (3)$$

where H is the embedment depth (m), B is the foundation width (m), and γ is the soil unit weight (kN/m^3). The frustum angle θ is dependent on the raw SPT N-value for granular soils, of, typically 15° for $10 \leq N < 20$ and 25° for $20 < N$.

1.2 Alternative uplift design approach

Alternative approaches for determining the uplift capacity of shallow OHL foundations have been investigated by Davidson and Brown (2021), showing that Giampa et al. (2019) best estimated the uplift capacity in granular soils. The method assumes the failure mechanism develops as an uplifted wedge at the dilation angle (ψ), mobilising shear resistance along the failure surface at the four triangular wedges along the perimeter (F_2) and conical wedges at the corners (F_3), and resistance from the weight of confined soil directly above the foundation (W_1), four triangular wedges along the perimeter (W_2), and conical wedges at the corners (W_3) (Eq. 4-9):

$$Q_G = F_2 + F_3 + W_1 + W_2 + W_3 \quad (4)$$

$$F_2 = \tfrac{1}{2}\gamma H^2 p\left(\tan\phi_{pk} - \tan\psi\right)\left[\left(\tfrac{1+k_0}{2}\right) - \tfrac{(1-k_0)\cos 2\psi}{2}\right] \quad (5)$$

$$F_3 = \tfrac{1}{3}\pi\gamma H^3\left(\tan\phi_{pk} - \tan\psi\right)\cos\left(\phi_{pk} - \psi\right) \quad (6)$$

$$W_1 = \gamma HA \quad (7)$$

$$W_2 = \tfrac{1}{2}\gamma H^2 p\tan\psi \quad (8)$$

$$W_3 = \tfrac{1}{3}\pi\gamma H^3\tan\psi \quad (9)$$

where A and p are the foundation's area (m^3) and perimeter (m^2), ϕ_{pk} is the peak friction angle, and K_0 is the lateral earth pressure coefficient (at rest).

2 PHYSICAL TESTING

The 1-g testing regime consisted of developing a reduced (1:10) plane-strain model grillage to investigate the influence of the grille-to-grille spacing ratio (s/w) where s is the spacing between grilles and w is the grille width, as illustrated in Figure 1.

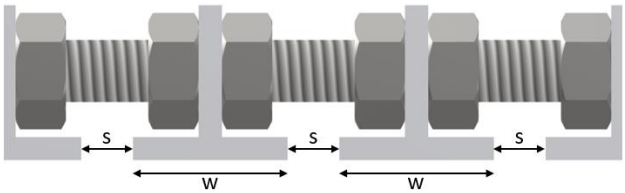

Figure 1. Illustration of grille-to-grille spacing ratio of (1:10) model grillage (s/w = ⅓ for the model shown).

2.1 Model setup

The grillage models developed allowed for multiple grille spacing (s/w = 1/2, 1/3, 1, 2, 5, and solid) while keeping the overall width of the foundation constant. The grilles were modelled using T-sections to allow for consistent compaction of sand between the grilles during sand bed preparation. The grilles were connected via three M8 threaded bars running perpendicular to an attached vertical shaft (stub connection). The positioning and spacing of individual grilles were controlled using M8 nuts placed on either side of the web. The dimensions and schematic of the model grillage are given in Table 1 and Figure 2, respectively.

The scale of the T-section, and thus the grillage, was chosen based upon the D_{50} particle size (0.14

mm (Lauder, 2010)) so that the particle scaling law requiring an opening between two embedded grilles to have a spacing ≤ 50 x D_{50}, (Garnier *et al.*, 2007), matching the smallest grille spacing (7mm). The grille length matched the box width to create plane-strain conditions for further investigation into the mechanistic behaviour.

Table 1. Grillage dimensions at model and prototype scale.

Grillage Property	Dimension	
	Model (mm)	Prototype (m)
Width, $\boldsymbol{B}$	260	2.6
Length, $\boldsymbol{L}$	440	4.4
Embedment, $\boldsymbol{H}$	260	2.6
Grille width, $\boldsymbol{w}$	20	0.2
Grille height, $\boldsymbol{h_g}$	20	0.2
Grille thickness, $\boldsymbol{t_g}$	3	0.03

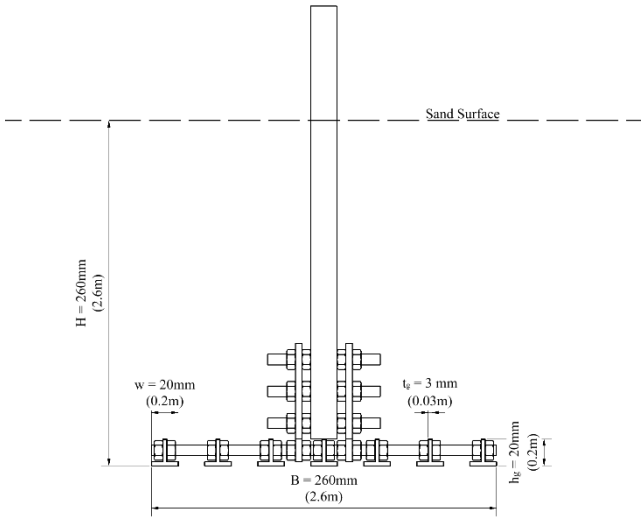

Figure 2. Dimension of assembled model grillage (assumed prototype dimensions shown in brackets).

2.2 Testing programme

The sand used for testing was dry HST95, which has been extensively characterised (Lauder, 2010). The relative densities investigated in this research are medium-dense (D_r = 42%) and dense (D_r = 82%). The properties relevant to determining the analytical capacity are given in Table 2.

Table 2. HST95 sand properties required for analytical comparison (Lauder, 2010).

Property	Relative Density, D_r	
	42%	82%
Dry unit weight, $\boldsymbol{\gamma}$ (kN/m^3)	15.8	17
Peak friction angle, $\boldsymbol{\phi_{pk}}$ (°)	37.4	45.4
Dilation angle, $\boldsymbol{\psi}$ (°)	6.5	16.9
Earth-pressure coefficient, $\mathbf{K_0}$	0.47	

The soil boxes (internal dimensions 900 x 448 x 448 mm) were prepared through pluviating sand to a bed thickness of h = 140 mm, the grillage placed at the centre of the box and sand pluviated above (i.e. wished in place) to a depth H = 260 mm (H/B = 1).

The uplift tests were conducted using an Instron-5985 UTM (Redhill 3 software) attached with a 10 kN load cell fitted with ¾ inch (19.05 mm) wedge action tensile grips fastened to the grillage stub. Uplift was tested under displacement-controlled loading at 10 mm/min, terminating after 50 mm of displacement at a logging rate of 0.1 Hz.

3 RESULTS AND DISCUSSION

3.1 Load-displacement response

Load-displacement responses at prototype scale (scale factor N = 10) are presented in Figure 3 and Figure 4, for D_r = 42% and 82%, respectively. The uplift resistances are the resistance mobilised from the soil shear and weight (i.e., excluding the grillage self-weight). At the prototype scale (i.e. Force x N^3 and displacement x N), the ultimate uplift resistance mobilised from a solid plate for D_r = 42% and 82% is 828 kN and 951 kN, respectively. Comparable uplift resistances are observed for s/w ratios of ⅓-to-1 (medium-dense) and ⅓-to-2 (dense).

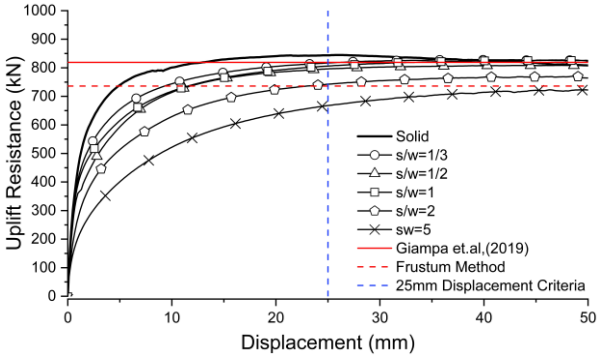

Figure 3. Uplift load-displacement response of grillages in medium-dense sand D_r = 42% at prototype scale.

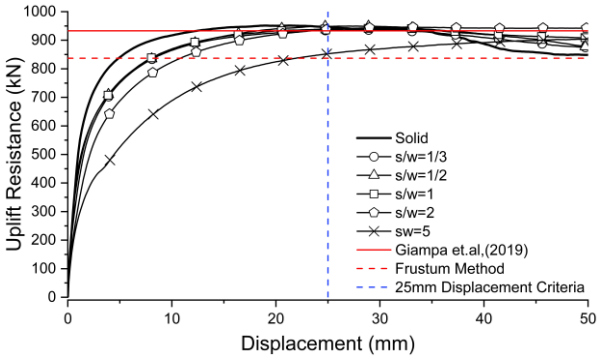

Figure 4. Uplift load-displacement response of grillages in dense sand D_r = 82% at prototype scale.

Whilst the peak uplift resistance is comparable to a solid plate (s/w = 0), the load-displacement responses reveal a reduction in stiffness with increasing s/w, as Danziger et al. (1989) observed due to soil flowthrough between the grilles. However, the reduction in stiffness is significant when assessing the design capacity against the permissible displacement of OHL foundations of 25 mm (denoted as the blue dashed line). The reduction in stiffness with increasing spacing ratio of these tests is likely suppressed by increased dilation experienced at 1g and the influence of the plain strain conditions.

The influence of grille spacing is better illustrated in Figure 5, which shows the normalised breakout factor, F_q^* = $(Q/\gamma HA)$, using a design load (Q) derived from the tangent intercept method. However, significant reductions in capacity are noted for larger s/w ratios, with an optimum spacing of s/w < 1 for D_r = 42% and s/w < 2 for D_r = 82%, in agreement with the findings of Martin (1975), who observed an optimum s/w = 1.75.

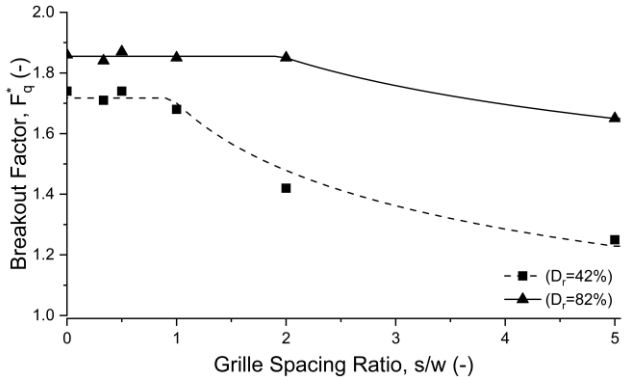

Figure 5. Influence of grille-to-grille spacing ratio (s/w) on breakout factor F_q^* for medium-dense and dense sands.

3.2 Comparison to analytical solutions

Comparing the uplift capacity to the analytical solutions (broken down into the plane-strain components, i.e. not including the wedge components along the Perspex interface), the method proposed by Giampa et al. (2019) (denoted by the solid red line in Figure 3 and Figure 4) provides a good estimate of 819 kN (-3%) and 933 kN (-2%) for D_r = 42% and 82% respectively, whereas the Frustum method (denoted by the dashed red line) underestimates the capacity, with predicted capacities of 736 kN (-13%) and 837 kN (-12%), respectively. Demonstrating that uplift capacity can be determined using existing analytical solutions assuming the net area of the grillage for spacing ratios of $1 \leq s/w < 2$. This is a significantly wider range of operation than the s/w = ⅓ specified in BS EN 50341-1 (2012), i.e. a potential for significant material savings in grillage adoption.

4 CONCLUSION

The results suggest that the optimum grille-to-width ratio in terms of uplift capacity (acting like a solid) lies between $1 \leq s/w < 2$ (density dependant), which is a wider operational range than the s/w = ⅓ proposed in BS EN 50341-1 (2012). However, an alternative design criterion may be required to consider the reduction of stiffness with increasing s/w. As these tests were undertaken at 1g, further investigation through scaled centrifuge modelling is needed to verify the observed reduction in performance in terms of stiffness.

Further investigation will focus on a series of centrifuge tests that first validate the observations of the influence of grille-to-grille spacing on both capacity and stiffness, scaling of uplift displacement, and influence of particle size before investigating means of enhancing the uplift load-displacement response (in terms of stiffness) through geogrid reinforcement and backfill compaction.

The SOURCE project: Quantifying and reducing the uncertainties associated with in situ stiffness measurements

Le projet SOURCE: Quantifier et réduire les incertitudes associées aux mesures de rigidité in situ

ABSTRACT: Offshore wind turbine foundations account for a significant portion of a wind farm's capital cost, and design optimisation is becoming increasingly important. While the soil or rock in situ shear stiffness is a vital input parameter in several foundation design methods, the reliability of current in situ stiffness measurements and interpretation techniques is known to be variable. The SOURCE (Improved In situ Stiffness Measurement for Offshore Wind Foundation Design Considering Uncertainty Repeatability and Common Sources of Error) project is underway to quantify and reduce uncertainty in soil/rock in situ stiffness measurements and improve the predictive capability of offshore foundation design methods. The project involves multi-method geophysical and in situ field testing at three onshore sites, each having distinct ground conditions representative of offshore sites. The in situ testing is supported by advanced laboratory testing on high-quality samples. This paper reviews typical challenges and presents preliminary insights from the carefully controlled experiments, which aim to identify inter and intra-method variability in estimating the small strain in situ stiffness.

RÉSUMÉ: Les fondations des éoliennes offshore représentent une part importante du coût d'investissement d'un parc éolien, et l'optimisation de la conception devient de plus en plus importante. Bien que la rigidité au cisaillement in situ du sol ou de la roche soit un paramètre d'entrée essentiel dans plusieurs méthodes de conception de fondations, la fiabilité des techniques actuelles de mesure et d'interprétation de la rigidité in situ s'avère très variable. Le projet SOURCE (Amélioration de la mesure de rigidité in situ pour la conception des fondations d'éoliennes offshore en tenant compte de l'incertitude, de la reproductibilité et des sources d'erreur communes) est en cours pour quantifier et réduire l'incertitude dans les mesures de rigidité in situ du sol/roche et améliorer la capacité prédictive des méthodes de conception de fondations OWT. Le projet implique des essais géophysiques et in situ multi-méthodes sur trois sites terrestres, chacun présentant des conditions de sol distinctes représentatives des sites offshore. Les tests in situ sont soutenus par des tests avancés en laboratoire sur des échantillons de haute qualité. Cet article passe en revue les défis typiques et présente des informations préliminaires issues d'expériences soigneusement contrôlées, qui visent à identifier la variabilité inter et intra-méthode dans l'estimation de la rigidité in situ des petites déformations.

Keywords: In situ stiffness; seismic tests; shear wave velocity.

1 INTRODUCTION

Recent research has led to the development of new offshore wind turbine (OWT) foundation design procedures and frameworks informed by numerical modelling and field testing (Byrne et al., 2017, Jardine et al., 2023). While these advancements have led to important innovations, there remains significant uncertainty in the definition of input parameters including the small strain in situ stiffness (G_{max}). The latter is an important input into soil constitutive models for finite element analysis and simplified 1D analysis frameworks (see e.g. Byrne et al., 2020, Zdravković et al., 2020). The stiffness of the soil also influences the eigen-frequency of the turbine-tower-foundation system, which must lie outside key excitation frequencies to avoid resonance (Arany et al., 2016). As OWT foundations substantially impact the cost of wind farms, accurate measurement of G_{max} at an early stage is crucial for optimisation. The in situ stiffness is typically characterised by measurement of shear wave velocity, V_s, in seismic tests. Errors in the measurement of V_s are amplified in the subsequent calculation of G_{max}, due to the squaring of V_s in its formula ($G_{max} = \rho V_s^2$; where ρ is bulk density of soil).

Existing field and laboratory methods can exhibit significant test method dependency, data scatter, and poor correlation with laboratory measurements. The challenges in data acquisition and interpretation include e.g. source arrangements, geophone arrays and interval distance, selection of arrival time and ray path

assumptions (Parasie et al., 2022). Sampling disturbance, material anisotropy, fractures and inclusions also play a role and can lead to stark differences between laboratory and in situ stiffness (Taborda et al., 2019). Masters et al. (2019) reviewed the most common methods conducted offshore including field P-S suspension logging (PSL), seismic cone penetration testing (SCPT) and laboratory resonant column (RC) and bender element (BE) testing. Significant scatter was seen in the results. Figure 1 plots another example from a sand profile in the Ten noorden van de Waddeneilanden (TNW) wind farm zone (RVO, 2023) that highlights the difficulties in establishing consistent profiles and integrating data sets. Difficulties in accurate measurement of V_s are not unique to offshore projects. Liu et al. (2017) found variations in in situ stiffness from SCPTs of up to 50% from adjacent areas at a dense marine sand site, while large variations of up to 2GPa were observed in SCPT tests at a relatively homogenous chalk site (Vinck et al., 2022).

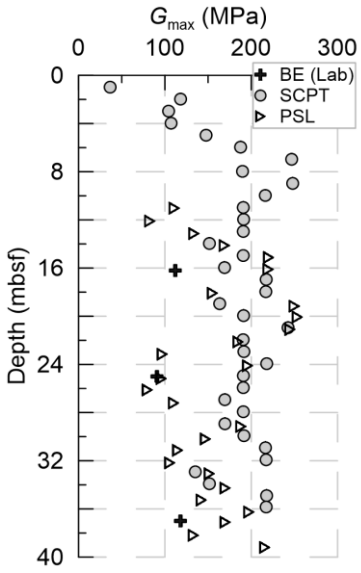

Figure 1. Example of divergence between methods to determine G_{max}: example from TNW-016-BH-CPT.

1.1 The SOURCE Project

The SOURCE (Improved insitu **S**tiffness measurements for **O**ffshore foundation design considering **U**ncertainty, **R**epeatability and **C**ommon sources of **E**rror) is a collaborative research project that aims to reduce the uncertainty associated with soil and rock in situ stiffness measurements and minimise the impact on the predictive capability of offshore foundation design methods. Comprehensive multi-method geophysical, in situ and laboratory testing is planned at three onshore test sites, in order to create benchmark datasets and develop robust, standardised guidelines for high-quality stiffness measurements. Each site involves drilling and sampling along with invasive methods including SCPTs, PSL, Down-hole (DH) and cross-hole (CH) borehole geophysics and pressuremeter tests (PMT). The field testing is supported by the extensive laboratory research undertaken at the University of Glasgow. The criteria for site selection are set to (i) be representative of typical profiles commonly encountered offshore and (ii) include sites where soil characterisation poses significant challenges. Site 1 was located at a disused chalk quarry in Kent close to the previous field-testing summarised by Jardine et al. (2023). Site 2 employed a dense sand site in Northern Germany while Site 3 will target over-consolidated clay ground conditions onshore UK.

2 IN SITU SHEAR STIFFNESS MEASUREMENTS

The in situ testing programme integrates various invasive and non-invasive methods each with unique capabilities and limitations; invasive seismic methods considered are shown in Figure 2. The SCPT and DH both work on the same principle, where a surface seismic source (a manually operated sledgehammer dropped onto a plate) generates seismic waves. These waves travel through the soil strata and are recorded by uni or multi-component sensors placed at depth. For the measurement of true interval velocity, a relative time difference between the received signals from dual receivers is calculated. Multiple shots are recorded at a particular depth to improve the signal-to-noise ratio.

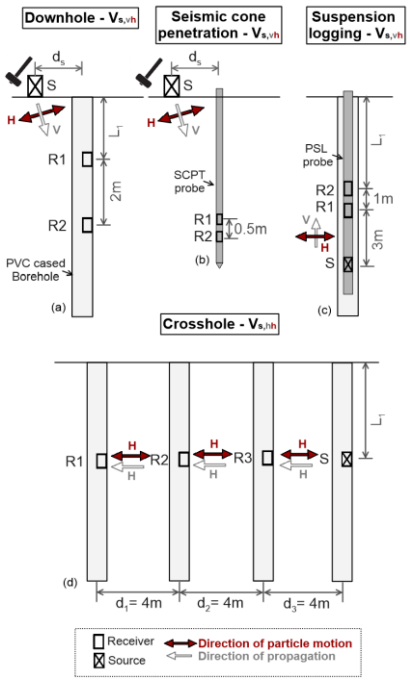

Figure 2. Invasive seismic methods considered in this study.

Cross-hole tests (CH) are conducted by placing a seismic source in one borehole and receiver(s) in another borehole(s). The PS Logging (PSL) probe consists of a seismic source together with hydrophone and geophone receivers within a single probe. The PSL system measures the compression wave velocity and formation shear-wave velocities of a portion of the soil or rock column around the borehole. PMTs determine stiffness and strength by measuring the pressure and displacement of an expanding membrane installed by self boring, placement in pre-bored holes or by pushing behind a CPT. In the laboratory, RC/BE and low-amplitude cyclic triaxial tests are performed on the high-quality samples.

3 KEY CHALLENGES

Measurements of V_s are known to be sensitive to the test procedure adopted including: (i) geophone arrays and spacing; (ii) source type, coupling and location (Koreta et al., 2022) and; (iii) testing mode e.g. DH/SCPT versus PSL, drilling versus seabed SCPT data acquisition Gibbs et al. (2018). The importance of targeting sampling frequency for a given receiver spacing is illustrated in Figure 3 for a V_s value of 450m/s (Rice, 1984). As the receiver spacing increases, the sampling frequency required to achieve a given level of accuracy in elapsed travel time, Δt, decreases which should be carefully considered when planning testing programmes.

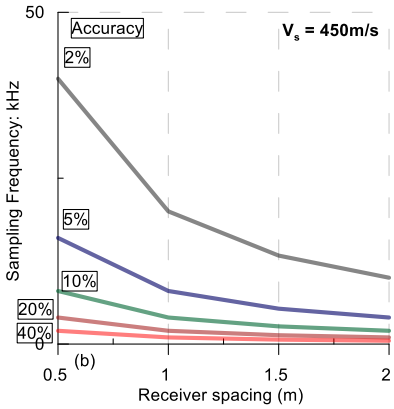

Figure 3. Relationship between sampling frequency, receiver spacing and accuracy in travel time estimation.

A comprehensive review of interpretation methods for downhole testing was provided by Stolte and Cox (2019). Classic approaches such as those that involve picking characteristic points on wave arrivals at sensors at different depths are prone to subjectivity and resist automation. The cross-correlation (CC) method (Campanella and Stewart, 1991) is often preferred where data quality allows, since it correlates information from the full signal and is less subjective to interpret. The method involves sliding one of the signals over a consecutive other signal recorded at a different depth and computing the similarity between the two signals at each time shift; CC was used for the majority of SOURCE interpretation. Once travel times have been evaluated, the analyst must make an assumption on ray path; inclined straight ray paths are typically assumed – with ray tracing based on Snell's law utilised for shallow layers and high stiffness contrasts.

Residual uncertainty in V_s due to poor data quality or ambiguous interpretation is rarely communicated to the end user of the data (Stolte and Cox 2019). There is no consensus yet on a consistent method to quantify epistemic or aleatory uncertainty. While the cross-correlation coefficient (CCC) is often used to quantify data quality, it is known to be unreliable since measurement noise is also correlated leading in some cases to unrepresentative high CCC values that can mislead investigators.

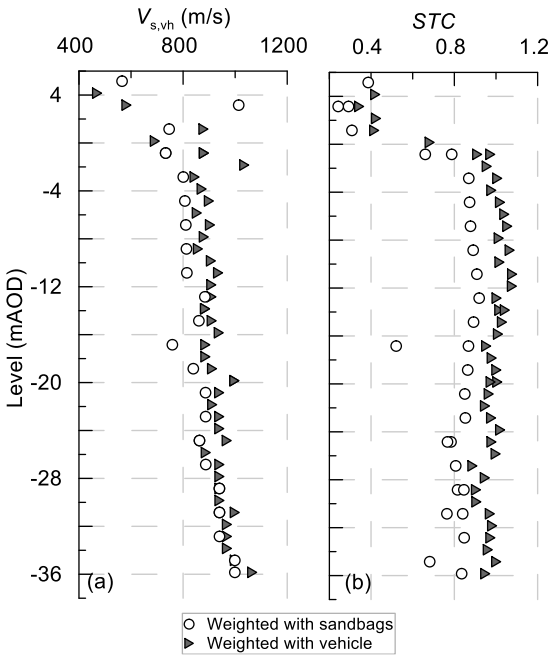

Figure 4. Influence of shear beam weighting on DH results.

Baziw and Verbeek (2017) proposed another approach: a data quality classification framework that combines CCCs with additional signal quality indicators related to linearity between receivers and the shape of the source input signal. The Seismic Trace Characterisation (STC) results in a numeric value between 0 (unacceptable) and 1 (excellent) that can be used to filter signals by flagging erroneous results and traces that require manual interpretation. Figure 4 demonstrates the usefulness of STC values when systematically assessing influence factors on (vertically propagating horizontally polarised) $V_{s,vh}$ obtained in DH testing at the chalk site. This particular

excercise assessed the influence of shear beam weighting or ground coupling on the obtained measurements. The STCs were higher, and the data less scattered where the shear beam was weighted using a vehicle (11kN) compared to when it was weighted using sandbags (1.5kN). While STC appears to be a reliable indicator of data quality, the framework alone cannot capture the complete set of uncertainties present in the shear profile and additional developments are required.

4 SUMMARY & CONCLUSIONS

The SOURCE project aims to quantify and reduce the uncertainties associated with soil and rock in situ stiffness measurements to minimise the influence on offshore foundation design. Benchmark data sets are being collected at onshore sites in the UK and Europe with ground conditions relevant to offshore ground conditions. The fieldwork is providing new insights into in situ stiffness in these materials and facilitating the development of new analysis procedures. While the focus here is on offshore foundation design, the outcomes will be equally applicable to onshore soil structure interaction problems.

ABSTRACT: Together with the constant preoccupation with the safety standards of new structure's foundations the worldwide awareness of climate change continues to increase, making these two elements together with costs the biggest parameters for any foundation project. From the beginning of any foundation project the methodology for a full-scale static load testing program can already optimise many of the requirements in terms of costs and safety, however, only now the environmental optimisation is truly valued. The bi-directional load testing method, by eliminating the reaction structures of the traditional top-down testing methodology, allows the reduction of the overall carbon footprint of the testing program in the most efficient, safe and cost-effective manner for all types of foundations, particularly for larger test loads. The benefits of using bi-directional load tests and how effective they are at reducing carbon emissions will be described. The inclusion of some case studies will illustrate the reduction of CO_2 for (bi-directional) static load testing of foundations in general.

RÉSUMÉ: Parallèlement à la préoccupation constante des normes de sécurité des fondations des nouvelles structures, la prise de conscience mondiale du changement climatique continue d'augmenter, faisant de ces deux facteurs, ainsi que des coûts, les paramètres les plus importants pour tout projet de fondation. Dès le début d'un projet de fondation, la méthodologie d'un programme d'essais de chargement statique à grande échelle permet déjà d'optimiser de nombreuses exigences en termes de coûts et de sécurité, mais ce n'est qu'aujourd'hui que l'optimisation environnementale est réellement appréciée. Du fait de l'élimination des structures de réaction nécessaires à la méthodologie d'essai traditionnelle, la méthode d'essai de chargement bidirectionnelle permet de réduire l'empreinte carbone globale de l'essai de la manière la plus efficace, la plus sûre et la plus rentable pour tous les types de fondations sur pieux, en particulier pour les charges d'essai plus importantes. Les avantages des essais de charge bidirectionnels et leur efficacité en matière de réduction des émissions de carbone seront décrits. La présentation de quelques études de cas illustrera la réduction des émissions de CO_2 pour les essais de chargement statique (bidirectionnels) des fondations en général.

Keywords: Foundation optimisation; bi-directional static load testing; Osterberg cell; decarbonisation of concrete pile foundations.

1 INTRODUCTION

When bi-directional load testing was first brought into pile testing environment, J. Osterberg (1991), predicted savings to the piling world would be in the billions of dollars with the possible reduction of pile size and concreted length for many major projects. As professor Osterberg put it, 'the most economical, functional and practical solution should be sought, followed by a study of how costs can be cut', however at that time he couldn't predict how valuable the bi-directional load testing method would be to reducing the CO_2 emissions for the construction industry.

The current paper is written with the assumption that the readers already understand the correlation between preliminary foundation testing, efficient dimensions of the foundations and the consequent reduction of CO_2 emissions. The focus will be on how the bi-directional load testing allows for a greater reduction of the CO_2 emissions in comparison to other full scale loading methods.

2 PILE DESIGN TESTING PROCESS AND FOUNDATION OPTIMISATION

Ideally, preliminary tests should be undertaken long before the working foundations are constructed, giving designers the chance to re-evaluate their designs and reduce the conservatism that is often introduced in the design due to uncertainties of construction and soil characteristics. The designs are often optimised to obtain an adequate safety factor and the most cost-effective foundations possible for the specific project. However, with the realisation of current damages to our planet provoked by the CO_2 emissions the designers should also take into consideration the environmental element of the project.

When efficiently used, the data obtained from a foundation testing program will allow the possible reduction of the foundation element dimensions and subsequently reduce the CO_2 emissions originating from the reduction of concrete used and equipment usage.

Not only during the actual foundation works are the CO_2 emissions potentially reduced. CO_2 emissions can be further reduced when the bi-directional static loading test method is selected instead of the traditional top-down testing.

3 BI-DIRECTIONAL STATIC LOAD TESTING METHODOLOGY

The bi-directional pile load testing utilises an individually calibrated hydraulic sacrificial loading device (Osterberg Cell® or O-Cell®) installed within the foundation unit. Working in two directions, upward against side-shear resistance and downward against side-shear and end-bearing resistance, the device automatically separates the resistance and displacement data for each component of the pile. By virtue of its installation within the foundation element, the load test is not restricted by overhead structural beam limits and reaction piles. Instead, the device derives all reaction from the soil. End bearing and lower side shear provide reaction for the upper side shear portion of the load test and upper side-shear provides the reaction for the end bearing and lower side-shear portion of the load test.

Once the O-Cell system has been installed within the pile shaft and the concrete has reached sufficient strength, the test can commence. Strain gauges are connected to a data logger (Figure 1) and the system can be run under computer control. When the load cells are first pressurised, the load applied will break temporary welds to prevent the cells from opening prematurely during assembly and form a horizontal separation across the pile at the load cell location.

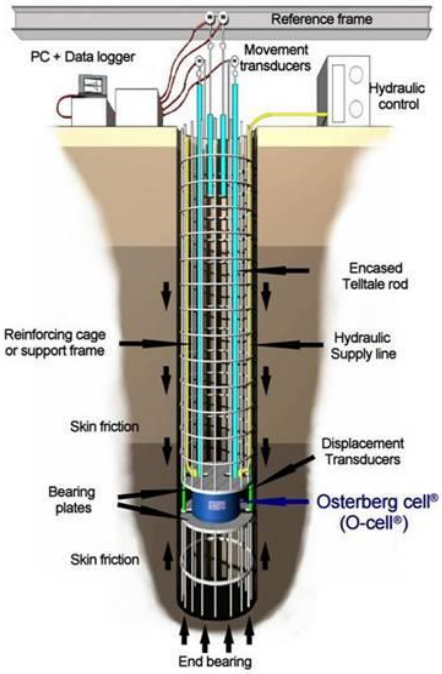

Figure 1. Schematic of a Bi-directional loading test (Fugro).

Once this is done, the test can be performed much the same as a top-down test, by applying the load in stages and measuring movements of each of the components. Testing schedules can be adopted from standard procedures or by recommendation.

4 TRADITIONAL TOP-DOWN TESTING

For the execution of a top-down test a reaction system above the foundation element has to be assembled, with the use of anchor piles combined with loading frames or the use of kentledge blocks.

For a pile/barrette with high loading, in the 10s of MN, a test might require 6 or even more anchor piles These additional anchors require drilling and constructing with steel and concrete, increasing the number of activities, material delivery and its consumption.

A traditional top-down loading system requires a large frame which needs to be constructed with multiple steel beams. The larger the test load requirement the larger these reaction structures need to be. These require to be transported from depot to site and a crane is required to erect the structure, which can be as tall as a 3 story building or more when the loads are as high as 40 to 60 MN.

5 ENVIRONMENTAL COMPARATION

In the following chapter we present a comparation from an environmental point of view between the two

foundation testing methods with the related CO_2 calculations and with project examples.

5.1 Concrete cut-off level in top-down testing

In a traditional top-down loading test the top of concrete needs to be at ground level or above, often with an additional pile cap. In contrast, for a bi-directional loading test, the CO_2 emissions can be reduced as the necessary volume of concrete can also be reduced if the concrete is not up to ground level.

As an example of this, a project executed in Switzerland included the testing of three 2800x800 mm barrettes where the concrete cut-off level was left on average at 12.3 m below ground (Figure 2, shows the empty panel is backfilled with dry sand). The possibility of leaving the concrete level at the desired cut-off elevation allowed a saving of approximately 82.66 m^3 of concrete. Assuming the Carbon Factor of 212 $kgCO_2e/m^3$ of CEM III/A GGBS (50%) based on the Inventory for Carbon and Energy (ICE) database, 17 TN of CO_2 were saved.

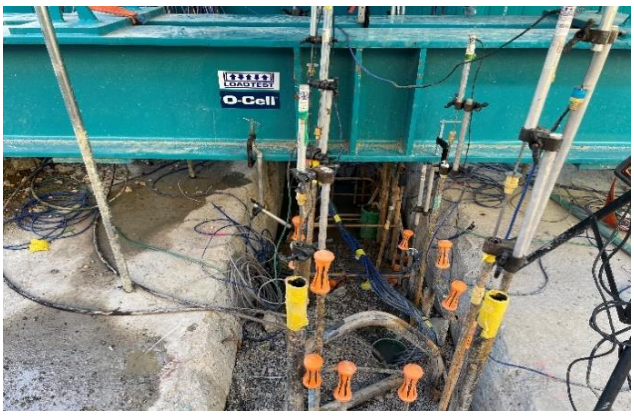

Figure 2. Bi-directional loading test on a pile with concrete cut-off level 12.3 m below ground level (Fugro).

5.2 Reaction structures and anchor piles

As described in section 4, a traditional top-down test requires external reaction structures, like a combination of anchor piles and reaction frames. The loading frame observed in yellow in Figure 3 is a good example of the dimensions and necessary material for reaction beams and anchor piles The CO_2 emissions originated by the production of these structures should be also taken into consideration.

Even if the multiple reuses of the structures on different tests can offer a sense of economic savings, the same isn't felt in terms of the environment as the transport and handling of these assemblies produces CO_2 by the combustion of fuel.

Together with transport and construction of the different reaction structures, the requirement to construct an extra number of piles to serve as anchors, increases the CO_2 emissions related with this type of test. An additional 4 anchor piles for a typical top-down test may not seem much in the total scheme of things but that might be an additional 400 m^3 for the concrete alone on deep large diameter piles, equivalent to more than 80 TN of CO_2. That is without the extra rig emissions for drilling the anchors, concrete and steel transportation and other auxiliary operations. Concrete emissions might be many times as much for high load testing of barrettes and larger piles.

Compared with a bi-directional static load testing the extra construction materials, excavation works and concrete for a top-down load test are avoidable producers of CO_2.

Figure 3. 30 MN top down reaction beams on a barrette test with multiple anchor piles (Fugro).

5.3 Transport for a kentledge test

If in the previous top-down testing method we could associate most of the unnecessary CO_2 emissions with the necessity to construct anchor piles, for a test using kentledge the CO_2 emissions originate from the transport and handling the heavy concrete blocks that will act as reaction system.

It is easily understandable by observing Figure 4 the number of trucks necessary to transport all the blocks. It is also important to note that the CO_2 emissions will directly increase with the requirements of the test load (higher the test load = more blocks needed) and added to this the distance between the depot and site. If we imagine that some remote sites can be more than 1000 km from the depot (example: Mohembo Bridge project and depot in Gaborone – Botswana), we can understand how the reduction of this transport can help reduce the CO_2 emissions.

Figure 4. Loading test using kentledge Dubai (Fugro).

In comparison, it is possible to observe in Figure 5 the equipment necessary, including O-Cells® and measuring equipment, for a bi-directional loading test designed to reach 70 MN. All the equipment was shipped via air to the closest airport and transported easily.

Figure 6, illustrates a typical test setup of a bi-directional loading test where the necessary reference beam was set over two concrete blocks. The final setup for a bi-directional pile load test may also require the use of short-term lifting equipment, it is important to notice that the same setup observed could be used in any test regardless of loading capacity, from 1 MN to over 300 MN. The test can also be performed offshore where the possibility of using top-down techniques becomes far more difficult, and substantially more expensive.

Figure 5. Instrumentation used for a designed 70 MN load test in a barrette (Fugro).

Figure 6. Bi-directional loading test underway (Fugro).

6 CONCLUSION

The bi-directional loading test was already a more economical, practical/functional and safer option over the traditional top-down loading method and with the information shared in this paper it is also noted that the bi-directional loading test is also a better environmental alternative, either when compared with a loading beam plus anchor piles or a kentledge system.

The current European and global norms have a clear goal of decreasing the CO_2 emissions and the construction sector, as one of the biggest producers of CO_2, should now give the same value to the environment as it gives to cost/profit, safety and time. For a preliminary foundation testing program or for proof tests on working piles (as post test grouting can restore the integrity of the structure) the bi-directional loading test will fulfil all those requirements, as shown in a few project examples.

ACKNOWLEDGEMENT

The authors show appreciation to all the foundation designers who have and do already take advantage of the potential design optimisation resulting from full scale static load testing using the bi-directional methodology.

ABSTRACT: This paper presents the experience and some lessons learned from the design and construction of Portugal's first High Voltage Alternating Current (HVAC) submarine power transmission cable, offshore Viana do Castelo. The paper focuses on the ground conditions and the engineering solutions along the marine section of the submarine power cable, namely: 1) trenchless cable landing in hard rock, 2) the cable installation and protection requirements along a rocky seabed and 3) trenching in soil.

RÉSUMÉ: Cet article présente l'expérience et quelques enseignements tirés de la planification et de la construction du premier câble sous-marin de transport d'électricité à haute tension et à courant alternatif (CAHT) du Portugal, au large de Viana do Castelo. L'article se concentre sur les conditions du sol et les solutions d'ingénierie le long de la section marine du câble électrique sous-marin, à savoir: 1) l'atterrage du câble sans tranchée dans la roche dure, 2) l'installation du câble et les exigences de protection le long d'un fond marin rocheux et 3) le creusement d'une tranchée dans le sol.

Keywords: Submarine cable; offshore surveys; trenchless landfall; cable installation; cable protection; floating offshore wind.

1 BACKGROUND

The Windfloat Atlantic project is Europe's first floating semi-submersible offshore wind farm, located approximately 20km offshore Viana do Castelo, northern Portugal. The offshore wind farm consists of 3no. 8MW wind turbine generators on floating semi-submersible platforms anchored to the seabed at a water depth of around 100m, with an installed capacity of 25MW. These turbines are connected through a series of dynamic inter-array cables to the Portuguese grid offshore interconnection point through a Dry-Mate Connector (DMC) laid in the seabed approximately 20km offshore.

In 2015, the Portuguese government allocated to Redes Energéticas Nacionais (REN), the Portuguese Transmission System Operator, the responsibility for the design and commissioning of the Portuguese grid offshore infrastructure in Viana do Castelo, designed for a maximum nominal power of 200 MVA when operated at 150 kV. This comprises Portugal's first High Voltage Alternating Current (HVAC) submarine power transmission cable, 225mm diameter with three 1164 mm2 cores and approximately 17km. The connected generation power of the initial phase, already completed with the infrastructure operating at 60 kV is 25 MW.

For the design, supply and installation of the infrastructure, REN awarded in 2018 an EPC&Mcontract to Hengtong, who subcontracted the offshore works to DeepOcean, the landfall Horizontal Directional Drilling (HDD) to HDI, and the onshore switchyard to CME. Cathie were contracted by REN to support the offshore and landfall projects from early planning, leading the pre-tender design activities, providing tender support and the construction support.

The power transmission cable is laid along the seabed before entering the ~630m of HDD duct and connection to the national distribution grid. For protection, the cable was trenched into the seabed where possible or buried under a rock berm. This paper

focuses on the ground conditions and the engineering solutions, namely: 1) trenchless cable landing in hard rock, 2) the cable installation and protection requirements along a rocky seabed and 3) trenching in soil.

2 GROUND CONDITIONS

2.1 Geological context

The geology along the cable route can be summarised in two major sections. Section 1 (approximately 1/3 of the cable route) closer to shoreline, characterised by the presence of exposed or sub-exposed Pre-Cambrian and Palaeozoic granitoids/schist, associated with high compressive strengths and strong NNW-SSE and WNW-ESE lineations, Figure 1. The lineations are the product of the significant folding and faulting in this area.

Section 2 is generally characterised by a minimum sediment cover of 2-3m increasing towards the west. The geology of this section consists of sub-exposed cretaceous rocks and quaternary sediments (mainly fine to coarse granular materials, sandy silt becoming silt to the West of the route).

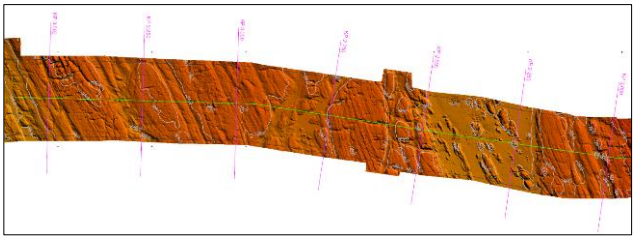

Figure 1. Bathymetry section showing rocky seabed. KP points shown every 250m.

2.2 Geophysical and Geotechnical characterisation

2.2.1 Offshore cable route

A geophysical survey of the anticipated export cable route was conducted in 2014 by GEOxyz (offshore section) and Lagoa do Ruiva Survey (nearshore section), providing multibeam echo sounder (MBES), side-scan sonar (SSS) and sub-bottom profiler (SBP) data in order to determine water depths, identifying seabed obstructions and features such as seabed sediments cover.

The nearshore survey was executed in April 2014. A zone of ~4km^2 was surveyed in the nearshore area with multibeam, where the cable was supposed to come onshore. The depth varied between +3.0m LAT and -30.0m LAT. The deepest zone was recorded in the southwestern part of the area, furthest away from the coast. This zone consists mainly of rocky outcrops.

Along the planned cable route, a corridor of 500m wide was surveyed with MBES, SSS and SBP. The first 10km of the cable route was noted to be covered with fishing gear. For this reason, side scan sonar survey was not possible in the nearshore area.

Multibeam data showed depths along the corridor varying from -10m LAT in the east, along the coast, up to -95m. Rocks were visible up to 8km from the shore, with depths up to -50m LAT. The rest of the corridor showed a smooth slope towards the west, with no rocky structures visible on the surface.

Lines for the SBP were recorded simultaneous with every multibeam or side scan line surveyed. Average penetration into the sediment resulted in 8-10m. Towards the west, the rocky structures were still visible but covered with a ~2m of sediment.

Towards the end of the corridors, rocky structures were not visible, however, in the western part of the cable route, shallow rocks were present again with only a small sediment cover. Where no rocks were visible on the surface, a mimimum of 3 meters sediment (and often more) was detected along the cable routes. Steep slopes were only visible in the rocky areas.

As part of the pre-engineering phase, an additional geophysical survey was carried out in September 2018 by MG3 under subcontract to DeepOcean, to ascertain expected free cable spans prior to finalisation of the route engineering. The scope of work involved the collection of bathymetric and geophysical data within a 200m wide corridor. The entire corridor was surveyed with MBES, SBP and seafloor dropdrown camera at certain intervals. Due to fishing activity and gear, the SSS and Magnetometer works were suspended and the MBES Backscatter Imaging was recorded as back-up in order to enable a seafloor sediment analysis.

The scope of the Export Cable geotechnical investigation, comprised a total of 32no. CPTs coupled with 32no. Vibrocore (VCs). The target penetration depth for both type of tests, was specified to be 3m to 5m below seafloor based upon the anticipated ground conditions along the cable route.

The geotechnical survey was performed by Fugro in 6 days during November-December 2016 using the MV Markab, a 63m dynamically positioned DP2 survey vessel. A 75kN Seacalf seabed CPT unit was mobilised on board of the MV Markab. Seabed CPTs were performed using a 12 tonne ROSON CPT system. Cones with a projected area of 10cm^2 and 5 tonne capacity were used for testing, with pore water measurements made on the shoulder of the cone, generally providing very good quality results, in

general, all within ISO Application Class 1 (ISO 22476-1, 2022) for ground conditions comprising loose to very dense sands and soft to very stiff clays. The CPT achieved good penetrations in the sands and occasional clays were encountered along the route up to ~10km from the shoreline, from where the CPTs recorded the presence of bedrock near surface and/or rock outcrops.

Sampling operations were performed using a high performance corer (HPC). The HPC had a base frame of 2.4m x 2.8m, an overall length of 8.1m and a weight (in air) of approximately 3.1ton. The HPC was fitted with a 6m core barre allowing for the recovery of soils samples of up to 84mm in diameter.

Only basic logging of the samples was performed offshore. Laboratory testing onshore was generally performed according to the BS 1377 (1990) procedures, including:

- Basic strength and Index laboratory Tests.
- Water content and Wet and Dry Density.
- Plasticity Index.
- Particle size distribution.
- Minimum and maximum density.
- Thermal conductivity test.
- Shear box test.
- Unconsolidated Undrained Triaxial Test.

2.2.2 Landfall

An onshore geoelectrical tomography survey supplemented by seismic refraction tomography and multichannel analysis of surface waves (MASW), calibrated with boreholes, was performed by Donié Geo-Consult in order to generate a geological model for the HDD working area. Rockhead was reported at a depth of 6-8 m, slightly inclined in the direction of the sea and underlying heterogeneous anthropogenic made ground.

Additionally, an offshore geophysical exploration in the planned landfall area was performed with MBES, SBP and electrical resistivity tomography techniques by Donié Geo-Consult and SSS and Seismic Reflection (with a boomer) by Instituto Hidrográfico. The aim of the investigation was to create a geological model for the cable landing area.

At least two to three critical sections with lengths of up to 100 m and apparently strongly fragmented hard rock were identified. On the last 100 m before the exit point, a remarkable resistivity minimum linked to a very rough surface of fractured rock according to the SBP results was identified, Figure 2. The Echo Sounder detected a strongly fractured rock surface with open fissures pointing in two main directions (NW-SE and WSW-ENE).

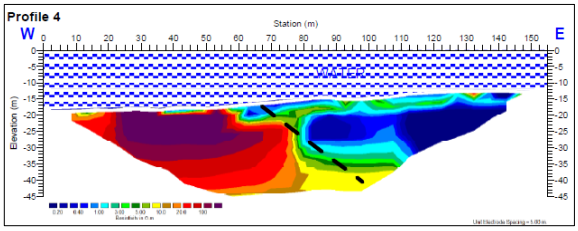

Figure 2. Geolectrical tomography of punchout area (red, high resistivity; blue low resistivity).

In 2018, a total of seven onshore rotary percussive boreholes were drilled by GeoSonda, six boreholes to a maximum depth of ~10.5m at the footprint of the switchyard building, and one borehole at the location of the HDD entry point, with total depth of 40m.

The borehole descriptions at the HDD entry point identified an upper layer of made ground, with cavities overlying solid rock composed of various types of schists, with subvertical schistosity.

Additionally, laboratory testing from five representative samples at different depths and lithologies were obtained from borehole S7 including:

- Point Load Test
- Uniaxial compressive test (UCS)
- Micro-Deval
- Cerchar Abrasivity
- D.R.I. (Drilling rate index).

Abrasivity results revealed very to highly abrasive samples, particularly in quartzitic schist. In general, medium to high D.R.I index values were obtained. Maximum values from the UCS tests ranged between ~39-80 MPa in quarzitic schist and ~12-61 MPa in andalusite schist. It was noted that the lowest values correspond to fractures along discontinuities during the test.

3 ENGINERING SOLUTION

3.1 Contractual cable burial and protection requirements

The governing basis for the design was protection for a minimum 30 year service life against fishing activity and 1:10,000 year anchoring events.

REN specified different protection requirements over two characteristic sections: rocky section (Section 1) and buried section (Section 2).

For Section 1, defined as rocky outcrops with thin or absent sediment cover, closer to shore, it was envisaged that cable armour and pinning/rock dumping compliant with environmental restrictions was required.

For Section 2, defined as minimum sediment cover, it was envisaged a minimum Depth of Cover (DoC) of

1.5m, and greater where appropriate, to guard against a 1:10,000 year anchoring damage event in accordance to Cable Burial Risk Assessment) methodology (Carbon Trust, 2015) where sufficient sediment existed.

3.2 Cable route

DeepOcean initially reviewed the GEOxyz geophysical data and the geotechnical data from Fugro 2016 to ground-truth the geophysical report and build a conceptual ground model. The cable corridor was then optimised and the route further surveyed by DeepOcean in 2018. The following items were considered in order of priority for route engineering:

- Permitted Operational Corridors.
- Avoidance of anchoring zones. An anchoring area was noted to be present to the south of the corridor. An exclusion boundary was drawn around the outside of this zone to ensure no operations were planned there.
- Avoidance of bedrock outcrops and minimisation of rock spans where possible.
- Avoidance of Archaeological excludion zones. A number of contacts with potential for archaeological content were identified. All the contacts had a 50m buffer applied to make sure that none of these buffers come within the cable corridor.
- No field infrastructure, crossings or boulders were reported to be within the corridor. Preliminary research indicated the UXO risk along the corridor to be very low.

The export cable route was designed from the Transition Joint Bay on land through the HDD westwards to the DMC. Approximately 8km consisted of subsea rock placement and ~9km corresponded to seabed trenching to a burial depth of 1.5m. Water depths along the route range from Landfall to a maximum of approximately -94m LAT.

The Cable Lay Vessel (CLV) OY Connector was used to support most offshore activities, namely rock and sandbags placement, cable lay and trenching activities. The Fall Pipe Vessel (FVP) Simon Stevin was used for the rock placement activities.

3.3 Landfall

HDD with forward reaming solution (drilling from onshore to offshore) was selected for the landfall with the use of HDI HK400 drilling rig (400t), Figure 3. The solution consisted of drilling an initial pilot hole, subsequently enlarged by a forward reaming operation, prior to the installation of a 24‘‘ steel pipeline through which the export cable was later on pulled-in.

Based on the findings from the offshore geophysical investigation, the initial HDD design trajectory was anticipated to cross an area of strongly fractured rock at exit point. The HDD trajectory was then adjusted to avoid this area and achieve an exit point 35m closer to shore.

Initial pilot hole with 12’’1/4 drill bit was aborted after 170m due to magnetic interferences afecting direction control. This pilot hole was plugged with cement grouting and abandoned. A second sucessfull pilot hole, approximately 625m long, was performed with a 9’’7/8 drill bit and with the assistance of a gyroscope to avoid magnetic interference.

Reaming was then performed in two steps, 26’’ performed to a length of 617m, and 36’’ performed to a length of 597m. Punch-out operations were performed following the same 26’’ and 36’’ drilling steps. First attempt was made with the drill bit and the 26’’ and 36’’ tools connected, in order to minimize amount of drilling fluid at sea. Shearing of a drill pipe occured during drilling; the contractor successfully engineered fishing gear to recover the drill bit, allowing to resume reaming with 26‘‘ and 36‘‘ performed separately.

Figure 3. Forward reamer and launching pit.

The final stage of the installation consisted of the installation of a 24’’steel pipeline welded on-site and pushed into the reamed hole. A messenger wire was installed at the completion of the job to allow later connection for the cable pull-in activities.

Due to the HDD exit changes to a shallower depth, approximately 40m cast iron half-shells (bend restrictors) were installed and connected to the HDD exit with diver support. Each section of half-shells incorporated a messenger wire connected to the main HDD pull in messenger wire. Thethered 4t rock bags filled with high density (3050 kg/m^3) angular quarry rock were placed over the shells to provide stability against combined wave and current loading under

extreme hydrodynamic conditions assumed for 1:50 year return period conditions.

3.4 Cable installation and protection requirements

3.4.1 Rocky seabed

A significant portion of the route along the rocky seabed involved placement of the cable on an irregular seabed with NNW-SSW ridges and NNE-SSW erosional channels, with anticipated cable free-spans. Pre-installation of rock bags and sandbags at pre-determined locations was adopted to provide support to the Export Cable, minimising free-spans along the lay route, Figure 4. After cable laying, the cable was mechanically protected by engineered rock placement.

Figure 4. Rock bags.

A Cable Protection System (CPS), consisting of half shells secured with carbon steel banding, was fitted to the portion of the cable to be laid in the rocky seabed during the cable spooling on the CLV carousel at Leixões Port in Portugal, with the purpose to provide abrasion and protection during rock placement operations.

For the cable section closer to the Port of Viana do Castelo anchorage (500-600m south of the cable route), the rock berm was designed to further protect the cable from anchoring associated with inclement weather conditions or anchor drifting in a northward direction, Figure 5. The rock berm was designed to protect against a 4000t vessel which based on the IACS rules would typically comprise an anchor of 1500kg.

Given the very low probability of an anchor strike of any size along the remaining of the cable route, assessed in the CBRA study, the rock berm design was governed by protection from fishing gear interaction and to maintain hydraulic stability.

Based on the varying governing design conditions along the route, the total rock placement length of the rocky area was subdivided into different sections, depending on the water depth. Two different rock gradings (LMA 5/40 and 1-8'') were adopted in combination with varying berm geometries and side slopes to obtain hydraulic stability. For the area adjacent to the anchorage area, a wider rock berm (1.5m) and a higher cover (total armour + cushion 1.5m) was adopted. A specific rock density of 3050kg/m³ (HD) was targeted.

For the shallowest section the rock installation placement was subject to the FPV draft limitations and was executed with the Inclined Fall Pipe system with the support of a survey support vessel. For the remainder of the rock placement scope the Fall Pipe ROV (FPROV) was used with survey systems onboard the FPV.

The rock material was mostly sourced from a quarry in the North of Spain, with some additional LMA5/40 material being sourced from Southwest Norway. The total rock weight required to create the berms protecting the cable was approximately 131,000t and involved 5 loadings at the Ferrol Port in Spain.

Figure 5. Rock berm construction operations (FPV).

3.4.2 Trenching in soil

The CBRA study concluded that there was a very low probability of an anchor strike along the buried section and the statistical analysis indicated that an unburied cable would be within REN specified target annual failure frequency of 1:10000 year. The recommended level of protection for the trenched section of the cable route was therefore governed by potential fishing gear interaction. Based on the shallow geological conditions along the route and on the varying penetration of different types of fishing gear in the region, a Minimum Depth of Cover (DoC) for protection against fishing of 0.5m was recommended by DeepOcean. For the trenching operations the following criteria was agreed:

- Target trench depth of 1.5m DoC, with results considered acceptable without further review for DoL between 1.0m and 1.5m.
- DoC between 0.5m and 1.0m: further review required between REN and DeepOcean to agree if further actions would be required based on a specific assessment of depth and lengths. This

was evidenced by an offshore field memo assessment of the TSS350 cable tracker survey results.

- DoC less than 0.5m: 2nd trenching pass required to try and achieve the above requirements.

During the pre-lay grapnel run (PLGR) along the proposed cable lay route, the grapnel train caught several fishing gear, long-lines and mono-filament tangle nets, which could prove hazardous for ROV operations during the cable lay and post-lay burial operations.

Cable trenching was completed between ~KP7.15 and ~KP16.4, with a transition zone between KP7.197 and KP7.212 where the cable was lowered into the seabed and also protected by extending the rock berm from the rocky section. From the start of trenching to approx. KP9 the trench depth was locally reduced due to the presence of bedrock within the trenching profile.

Considering the anticipated ground conditions and target burial objectives, DeepOcean selected their T1 tracked subsea jet-trencher, capable of independently loading and unloading laid product from the seabed, then digging a trench using hydraulic power whilst simultaneously burying the product behind it, Figure 6. The T1 was fitted with 3.5m jet swords which could extend to 2.2m below the seabed with the aim to lower the cable to target depth in one pass. An average speed of 200m/h was envisaged. The nozzle configuration was selected to optimise the trencher performance, with an output of 750m^3/h at 4 to 5bar.

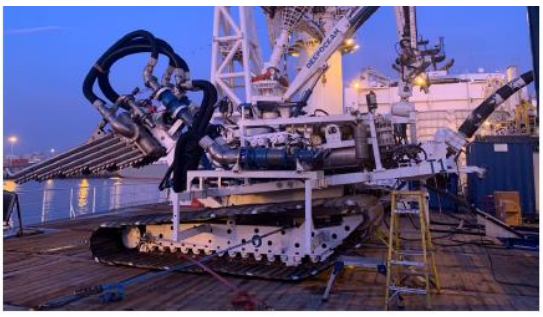

Figure 6. T1 DeepOcean Jet trencher.

Extremely low strength clay, with thickness between 0.40m and 0.6m, was noted at seabead between approx. KP14 and approx. KP15.3, overlying sand. For this section, trafficability was anticipated to be potentially difficult and several methods were employed to reduce the effective bearing pressure of the trencher and to maintain traction, namely through locking the trencher in the bullet, crane assistance to reduce the overall weight, and fitting of grousers.

At limited sections of the route, the DoC did not meet the requirements upon the trencher first pass. Following thorough review of results and consideration of potential risks and benefits of a second pass, limited sections of 1-8'' rock grading were installed to provide suitable cover where required.

At the western end of the static cable a transitioning out trenching profile was adopted until reaching the DMC position, Figure 7. A total of 31 2t rock bags were subsequently installed over the DMC and the area of exposed cable to the east of the DMC.

Figure 7. Dry-mate connector deployment.

4 CONCLUSIONS

This paper presented the experience and some lessons learned from the planning and construction of Portugal's first HVAC submarine +ower transmission cable, offshore Viana do Castelo. Operations included trenchless construction of the landing area, rocky seabed routing and free-span management, CPS fitting and deployment, rock berm construction, seabed trenching and DMC deployment and protection. The cable was successfully designed and installed and is currently operational.

ABSTRACT: Climate change is demanding cleaner industrial processes besides new techniques. Waste materials, such as water treatment sludge (WS), biomass ashes (BA), mining wastes (MW), and iron slags (IS) are largely produced around the world from varied industrial activities, they represent a hazardous when incorrectly disposed due to contamination potential of soils and waters, highlighting the necessity to find new applications for them. Geotechnical engineering has been a major area for employing new materials to improve current methods. Regarding geotechnical applications, soils can have problems like high volumetric variation, high plasticity, and elevated water absorption/retention capacity, causing fissures, cracks, and low mechanical strength. Several researches have exposed the above-mentioned residues' value while improving overall aspects of the soils, successfully mitigating undesired characteristics, and making them feasible for geotechnical applications. Therefore, this paper aims to present and evaluate physical characteristics of residues alone, granular soils and mixtures of wastes-soils using varied introduction percentages of the residues into the soil, to assess their feasibility for improving the soil towards a geotechnical material for varied applications. Found results have shown all mixtures were considered as material for subgrade, according to AASHTO. Residues impacted the soil differently, WS, BA and MW led the granular soil to a finer material, while IS to a more granular material. Plasticity reduction up to 100% was achieved by WS, BA, and IS. Density was considerably increased by IS while MW sustained, and WS and BA have shown susceptibility into being light-weight materials.

RÉSUMÉ: Le changement climatique requiert l'adoption de nouvelles techniques. Les résidus, comme le boues de traitement de l'eau (WS), les cendres de biomasse (BA), les déchets miniers (MW) et les scories de fer (IS), sont générés partout le monde. Leur élimination inadéquate peut représenter un risque de contamination des sols et des eaux, soulignant la nécessité de trouver de nouvelles applications pour ces résidus. L'ingénierie géotechnique joue un rôle majeur dans l'utilisation de nouveaux matériaux pour améliorer les méthodes existantes. Les sols peuvent présenter des problèmes tels que des variations volumétriques élevées, une plasticité élevée, provoquant des fissures et une faible résistance mécanique. Diverses recherches ont révélé la valeur économique des résidus mentionnés, tout en améliorant les caractéristiques globales des sols, atténuant avec succès les caractéristiques indésirables et les rendant adaptés à des applications géotechniques. Cet article vise à présenter les caractéristiques physiques des résidus seuls, des sols granulaires et des mélanges de déchets-sols. Les résultats obtenus montrent que tous les mélanges sont considérés comme des matériaux appropriés pour les sols de fondation, selon les normes de l'AASHTO. Les WS, BA et MW transforment le sol granulaire en un matériau plus fin, tandis que les IS le transforment en un matériau plus granulaire. Une réduction de la plasticité allant jusqu'à 100% a été obtenue pour WS, IS et BA. La densité a été considérablement augmentée par les IS, tandis que les MW sont restés stables, et les WS et BA ont montré une propension à être des matériaux légers.

Keywords: Residues valorisation; geomechanical properties; circular economy; soil reinforcement.

1 INTRODUCTION

Society´s evolution requires a higher demand of natural resources to produce energy, treat the water for consumption, and create construction materials. Consequently, several residues tend to have their production to grow, due to the ever-growing demands, generating high amounts of industrial wastes. Some examples are water treatment sludges (WS), mining wastes (MW), iron slags (IS), and biomass ashes (BA)

from water treatment processes, mining activities, metallurgic and thermoelectrical industries, respectively. All of which are responsible for a large sum of these waste production while equally important for providing society the necessary resources.

Their production without a correct disposal can create several contamination problems due to the percolation of heavy metals and chemical contaminants, impacting soils and groundwater. Most of these residues are disposed in landfills, although this technique is land-consuming and could not be feasible in the long term, while demanding constant maintenance and representing a rupture risks or disasters, as in Brumadinho, Brazil (Salvador et al., 2020).

In 2016, IS generation was around 300 million tons only in China, although not reused (Guo et al., 2018). WS production in a water treatment plant (WTP) can reach up to 100.000 ton/year (Ahmad et al., 2016). MW production is estimated to be around 20 to 25 billion tons/year (Almeida et al., 2020). Although BA's exact production number is unknown, biomass is used for up to 10% of the world´s energy production, giving the magnitude order of waste generation (National Biodiesel Board, 2015).

Thus, the reuse of those residues emerges as a necessity for reducing world´s disposal and valorisation of waste materials. Regarding geotechnical engineering need for new materials, the application of waste-based materials can represent advantages for varied applications according to the wastes' characteristics.

Some soils tend to present undesired characteristics for geotechnical design, such as high volumetric variation, high water absorption-retention capacity, high plasticity, and low mechanical properties. Hence, considering the residues are materials produced by industrial processes, their introduction could mitigate these characteristics. Such characteristics are also due to the soil´s particle sizes distribution, causing variations in the particle's entanglement, water permeability and, hence, interaction of the soil skeleton within the system soil-water-air. Residues´ introduction could impact the soil skeleton, which can lead to an amelioration or enhancement of these mechanical properties.

Therefore, this paper characterizes physically four named residues, granular soils, and mixtures in varied percentages, to assess their impacts on physical properties.

2 MATERIALS AND METHODS

The tested materials were two granular soils – CB and O2 – and four industrial wastes – WS, BA, MW and IS. The soils were collected from a construction site in Castelo Branco, Portugal. The WS was collected from a WTP located in Guarda, Portugal. The BA and MW were collected in local companies from Castelo Branco and Guarda, Portugal, respectively, while IS was collected from a thermoelectrical plant in Alcochete, Portugal.

The chosen introduction ration of each residue was based on the dried masses percentages and consisted of 5, 10, 15 and 20% for WS with O2 soil while the same ratios were applicable for BA, but with CB soil. MW and IS were tested with 25 and 50% within CB soil. Mixtures were identified by the introduced percentage of the residue followed by the abbreviation of the residue.

Laboratorial geotechnical characterization was based in ISO 17892 for particle size distribution, specific gravity, and consistency limits.

3 RESULTS AND DISCUSSION

3.1 Physical identification

The analysed soils – O2 and CB – are sands with a small portion of silt and clay. O2 has a higher concentration of iron oxides´ concentration, while CB´s matrix corresponds to the region´s soil, majorly composed by schists, composed by feldspars and quartz minerals with muscovite presence and kaolinite for the clay-portion.

As for the residues, IS is highly granular, WTS and BA are silty sands, and MW is a silty-sand with low portion of clay particles. Their mineralogy are hard to assess as the several taken industrial process affect their overall characteristics and properties (Marchiori et al., 2021).

Figure 1 presents the particle size distribution of the analysed soils, residues and optimal mixtures, considered as the ones that had better workability.

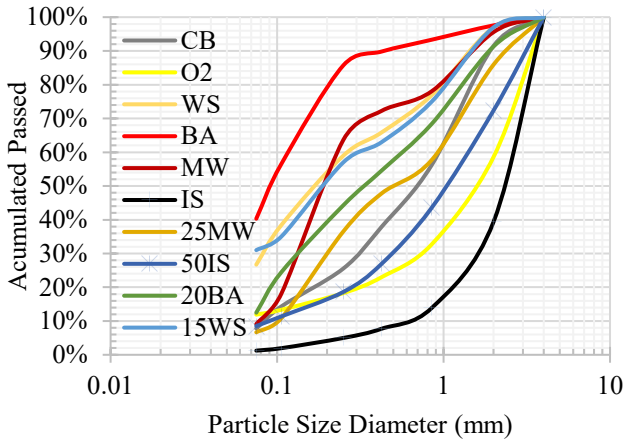

Figure 1. Particle size distribution curves.

According to USCS, both soils were characterized as silty sands. The residues vary in classification, BA, MW and WS, for example, are also classified as silty-sands, although their fine range varies considerably. Besides, IS is a well-graded gravel. Table 1 below synthetizes comparison between USCS and AASHTO classification for all materials.

Table 1. Particle size parameters.

Samples	AASHTO	USCS
O2	A-2-4	SW-SM
CB	A-2-4	SW-SM
WS	A-2-4	SW-SM
15WS	A-2-5	SW-SM
BA	A-4	SM
20BA	A-2-5	SM
MW	A-2-6	SM-SC
25MW	A-2-6	SM
IS	A-1-b	GW
50IS	A-1-b	SW-SM

Thus, both soils are well-graded sands containing silts. Each residue impacts the soil differently, BA is the finest material, being classified as a fair to poor material for subgrade application, according to AASHTO. Through USCS, BA´s granulometry is more characteristic of silty materials, causing the optimal mixture being classified as silty-sand (SM). WS is also majorly fine, although the mixture is still classified as well graduated sand with a fine portion.

MW is the residue with highest plasticity, pushing the mixtures to behave like a finer material. IS tends to push the mixture´ classification towards a more granular material. It is important to reiterate that such standards consider the analysed material as soils. Therefore, the results here exposed are an approximation of residues being treated as soils for their classification.

In addition, all the mixtures had a classification of "excellent to good" for subgrade application based on AASHTO. To further assess the impacts on the soil behaviour, Table 2 below presents specific gravity (Gs) and Atterberg limits.

MW was the only residue workable enough to do the Atterberg limits. IS lacked cohesion between the particles, while the workability of WS and BA were very low and thus, hard to properly execute the test.

Nevertheless, WS and BA tended to reduce the overall density of the mixture. MW does not seem to impact the density of the soil, although it increases its plasticity. IS is much heavier than the soil, mostly due to the high content of iron oxides, although it does not have plasticity due to its granular size. Such results indicate that WS, BA and IS can reduce plasticity, while MW could contribute for the plasticity maintenance.

Table 2. Specific gravity and Atterberg limits values.

Samples	Gs	W_L	W_P	PI
O2	2.75	35	27	8
CB	2.73	30	21	9
WS	2.00	-	-	-
15WS	2.63	42	39	3
BA	2.36	-	-	-
20BA	2.62	45	NP	NP
MW	2.63	37	25	12
25MW	2.61	37	26	11
IS	3.58	-	-	-
50IS	2.98	NP	NP	NP

Specific gravity values also could indicate the feasibility of WS and BA as light-weight material generation, while MW does not seem to impact the overall density. On the other hand, IS could lead to a harder workability and material development due to its high density.

4 CONCLUSIONS

Found results have indicated WS, MW, IS and BA are susceptible for introduction with different ratios into soils.

WS, BA and MW have led the soil to a finer material while IS led to a more granular material. Although WS and BA are finer, they seem not to contain any clayey properties, as no plasticity was found. Reduction of plasticity was achieved up to 100% for all residues, except MW which contributed for a slightly more plastic behaviour.

The major impact was on the particles´ density, being IS the one that had the highest impact, and which could affect a product or material IS-based due to its

heavy weight and possible hard workability that could difficult logistics.

Such results are part of an on-going investigation of these residues for soils´ reinforcement and liner application, which more tests shall be conducted and replicated *in-situ*, when possible, for further characterization and validation.

ACKNOWLEDGEMENTS

The authors acknowledge the companies for providing the soils and wastes here-described, namely João Tomé Saraiva, and Grupo Valor. Also, the University of Aveiro for providing the necessary support on the on-going investigation. The research was supported by national funds within UIDB/00195/2020 (FibEnTech) and UIDB/04035/2020 (GeoBioTec) projects, both funded by the Foundation for Science and Technology (FCT), Portugal.

ABSTRACT: Foam Glass Aggregate (FGA) has a wide particle size distribution, in addition to being lightweight and thermally insulating, which extends its potential applications to various infrastructure and construction purposes. For infrastructure projects, it can be used as a lightweight backfill material, allowing the use of soil-improvement methods to be dispensed with in soft subsoils. In buildings, it can be used as thermal insulation under floors, thus helping to improve the energy efficiency of buildings. It acts as a static load for building and earthwork structures, while vehicles or forklift cyclic loads act in case of pavements and industrial floors. It is essential to investigate the effect of different compaction ratios in order to ensure efficient use of materials. In this study, the effects of different compaction ratios (10%, 20%, 30% and 40%) on the elastic modulus (Eoed) and dynamic parameters (Resilient modulus) of the material were investigated. For cyclic loads, elastic and plastic deformations were separated to determine the short and long term behaviour of the material. Different deviator stresses were operated on the FGA for both static and cyclic loads. The results were evaluated by comparing the behaviour of FGA under static and cyclic loads.

RÉSUMÉ: L'agrégat de verre mousse (FGA) a une distribution granulométrique élevée, en plus d'être léger et thermiquement isolant, ce qui étend ses applications potentielles à diverses fins d'infrastructure et de construction. Pour les projets d'infrastructures, il peut être utilisé comme matériau de remblai léger, ce qui permet de renoncer au recours à des méthodes d'amélioration des sols dans les sous-sols mous. Dans les bâtiments, il peut être utilisé comme isolant thermique sous les planchers, contribuant ainsi à améliorer l'efficacité énergétique des bâtiments. Il agit comme une charge statique pour les structures de bâtiments et de terrassement, tandis que les charges cycliques des véhicules ou des chariots élévateurs agissent dans le cas des trottoirs et des sols industriels. Il est essentiel d'étudier l'effet de différents taux de compactage afin de garantir une utilisation efficace des matériaux. Dans cette étude, les effets de différents taux de compactage (10%, 20%, 30% et 40%) sur le module élastique (Eoed) et les paramètres dynamiques (module de résilience) du matériau ont été étudiés. Pour les charges cycliques, les déformations élastiques et plastiques ont été séparées pour déterminer le comportement à court et à long terme du matériau. Différentes contraintes de déviation ont été appliquées sur le FGA pour les charges statiques et cycliques. Les résultats ont été évalués en comparant le comportement du FGA sous charges statiques et cycliques.

Keywords: Foam glass aggregate; thermal insulating material; oedometric modulus; resilient modulus; industrial floor.

1. INTRODUCTION

The foam glass aggregate (FGA) is a new material in Hungary. Foam glass was produced from the 1930s, but it appeared in aggregate form only around the 2000s. The material is popular in the Scandinavian countries, Switzerland and the USA. In the Scandinavian countries, it is used to reduce the depth of frost penetration under road pavements, while in other places it is used as a light material filling in road and railway construction, as well as for the construction of heat-insulating bedding under industrial floors. During the production of FGA, the material is suddenly cooled, so internal stresses arise in it. Due to these internal stresses, it is broken into

more or less regular particles of the same size at the end of the manufacturing process.

Its advantageous feature is its durability. Since it does not age, regardless of environmental effects, it behaves in the same way as it did at the time of installation, even years after its installation, in terms of both its physical and chemical properties. Therefore, the material is not collapsing over time, such as polystyrene insulation materials.

Another beneficial feature - it's true that it's only the XXI. became an important aspect in the 19th century - that it is environmentally friendly. It can be produced from waste materials with low energy investment and can be recycled almost endlessly. In addition, it does not react with its environment, so no environmentally harmful substances are released from it.

Having the material's stiffness is essential for construction and infrastructure design purposes. The static and dynamic moduli are used as a design parameter to show the possibility of using the material under the impact of static and dynamic loads. In this regard, many types of recycling and manufacturing aggregates have been studied due to the increasing interest, high cost, and limited supply of high-quality naturally occurring aggregates that satisfy thermal insulation properties and get more sustainable environmental conditions. In recent years the possibility of using various types of recycled construction and demolition materials in road embankments and pavement applications such as recycled concrete (Jitsangiam et al., 2015), recycled crushed glass (Mohajerani et al., 2017) and foam glass aggregate (Arulrajah et al., 2015; Lenarta and Kaynia, 2019; Mustafa et al., 2022; Mustafa and Szendefy, 2023; Swan, Seungcheol Yeom, et al., 2016; Szendefy and Huszák, 2019) has been investigated.

The lightweight characteristics of such materials are typically due to the substantial part's low unit weight and large amounts of interconnected or nonconnected pores (Scheffler and Colombo, 2005). Different types of lightweight materials are used in civil engineering applications, including lightweight clay aggregate (Ayati et al., 2018), and foam glass aggregate (Emersleben and Meyer, 2014).

Regarding infrastructure constructions, vertical loads on soft subgrades can be reduced by using lightweight fill materials such as FGA as an alternative and in addition to bearing capacity improvement techniques (Emersleben and Meyer, 2014). FGA, as a lightweight construction material, can be used in many applications such as retaining walls, road embankments, bridge abutments, and slope stability (Szendefy et al., 2020). FGA has several technological benefits, including low density, high strength, thermal insulation, frost resistance, fire resistance, rat resistance, acoustic insulation, non-toxicity, low water absorption, and short constructing time (Hurley, 2003).

Although FGA is considered a beneficial construction material, limited studies are available on the static and dynamic behavior of the material. Therefore, more extensive research is needed to understand the factors influencing the material response under static compressional and cyclic loadings, especially the impact of different compaction ratios due to broad grain size distributions. According to the findings of (Swan, Yeom, et al., 2016), FGA has unbound compressibility behaviour. Regarding FGA, Ghafari et al. (2019) studied the resilient modulus under repeated deviatoric loads in a triaxial apparatus following the standard (AASHTO T 307-99, 2007) for the granular base and subbase materials with some particular adaptations to prepare the samples in a small triaxial scale. They concluded that the FGA resilient modulus was higher for the bigger particle size range of 20-31.5mm (Mr=150MPa) than the smaller one of 0-31.5mm (Mr= 120MPa). Depending on big-scale triaxial tests with monotonic and cyclic loading, Lenarta and Kaynia (2019) studied the properties of FGA, focusing on the stiffness and damping properties of the material. They observed a high initial stiffness, a small elastic threshold strain, and a significant modulus reduction in the first cyclic loading stage compared to other natural materials referring to a brittle structure component.

This study investigated the impact of different compaction ratios (10%, 20%, 30%, and 40%) on static and dynamic stiffness as well as the elastic and plastic strains the cyclic behavior of FGA. To determine the static compressional modulus of FGA series of loads started from 50 kPa to 300 kPa with 50 kPa intervals were applied. A sequence of uniaxial deviatoric stresses (25kPa, 100kPa, and 200kPa) with various cycle numbers were applied to the material samples. Due to the availability of high amounts of internal pored which was 92.7% for the studded FGA, this may lead to severe accumulated strains; therefore, the effect of compaction ratio and cycle numbers on accumulated plastic strains (ε_{acc}) behavior of the material have been evaluated. The resilient modulus at various compaction ratios was calculated to show the impact of elevated compaction ratios. Furthermore, this study presents a comparison between the ε_{acc} values obtained from the dynamic test and the vertical strains obtained from the static compressional test (oedometer test).

2. MATERIAL AND METHODOLOGY

2.1 Material

For the present study, the used FGA material produced by a Hungarian company has a grey color, broken-edge surface like crushed stone, while its bulk density without any compaction is around 170 kg/m3.

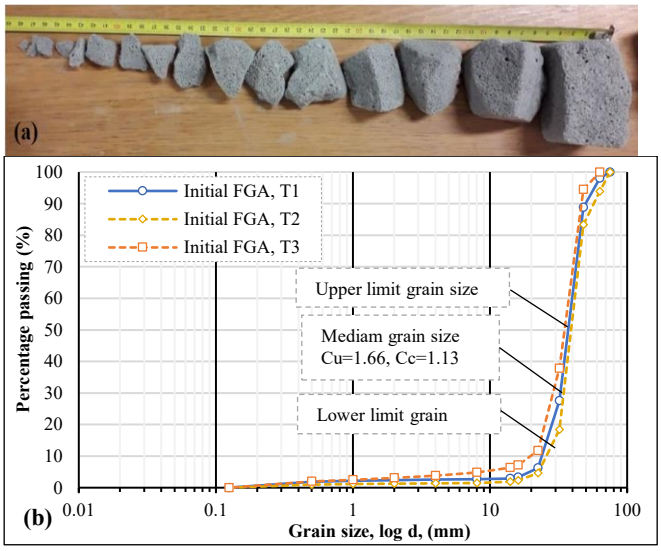

Figure 1. a) Foam glass aggregate, b) grain size distribution curve of FGA.

The material mainly contained gravel-sized particles, as shown from the particle size distribution curve of the received FGA. The initial FGA has a coefficient of uniformity Cu=1.66 and a coefficient of curvature Cc=1.13, which makes the material classified as poorly graded based on the USCS classification system, with one primary grain size range of 10-60 mm. The initial FGA material underwent over ten tests to determine its grain size distribution. However, for the purpose of clarity, only three key trials displaying significant differences in their distribution curves are included in Figure 1 (a, and b).

2.2 Methodology

A customized testing setup specifically designed for conducting static compression tests on foam glass aggregate (FGA). Since utilizing a conventional geotechnical apparatus for static compression tests on FGA samples is not feasible due to the impracticality of accommodating the individual particle size, which may exceed the conventional sample size range of 10 to 60 mm in diameter (Mustafa et al., 2022). Therefore, a cylindrical steel frame was constructed adheres to the 5D (largest particle diameter) size criterion. FGA was compacted into the mold by one layer at both 10% and 20% compaction ratios, while to reach the 30% and 40% compaction ratios the material was compacted into the mold in two layers using a heavy load plate. During the static compression test different series of static loads was tested starts at 50 kPa to 300 kPa with 50 kPa intervals were applied on samples To reach each compaction ratio, the initial FGA has been compacted into the mold till the desired mass per volume has been obtained. The 10% ration means the density is 10% higher as the origin bulk, while the weight is 20% more in case of 20% and etc.. Each loading stage was performed to the vertical strain reached the 0.01 mm/min strain value. During the tests, five trials were conducted on FGA samples to show the diversity.

To do the uniaxial dynamic compression test on the material in oedometric condition (fully side restrained) two load types of vertical stresses have been applied to FGA samples. First, a sustained conditioning load (25 kPa) was applied to the samples to represent the self-weigh of the pavement and capping layers. Then, depending on the stress distribution profile of road application sections under the pavement where FGA can be used as filling material, three different values of cyclic deviatoric vertical stresses (25 kPa, 100 kPa, 200 kPa) were selected to generate the effect of the repeated moving traffic loads. Where, the 200 kPa represent the stress at the top of the base layer, 100 kPa is at bottom of the base layer, while 25kPa is a general load in the embankment. Besides the selected deviatoric stresses, various cycle numbers have also been selected. For all compaction ratios and under the impact of 25 kPa and 100 kPa the samples were loaded for 40,000 cycles while under the impact of 200kPa the samples were loaded for 100,000 cycles. The selected cyclic stresses have been applied to the samples sequentially after the desired number of cycles has been reached.

Furthermore, because FGA contains a high amount of pores according to the nature of the structural composition of the material, in the case of the used FGA, it was 92.7%; also, there were a high amount of void ratios between the particles in their bulk condition due to the big particle size nature of the material. Therefore, the impact of long-term cycle stresses on the dynamic behavior of the material has been investigated in this study. An electro-hydraulic actuator with a 100 kN capacity was used in the axial loading condition. To measure the vertical strain (ε), a pair of linear variable displacement transducers (LVDTs) were placed on both sides at the top of FGA samples. The applied cyclic load frequency in the one-way dynamic compressional test was set to be 1.0 Hz simulating traffic loads on the roads.

3. RESULTS AND DISCUSSION

3.1. Static compressional modulus

Based on the stress-strain curves obtained from the static compressional tests conducted on five to eight FGA test samples, the compressional modulus (E_{oed}) values have been calculated. The mean values the E_{oed} under varying compaction ratios and static compressional loads ranging from 50 kPa to 300 kPa with 50 kPa intervals are presented in Table 1.

Table 1. Calculated values of Eoed (MPa) for all loading steps and compaction ratios.

Comp. ratio (%)	E_{oed} (MPa) Applied loads (kPa)					
	50	100	150	200	250	300
10	7.5	8.5	8.0	6.0	5.0	4.0
20	9.5	12.5	14.0	15.0	15.5	13.0
30	8.5	11.0	13.5	15.5	17.5	19.0
40	10.0	14.5	17.5	19.5	21.5	23.0

According to the Table 1, it is strange that the oedometric modulus was decreasing in 10% and 20% compaction ratios, while in 30% and 40% compaction ratios, the oedometric modulus continued to increase under all tested compressional loads. These findings indicate that the material at lower compaction ratios (10% and 20%) became progressively softer with higher compressional loads. Conversely, the consistently elevated oedometric modulus values suggest that the material exhibited stiffness and stability similar to conventional soils like sandy soil, which hardens. This implies that the material could be considered for geotechnical applications under similar loading conditions by providing the valuable insights for geotechnical engineers in selecting suitable compressional modulus for specific projects or applications.

As appears from the results of Table 1, the oedometric modulus of the examined FGA at 10% compaction and under the impact of 50kPa was about 7.5 MPa then it raised up to 23 MPa when compacted by 40% under the impact of 300 kPa. In this regards, the present study results is in harmony with the study of Steurer Steurer (2012) conducted a comprehensive study involving large-scaled and oedometric laboratory compression tests to investigate the load-deformation behavior of foam glass aggregates. According to his study finding, by rising the compaction ratio from 10% to 25% an increase in the stiffness modulus was also appeared. Additionally, Steurer (Steurer, 2012) observed a higher stiffness modulus compared from the long-term confined compression test ranging from 30 MPa to 43 MPa under the same compressional stress impact compared to the of the present study ranging from 100 kPa to 300 kPa. According to the authors' perspective, the higher compressional modulus observed in the mentioned study can be attributed to the greater compressive strength of the foam glass aggregate grains, which was measured at 2100 kPa. In our case, the compressional strength was approximately 1200 kPa.

3.2 Resilient modulus

The Mr values of FGA samples at different compaction ratios and under various deviatoric stresses are shown in Figure 2.

As it can be seemed from Figure 2 the decrease in Mr value was appeared parallel with an increase in the amount of compaction ratios from 10% to 40%. This considered a reverse behavior compared to other geomaterials. According to the study of Liu et al. (2019) which has been executed on dynamic and static resilient modulus of six types of sub-grade soils. They observed that dynamic and static resilient modulus was positively related to increasing the compaction degree and increased the amount of dynamic, resilient modulus by about 21%-26% when the compaction degree elevated from 90% to 93%. This behavior of FGA may be related to the impact of extra applied compaction energy to get the desired compaction ratio, which affects the material's dynamic response. FGA is considered a fragile material; this reality was practically observed by previous scholars (Lenart and Kaynia, 2019), making the material particles behave in a brittle condition under the effect of impact actions that happened during the sample preparation process. At a low compaction ratio, the material subjected to a lower amount of compaction energy saves the manufacturing properties of the particles connected at small connection areas. While to reach a high compaction ratio, a much higher amount of impact compaction energy was applied over the samples of FGA, leading to an increase in the connection area between the particles. Although, the overall skeleton of the material became stiffer to resist the applied external stresses due to better interlocking. But on the other hand, under the impact of high compaction energy, the walls, and the struts of the pores at the connection areas of FGA particles locally (completely or partially) failed and led to collect microfine deposits between the connection areas of the particles. This reality was observed clearly during the experimental work when the material was taken out from the molds. Therefore, the particles of the material were only crushed under the effect of applied impact compaction at the connection areas when the maximum strength was generated. In this regard Mustafa et al. (2022) observed from the density and porosity analysis of

foam glass material and foam glass aggregates that the total voids decreased by 4.8% compared to the material density and by 3% compared with as received bulk density after compacting FGA by 40% compaction. These were because of a decrease in the void ratios and the micro- or macropores crushing under the impact of the elevated impact compaction process. As a result, due to the material's lightweight properties, the particles' connected area behaved like a micro spring when subjected to cyclic loads and made the material gain some extra elastic recoverable strain. Since the same equation (2) was used during the calculation process for all compaction ratios, a less resilient modulus was obtained when the compaction ratio elevated due to a bigger amount of recoverable elastic strain.

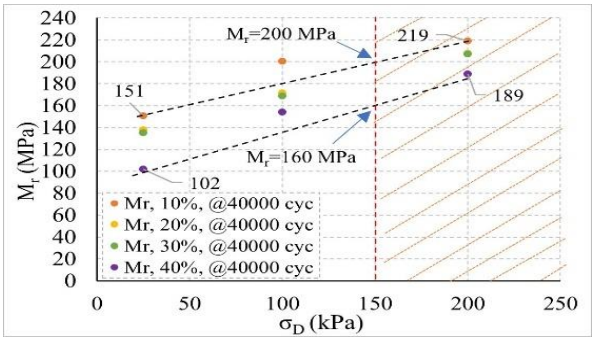

Figure 2. Boundary limits of the resilient modulus of FGA at different compaction ratios.

3.3 Elastic and plastic vertical strains

The results which obtained from both of static and uniaxial cyclic test that applied at the same boundary conditions (oedometric test) and compaction ratios (10%, 20%, 30%, and 40%) on FGA samples are presented in Figure 3. Since all samples were subjected to the same amount of loads starting from 50kPa to 300kPa with 50 kPa. Therefore, the evaluations have been made between amounts of total vertical strains obtained from both of static and dynamic tests.

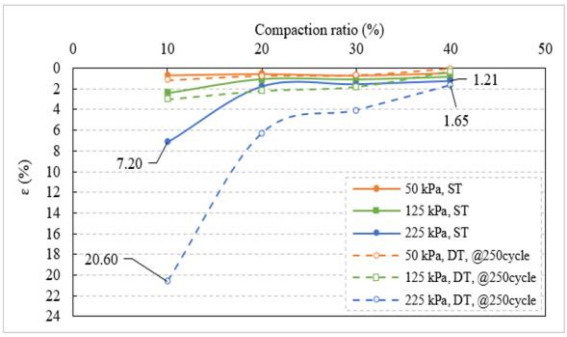

Figure 3. Effect of static and one-dimensional dynamic compression loads at various compaction ratios after 250cycles at 40,000cycle.

As appeared from Figure 3, the vertical strain exhibited by FGA in both static and uniaxial dynamic tests displayed a similar pattern of improvement. The dynamic test showed a greater disparity in strain values at lower compaction ratios of 10% and 20%, with an increase of around 15%. However, this disparity was reduced at higher compaction ratios of 30% and 40%, resulting in a difference of approximately lower than 3% at the same applied load. This condition was observed after deducting the amount of settlement obtained at the beginning 250cycles for both 30%, and 40%. This condition obtained in site under the impact of construction machine and before starting the real service life of the material as a construction material. This result considered very valuable for the practical purposes since it is more convenient to rely on static tests rather than dynamic tests to determine the final vertical strains, because static tests are easier to execute and analyse.

4. CONCLUSIONS

FGA is an extremely innovative material made from recycled glass waste. The material is durable and resistant to environmental effects, so it can be used in structures under the ground. Due to environmental protection requirements, it is a good technical solution for the thermal insulation of the underground parts of buildings, and it is also possible to reduce the amount of primary aggregate used in these places. As a light filling material, in the case of roads passing through soft, organic soils, it can be used as a filling material to avoid costly embankment foundations, which is also more beneficial from an environmental point of view. In contrast, retaining structures have advantages, where the reduction of lateral earth pressure can reduce the cross-section of structures.

When designing these structures, it is essential to know the strength characteristics of FGA. The oedometric modulus of the FGA was determined with laboratory measurements.

The compression modulus of the FGA was determined with laboratory measurements under different compaction conditions. The test results (elastic modulus) illustrated that at 10% and 20% compaction ratios, the material shows behavior similar to compressible soils, while at 30% and 40% compaction ratios, it can already provide the properties of good soils, such as sand and gravely sand soils. Based on the cyclic load tests, the material is also sufficiently resistant to dynamic loads, so it can also be designed for cyclic loads caused by vehicles using the Mr value determined by our measurements.

By comparing the settlements caused by static and dynamic loads, it was seen that the FGA is not sensitive to cyclic loading. It does not develop a larger settlement under cyclic loading in the long term than if it were statically loaded with the same pressure.

ABSTRACT: The adoption of advanced constitutive models based on the Critical State Soil Mechanics framework present both advantages and challenges. The former are well established and relate to improvements in accuracy and, due to the frequent use of the framework in explaining soil behaviour, a calibration process which is frequently simpler. However, their use in modelling of clays means that consistency between different soil properties, such as undrained shear strength and overconsolidation ratio, needs to be insured. The application of one of such models is explored in this paper in the context of offshore foundations. The influence on the lateral capacity of the foundations of different profiles of undrained shear strength, a property which is not prescribed but rather interpreted from the model parameters and initial conditions, is shown to be substantial at all values of displacement. Similarly, the use of a highly non-linear model for the shear stiffness is explored and the impact of the associated parameters is observed to be confined to the lateral stiffness of the monopile under small lateral loads.

RÉSUMÉ: L'adoption de modèles constitutifs avancés basés sur la mécanique des sols à l'état critique présente des avantages et des défis. Les premières sont bien établies et concernent l'amélioration de la précision et, en raison de l'utilisation fréquente de la mécanique des sols à l'état critique pour expliquer le comportement du sol, il est plus facile de calibrer le modèle de sol. Cependant, leur utilisation dans la modélisation des argiles signifie que la cohérence entre les différentes propriétés du sol, telles que la résistance au cisaillement non drainée et l'état de surconsolidation, doit être assurée. L'application de l'un de ces modèles est explorée dans cet article dans le contexte des fondations monopieux. La capacité latérale des fondations de différents profils de résistance au cisaillement non drainé, une propriété qui n'est pas prescrite mais interprétée à partir des paramètres du modèle et des conditions initiales, est substantielle à toutes les valeurs de déplacement. L'utilisation d'un modèle non linéaire pour la rigidité au cisaillement est explorée et l'impact des paramètres de ce modèle est limité à la rigidité latérale des fondations monopieux soumises à de faibles charges latérales.

Keywords: Monopile foundations; offshore geotechnics; numerical modelling; clays.

1 INTRODUCTION

The use in design of constitutive models based on Critical State Soil Mechanics (Schofield and Wroth, 1968), a framework employed for explaining the observed behaviour of clays prepared to a variety of initial conditions, facilitates their effective calibration, as model parameters tend to match well described properties (e.g. compressibility, shear strength at Critical State, effect of overconsolidation). However, there are considerable challenges arising from translating properties that are often measured, but are not intrinsic to the material, as they depend fundamentally on its current state, such as the undrained shear strength. This paper explores these issues using the extended version of the Modified Cam-clay model (MCC) described in Tsiampousi et al. (2023) in the context of the capacity of monopile foundations subjected to lateral loading.

2 NUMERICAL MODEL

2.1 Details of the model

A monopile foundation with diameter $D = 5\,m$ and embedment depth $L = 50\,m$ (i.e. embedment ratio $L/D = 10$) was considered in this study. The load was applied as a prescribed displacement at a height $H = 50\,m$ (i.e $H/D = 10$) The problem was simulated in

PLAXIS 3D, with the soil domain extending to $50\,m$ (i.e $10D$) either side of the monopile and down to a depth of $70\,m$ (i.e. $14D$). The soil was modelled using 193167 10-noded tetrahedral elements, with smaller elements used in the immediate vicinity of the pile. The monopile was modelled using 4402 6-noded plate elements (linear-elastic, $E = 200\,GPa$, $\nu = 0.3$), with a simulated thickness of $t = 62.5\,mm$ $(t/D = 80)$. The interaction between the monopile and the surrounding ground was modelled using 12-noded interface elements, the strength of which (denoted herein by τ_{int}) was obtained using the methodology proposed in API (2011) and DNV (2014):

$$\tau_{int} = \alpha \cdot S_{u,TXC} \quad (1)$$

$$\alpha = \begin{cases} 0.5 \cdot R^{-0.5}, & R \leq 1 \\ 0.5 \cdot R^{-0.25}, & R > 1 \end{cases} \quad (2)$$

where $R = S_{u,TXC}/\sigma'_v$, σ'_v is the vertical effective stress and $S_{u,TXC}$ is the undrained shear strength of the soil under triaxial compression loading conditions. In general, this approach produces a slight non-linear variation close to the surface, where σ'_v approaches 0. Therefore, linear profiles approximating the outcome of Equation (1) were used, described in Section 2.3. Crucially, for this type of problems, these elements are able to simulate the opening of a gap under tensile stresses that tend to be observed at the back the pile when subjected to lateral loading.

2.2 Constitutive model

An enhanced Modified Cam-clay model was used, combining the original formulation for normally consolidated and lightly overconsolidated clays with a non-linear Hvorslev surface (Tsiampousi et al., 2013) on the dry side of critical and a hypoelastic model linking the shear stiffness of the material to the stress and strain levels (Taborda et al., 2016). This model differs from that used previously in the PISA project for the simulation of Cowden till (Zdravkovic et al., 2020b) only in the fact that it employs a Mohr-Coulomb shape in the deviatoric plane, rather than a generalised shape. Therefore, the strength at Critical state, as measured by the mobilised angle of shearing resistance, is independent of the loading conditions, which means that the slight stress-induced anisotropy observed for Cowden till (Zdravkovic et al., 2020a) cannot be reproduced using the formulation adopted herein. The full formulation of the model, designated IC MAGE M06, is described in Tsiampousi et al. (2023). It has been implemented as a User-Defined Soil Model in PLAXIS within the UMIP framework (Taborda et al., 2023) and is integrated using a modified Euler scheme with automatic substepping and error control.

The model parameters adopted for Cowden till are outlined in Table 1 and are based on those reported in Zdravkovic et al. (2020a, 2020b).

Table 1. Parameters for Cowden till based on Zdravkovic et al. (2020b).

Parameters for Cowden till			
G_{ref}	$110\,MPa$	ν_1	2.200
p'_{ref}	$100\,kPa$	κ	0.021
m_G	1.0	λ	0.115
a	9.78×10^{-5}	α_{HV}	0.250
b	0.987	n	0.400
$R_{G,min}$	0.050	β_{HV}	0.200
ϕ	27.0°	m	1.000

2.3 Analysed cases

The first objective of this paper was to evaluate the impact of the assumed undrained shear strength profile. Given that properties, such as compressibility and shear strength at Critical State, are considered to be intrinsic to the material, matching a given value of undrained shear strength is achieved by determining the required value of OCR, a process which is detailed in Zdravkovic et al. (2020b). In the implementation of IC MAGE M06, this is an automatic procedure, i.e. in practice, S_u is supplied as an input parameter, though this is then converted into OCR, which varies in depth. The three profiles studied – listed in Table 2 together with the corresponding undrained shear strength profile for the interfaces – include an approximation to that assumed in Cowden, as well as two variations consisting of lower and higher values of this property ($\pm 60\,kPa$ at surface but same value at a depth of $100\,m$). Moreover, when adjusting the value of OCR, the coefficient of earth pressure at rest, K_0, is also adjusted using $K_0 = (1 - \sin\phi) \cdot \sqrt{OCR}$. The three cases are illustrated in Figure 1.

Table 2. Analysed strength soil and interface strength profiles.

Soil strength	**Interface strength**
$S_u = 90 + 3.2\,z$	$\tau_{int} = 28 + 3.2\,z$
$S_u = 30 + 3.8\,z$	$\tau_{int} = 10 + 3.3\,z$
$S_u = 150 + 2.6\,z$	$\tau_{int} = 48 + 3.0\,z$

The second objective is to analyse the effect of the non-linear law assumed for the elastic shear modulus which is described using the model proposed in Taborda et al. (2016). Of the various parameters employed in this expression, the value of a is chosen for further investigation, since it controls the value of strain at which the stiffness at very small strains

(G_{max}) reduces to half of its value (i.e. larger values of a mean larger values of shear modulus).

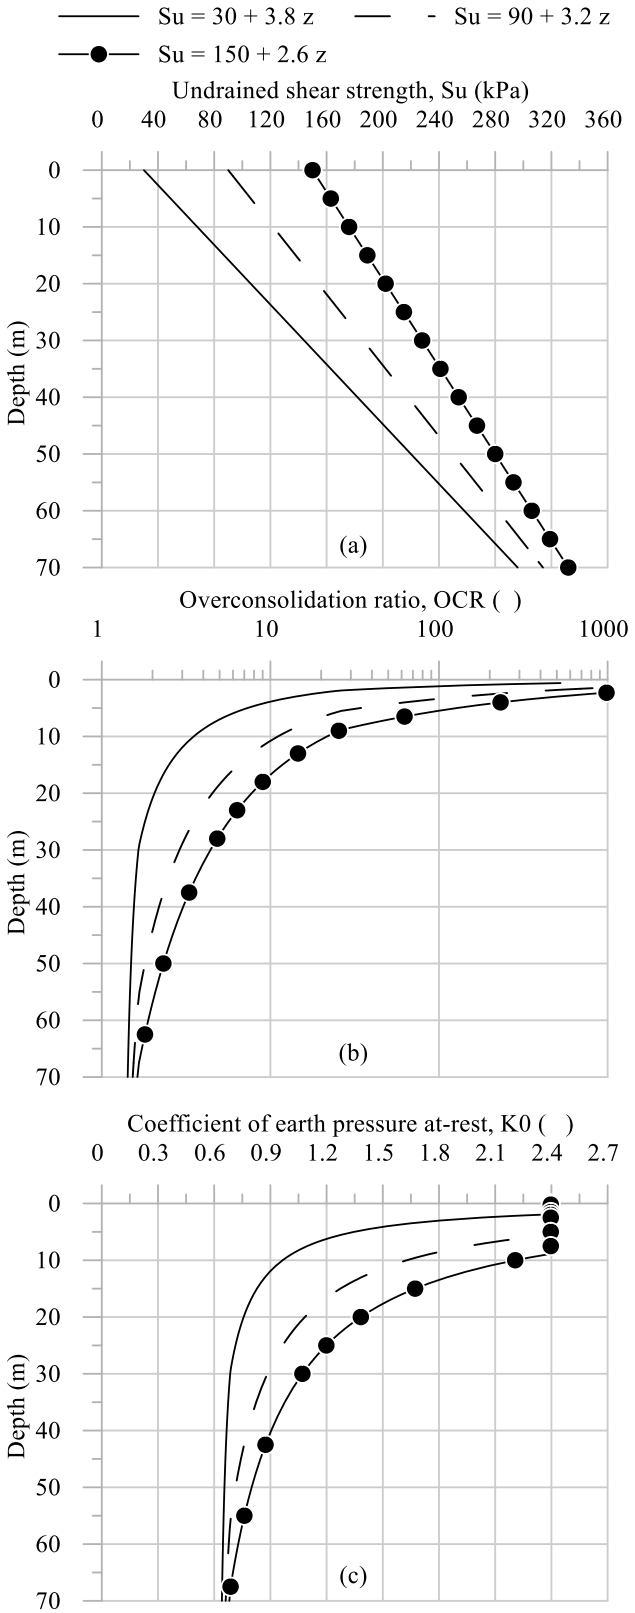

Figure 1. Profiles of (a) undrained shear strength in triaxial compression conditions, (b) overconsolidation ratio and (c) coefficient of earth pressure at-rest.

3 RESULTS

3.1 Effect of undrained strength profile

The obtained results for the three considered profiles are illustrated in Figure 2. As expected, the larger undrained shear strength leads to considerably larger capacities at failure, ranging from about 42 MN to almost 70 MN. It is also interesting to note that the shapes of the three load-displacement curves are similar at very small displacements ($< 0.1\%\ D$), suggesting that this aspect of the response is controlled by the elastic stiffness, which is identical for the three cases considered. Moreover, the capacity of the monopile is reached at different deformations: $50\%\ D$ for the lower strength profile, increasing to $100\%\ D$ for the larger strength case. This shows the difference in the hardening process associated with the various initial OCR profiles, i.e. larger $OCRs$ require larger strains to reach Critical State.

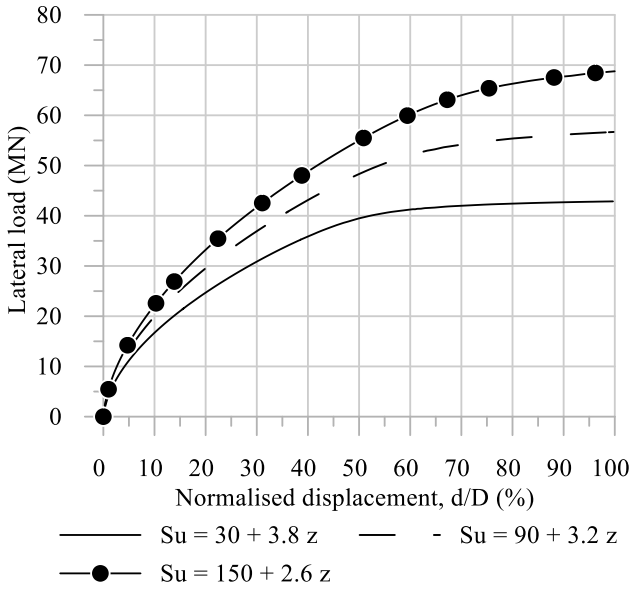

Figure 2. Lateral load-normalised displacement obtained for the various undrained shear strength profiles.

3.2 Effect of stiffness reduction parameters

The impact of varying the value of parameter a by an order of magnitude is shown in Figure 3. As expected, this parameter does not affect the ultimate capacity, though a measurable impact on the load at $10\%\ D$ is still visible ($\pm\ 1\ MN$). Clearly, a much greater impact is observed in terms of lateral stiffness, where a smaller value of a is naturally characterised by a sharper reduction in pile stiffness with lateral deformation. At very small displacements (e.g. $0.1\%\ D$), the stiffness values vary considerably.

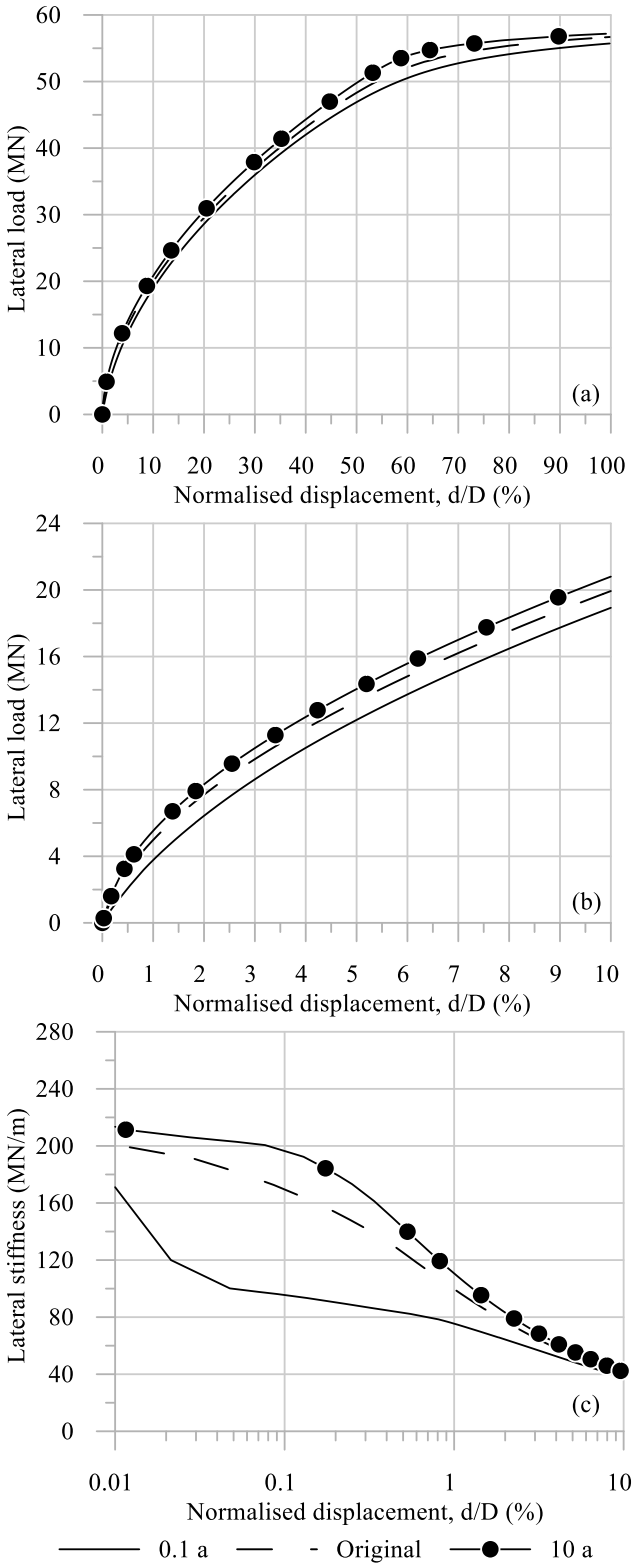

Figure 3. Effect of a on pile response for displacements up to (a) 100%D and (b) 10%D, and on (c) lateral stiffness.

4 CONCLUSIONS

Detailed finite element simulations of laterally loaded monopile foundations in clay deposits using an advanced constitutive model based on Critical State Soil Mechanics highlight the impact of the S_u profile on the pile response – not only in terms of results, but also in terms of the procedure followed to determine the initial conditions (OCR and K_0). Moreover, while the non-linear elastic shear modulus was shown to have limited impact on pile capacity, a substantial effect on monopile stiffness was observed, indicating the importance of adequately characterising and modelling this aspect of soil behaviour.

ABSTRACT: There is growing interest to utilise advanced numerical methods by industry practitioners in the prediction of the long-term response of monopile foundations under lateral cyclic loading. One framework of interest is the High Cycle Accumulation (HCA), as it can overcome the limitations of computational expense and error accumulation encountered by conventional cycle-by-cycle finite element analyses. The authors' implementation of HCA within the finite element package PLAXIS is presented with an emphasis on the framework's key components and underlying assumptions. Furthermore, by coupling HCA with a practice oriented elasto-plastic model for sands, predictions using different HCA calibration approaches are evaluated against the field measurements of a medium sized cyclic lateral pile load test from the Pile-soil analysis (PISA) joint industry project.

RÉSUMÉ: Les professionnels de l'industrie montrent un intérêt croissant pour l'utilisation de méthodes numériques avancées afin de prédire la réponse à long terme des fondations monopieux soumises à des chargements cycliques latéraux. L'Accumulation à Haute Fréquence (HCA) est une des méthodes considérées, car elle peut surmonter les limitations de coût computationnel et les problèmes d'accumulation d'erreurs rencontrées par les analyses conventionnelles par éléments finis cycle-par-cycle. L'implémentation du HCA par les auteurs dans le logiciel de calcul par éléments finis PLAXIS est présentée ici, mettant l'accent sur les composants clés de la méthode et les hypothèses sous-jacentes. De plus, en couplant le HCA avec un modèle élasto-plastique orienté vers la pratique pour les sables, on évalue les prédictions utilisant différentes approches de calibrage du HCA par rapport aux mesures sur le terrain d'un essai de charge latérale cyclique de taille moyenne réalisé lors du projet industriel conjoint Pile-soil Analysis (PISA).

Keywords: Cyclic loading; monopile; finite element analysis; high cycle accumulation; calibration.

1 INTRODUCTION

There is a growing body of research focused on numerical methods for the prediction of long-term rotation of monopile offshore foundations subjected predominantly to regular lateral cyclic loading (Achmus et al., 2009; Staubach & Wichtmann, 2020; Abadie et al., 2023). However, translating these methods from research to design practice require both rigorous validation against large scale field tests and studies on calibration sensitivity. Greater applicability will also be found for methods whose calibration intensity can be adapted to availability of site-specific data.

The High Cycle Accumulation (HCA) framework proposed by Niemunis et al. (2005) is used here to predict the accumulated rotation of the 0.76m diameter (D) lateral cyclic pile load test in Dunkirk Sand from the PISA project (Byrne et al., 2020). Single element and field scale predictions from two calibration approaches are presented.

2 THE HCA FRAMEWORK FOR SANDS

In response to the numerical difficulties of simulating the cycle-by-cycle response of thousands of loading cycles, the HCA framework for sands proposes that the magnitude and direction of stress and strain changes due to repeated loading can be characterised directly by:

- A one-cycle cyclic strain amplitude $\|\varepsilon_{ampl}\|$,
- a history variable g^A capturing the number of cycles N and evolution of $\|\varepsilon_{ampl}\|$,
- the current (average) stress state $\{\sigma\}$,

- the current (average) void ratio e, and
- a set of material dependent properties.

When using the HCA framework in conventional finite element (FE) analyses, $\|\varepsilon_{ampl}\|$ is determined at each integration point by processing the strain path undergone over one regular loading cycle (Niemunis et al., 2005).

2.1 Low-cycle sand model

The low-cycle elasto-plastic model used herein is a non-linear elastic model capable of Masing hysteresis (Taborda et al., 2016) coupled with state-parameter driven plasticity based on the Mohr-Coulomb yield criterion (Taborda et al., 2022). Implementation details are found in Taborda et al. (2023).

2.2 High-cycle framework implementation

The incremental HCA stress-strain relation is:

$$\{\Delta\sigma\} = \left[D_{HCA}^{ela}\right]\{\Delta\varepsilon^{ela}\} \quad (1)$$

$$\{\Delta\varepsilon^{ela}\} = \{\Delta\varepsilon^{t}\} - \{\Delta\varepsilon^{acc}\} - \{\Delta\varepsilon^{p}\} \quad (2)$$

$$\{\Delta\varepsilon^{acc}\} = \left\{\frac{\partial\varepsilon^{acc}}{\partial N}\right\}\Delta N \quad (3)$$

where $\{\Delta\sigma\}$ is the local stress step, $\Delta\varepsilon^{ela}$, $\Delta\varepsilon^{t}$, $\Delta\varepsilon^{p}$, $\Delta\varepsilon^{acc}$ are respectively the elastic, total, plastic and accumulated strain steps. $\left[D_{HCA}^{ela}\right]$ is the HCA isotropic elastic stiffness matrix described by K_{HCA} and ν_{HCA}, and is dependent on e and mean effective stress (p'):

$$K_{HCA} = K_{HCA}^{ref} \cdot f_K(e) \cdot \left(\frac{p'}{100}\right)^{m_{K,HCA}} \quad (4)$$

where K_{HCA}^{ref} and $m_{K,HCA}$ are material parameters and $f_K(e) = (1.63 - e)^2/(1 + e)$ follows Wichtmann et al. (2013) as modified from Hardin & Richart (1963).

The plastic strain step is determined via standard elasto-plastic integration employing the low-cycle model yield surface and plastic potential, using a modified total strain step $\{\Delta\varepsilon^{t}\} - \{\Delta\varepsilon^{acc}\}$.

The empirical function from Wichtmann (2016) driving the prediction of the average strain change due to an increment of stress cycles (and vice-versa) is formed of a direction $\{\vec{m}\}$ and a scalar magnitude:

$$\left\{\frac{\partial\varepsilon^{acc}}{\partial N}\right\} = \{\vec{m}\} \cdot \frac{\partial f_N}{\partial N} f_{ampl} f_e f_p f_Y \quad (5)$$

where $\{\vec{m}\}$ is the unit norm of the Modified Cam Clay surface, whose size (and hence the accumulation direction) is described by a single material parameter ϕ_{HCA}. The magnitude is dependent on 9 material parameters: ϕ_{HCA}, and C_{ampl}, C_e, e_{max}, C_p, C_Y, C_{N1}, C_{N2}, C_{N3}, three state variables e, g^A and $\|\varepsilon_{ampl}\|$, and the current stress state represented by invariants p', J and θ with $\eta = J/p'$ (where J is the deviatoric stress invariant and θ the Lode-angle). The f-factors are:

$$\frac{\partial f_N}{\partial N} = C_{N1}C_{N2}\, exp\frac{-g^A}{f_{ampl}C_{N1}} + C_{N1}C_{N3} \quad (6)$$

$$f_{ampl} = \left[min\left(\frac{\|\varepsilon_{ampl}\|}{10^{-4}}, 10\right)\right]^{C_{ampl}} \quad (7)$$

$$f_e = \left(\frac{C_e - e}{C_e - e_{max}}\right)^2 \cdot \frac{1 + e_{max}}{1 + e} \quad (8)$$

$$f_p = exp\left(-C_p\left(\frac{p'}{100} - 1\right)\right) \quad (9)$$

$$f_Y = exp(C_Y \cdot Y) \quad (10)$$

where Y is a measure of stress ratio normalised by the Matsuoka-Nakai yield surface defined using ϕ_{HCA}.

$$Y = \left[\frac{9 - 3\eta^2}{1 - \eta^2 + \frac{8\sqrt{3}}{9}\eta^3\left(\sin^3\theta - \frac{3}{4}\sin\theta\right)} - 9\right] / [8\, tan^2\, \phi_{HCA}].$$

g^A initialises as 0 assuming no pre-cycling; its evolution incorporates the combined effect of ΔN and strain amplitude magnitude via f_{ampl} as follows:

$$\Delta g^A = \Delta N f_{ampl} C_{N1} C_{N2}\, exp\frac{-g^A}{f_{ampl}C_{N1}} \quad (11)$$

2.3 Implementation in PLAXIS

A user-defined soil model (UDSM) "flag" allows different integration behaviour using the same UDSM at different phases: (1) Low-cycle, no record, (2) Low-cycle, strain recorded, (3) Strain processed or 'HCA initialisation' and (4) HCA accumulation.

A two-stage modified-Euler with automatic sub-stepping and error control integration algorithm is used during (4). Given an incoming total strain step $\{\delta\varepsilon^{t}\}$, a forward $\{\delta\varepsilon^{acc}\}_1$ and a backward $\{\delta\varepsilon^{acc}\}_2$ accumulation step is first calculated using equations (3) and (5) to (11). Intermediate forward and backward stresses are then calculated, and their average and difference are used as the initial error control measure. After a suitable sub-step size is determined, a 'modified' total strain sub-step $\{\delta\varepsilon^{t}\} - \frac{\{\delta\varepsilon^{acc}\}_1 + \{\delta\varepsilon^{acc}\}_2}{2}$ is used in the conventional elasto-

plastic integration. If the underlying yield surface is inactive, the first stage suffices.

3 MODEL CALIBRATION FOR DUNKIRK SAND

3.1 Low-cycle (conventional) model

The low-cycle calibration used the laboratory and field data reported during the PISA project (Taborda et al., 2020) and followed the method outlined by Taborda et al. (2022). Material parameters used here are those reported by Pirrone and Taborda (2023).

3.2 High-cycle strain accumulation

Dunkirk sand laboratory test data for $\varepsilon_{ampl}(N)$ and $\varepsilon_{acc}(N)$ for eleven drained cyclic triaxial tests (DcycTX) is available in Liu (2018). Two parameter sets were calibrated for Dunkirk Sand:

(i): Using granulometry correlations (Wichtmann, 2016) for all $C_$ parameters and $\phi_{HCA} = \phi'_{cs}$, and

(ii): C_{ampl}, C_e, C_p, C_Y, C_{N1}, C_{N2}, C_{N3}, ϕ_{HCA} fitted to all 11 DcycTX tests.

For brevity, the simple brute-force strategy in Wichtmann et al. (2015) was used to fit (ii). 100,000 parameter combinations were picked out using a latin hypercube sampler. The value of $\|\varepsilon^{acc}\|$ was calculated using an integration driver for equation (5). A non-weighted average root mean squared error was calculated for each laboratory test at 21 cycle numbers evenly (log-) spaced between $N = 1$ and $N = 10000$. A simple mean of this error across all eleven tests is then calculated to determine the best (smallest error) set of parameters.

As expected, calibration procedure (ii) produced a better fit against strain accumulation measured in element laboratory tests. However, the granulometry correlations also gave a reasonable fit against element tests and a first estimate of HCA parameters.

Table 1. Summary of calibrated HCA parameters.

	(i)	(ii)
C_{ampl}	1.7	1.8
C_e	0.51	0.0050
C_p	0.46	0.28
C_Y	2.2	2.9
C_{N1}	7.0E-4	1.2E-4
C_{N2}	0.22	0.57
C_{N3}	4.7E-5	1.5E-5
ϕ_{HCA}(°)	32	29
e_{max}	0.91 (Liu, 2018)	
K_{HCA}^{ref} *	120,900 kPa	
ν_{HCA}^{ref} *	0.32	

*Values from Wichtmann (2016:p.211) for fine sand

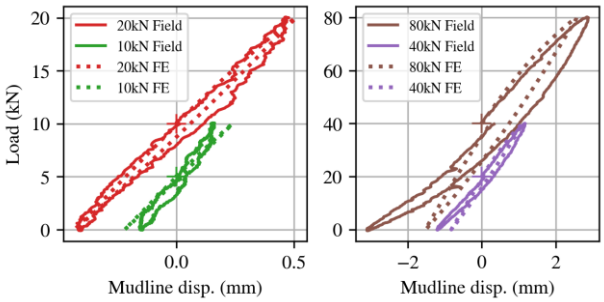

Figure 1. Low-cycle FE versus one-way field response.

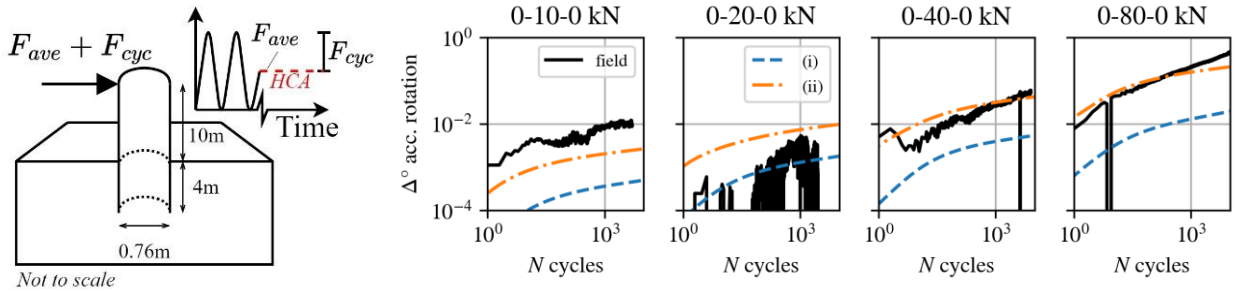

Figure 2. FE schematic and HCA simulation results compared against measured field response at mudline level.

4 FE MONOPILE PREDICTION

The initial HCA recording stage showed a reasonable match between the low-cycle model prediction and the field response (Figure 1) for the medium-sized (D=0.76m) one-way cyclic lateral pile test at Dunkirk (Byrne et al., 2020) loaded to 10 kN (N=5100), 20 kN (N=3300), 40 kN (N=8100) and 80 kN (N=11110). All analyses assumed a drained response in the sand.

In contrast to the single element response, the two calibration procedures differed by an order of magnitude in the prediction of accumulated pile head rotation (Figure 2). This is likely associated with the highly sensitive C_e parameter. The single element sensitivity reported in Wichtmann et al. (2015) seems further magnified for field-scale predictions.

5 CONCLUSION AND FURTHER WORK

A brief evaluation of the use of the HCA framework to design monopiles subjected to regular lateral loading is presented. Comparison between FE results and the field response suggests that a detailed programme of site specific drained cyclic triaxial tests is required to calibrate HCA parameters for engineering use.

Further sensitivity studies are essential to guide practitioners in the use of the HCA framework for long-term cyclic predictions, especially if calibrating using a combination of correlations and laboratory tests. An assessment of drainage effects, strain amplitude update, incorporation of sophisticated low-cycle models, and associated problems with state variable update are all keenly needed. A next step for design is to assess HCA's capability to predict soil state (e.g. void ratio distribution) and global stiffness evolution to inform dynamic and fatigue limit state design.

ABSTRACT: The objective of this study is to examine geotechnical research trends in floating offshore wind energy during a period from 1972 to 2022 via a bibliometric analysis. Using Web of Science database, 7600 articles were obtained in a variety of journals, conferences, books and series. The results indicate that the number of published articles in geotechnical engineering topics in offshore wind, and specifically on floating offshore wind, are increasing worldwide each year. Among the offshore geotechnical studies Norway, Denmark and the UK are the top contributing countries. Majority of the articles belonging to the GEO-group are about the fixed-bottom type offshore wind turbines (monopile, jacket, tripod etc.). Among the articles related to floating-type offshore wind turbines, drag embedded anchors, vertically loaded anchors, multiline anchors, pile driven plate anchors, dynamically embedded plate anchors, suction embedded plate anchors were commonly studied. As technological developments in floating offshore wind are gaining attention (e.g. seabed anchor alternatives, buried cables in seabed, shared mooring lines and shared anchors etc.) we foresee an increase in the number of articles. There seems to be a limited number of research which combines experimental and numerical modelling approaches. Research on risk, reliability-based probabilistic methods is expected to increase. Among the loading conditions, limited studies are available for seismic loading. These aspects are expected to be further investigated in the coming years. Results from this bibliometric study may highlight the current status and future trends in offshore geotechnical engineering research.

RÉSUMÉ: L'objectif de cette étude est d'examiner les tendances de la recherche géotechnique sur l'énergie éolienne offshore flottante sur une période allant de 1972 à 2022 via une analyse bibliométrique. Grâce à la base de données Web of Science, 7 600 articles ont été obtenus dans diverses revues, conférences, livres et séries. Les résultats indiquent que le nombre d'articles publiés sur des sujets d'ingénierie géotechnique liés à l'éolien offshore, et en particulier sur l'éolien offshore flottant, augmente chaque année dans le monde. Parmi les études géotechniques offshore, la Norvège, le Danemark et le Royaume-Uni sont les principaux pays contributeurs. La majorité des articles appartenant au groupe GEO concernent les éoliennes offshore de type à fond fixe (monopile, jaquette, trépied etc.). Parmi les articles relatifs aux éoliennes offshore de type flottant, les ancres encastrées par traînée, les ancres chargées verticalement, les ancres multilignes, les ancres à plaques enfoncées sur pieux, les ancres à plaques encastrées dynamiquement, les ancres à plaques encastrées par aspiration ont été couramment étudiées. À mesure que les développements technologiques dans le domaine de l'éolien offshore flottant attirent de plus en plus l'attention (par exemple, alternatives d'ancrage au fond marin, câbles enterrés dans le fond marin, lignes d'amarrage et ancres partagées, etc.), nous prévoyons une augmentation du nombre d'articles. Il semble exister un nombre limité de recherches combinant des approches de modélisation expérimentale et numérique. La recherche sur les méthodes probabilistes basées sur le risque et la fiabilité devrait se développer. Parmi les conditions de chargement, des études limitées sont disponibles pour le chargement sismique. Ces aspects devraient être approfondis dans les années à venir. Les résultats de cette étude bibliométrique peuvent mettre en évidence l'état actuel et les tendances futures de la recherche en ingénierie géotechnique offshore.

Keywords: Bibliometric analysis; offshore wind; geotechnical engineering.

1 INTRODUCTION

There is a global goal of reaching to 380 GW of offshore wind energy by 2030, as stated by The Global Offshore Wind Energy Compact (IRENA and GWEC, 2021). Fixed-bottom offshore wind has been in research forefronts, whereas research on floating offshore wind is accelerating. It is estimated that the number of floating wind turbines is expected to far exceed, by at least an order of magnitude, the number

of installed oil and gas facilities, by the end of this decade (Gourvenec et al., 2022).

The objectives of this study is to investigate the current status of geotechnical research and publications on offshore wind energy, specifically for floating offshore wind, in terms of its change over the years, classification of published articles with their topics, comparison of the countries' performance, type of foundations, research methods used in geotechnical articles, and the loading conditions studied. The analyses may highlight the current research trends and future research needs in geotechnical engineering specifically for floating offshore wind energy.

2 METHODOLOGY AND DATA

Bibliometric analysis is a quantitative method for processing and analysing data on publications in the literature. It can help identify the current status, trends and topics for guiding future studies (Tsay, 2008).

The data was obtained from Web of Science (WoS) collection as it is one of the widely used and trusted international databases on publications. Furthermore, the data can be downloaded and processed in an easy way and format. The data collection was completed in July 2022. Although, the data does not include all of the publications in 2022, it can provide sufficient information on research trends for the purposes of this study.

From 1945 to present, the Web of Science all databases system is searched with keywords and their combinations, such as: offshore wind, floating wind turbines, floating offshore wind / geotechnics / power system / energy / CFD / farm / liquefaction / platform / power plant / structure / turbine, FOWT and OFWT.

This study analyses 7600 papers which were published between 1972-July 2022. The dataset includes publication type, authors, author affiliations, article title, keywords, classification, corresponding author country, source title (journal, conference name), publication date, times-cited in WoS all databases, and their abstracts. The data is checked for duplicate information and organized via a spreadsheet, then it was analysed.

The articles are classified in seven groups which are abbreviated as ECON, ELEC, ENV, HYD, MEC, GEO, and OTHERS (see Table 1 for keywords of groups). For instance, articles in the GEO group cover geotechnical engineering related topics such as reliability of offshore wind farms with multiline anchors, lateral capacity of monopiles in sand etc. The titles, keywords and abstracts were evaluated to determine the group of the articles. The reason for this classification was to investigate the number of studies and trends in different research areas, focusing more on geotechnical engineering.

Table 1. Article groups used in classification of 7600 articles on offshore energy topics.

Article Groups	Example keywords
ECON (Economy / Planning)	Economy, resource assessment, Levelized Cost of Energy (LCOE), site selection, micro-siting, GIS, renewable energy, life-cycle assessment, policy
ELEC (Electricity / grid)	Electricity, grid, HVDC, AC-DC, transistor, automation and control, drivetrain, gear, power, computer science
ENV (Environment)	Environment, biology, sea temperature, marine life, meteorology & climate, atmosphere, global warming
HYD (Hydraulics / Hydromechanics)	Hydrodynamics, Computational Fluid Dynamics (CFD), wave model, wave energy, FAST, WASP, openFOAM, ship, tidal energy, naval
MEC (Mechanics)	Materials science, mechanical design, gear, structural stability, fatigue, wake, foil, aerodynamics
GEO (Geotechnics)	Geotechnics, foundation design, floating systems, soil, geology
OTHERS	Oil and petroleum, natural gas

3 RESULTS

3.1 Total number of publications in all floating offshore energy topics according to countries & years

The data includes 7600 articles from 85 countries. 5471 of these articles are journal articles, and the rest are published in conferences, books and series. In Figure 1, the number of published articles in each year from 1972 to July 2022 can be seen. Between 1972 and 1997 the number of publications were less than 5 per year (Figure 1). After 2000′s, the rate of increase in the number of publications increases.

Between 2020-2021, the number of published articles decreased, which might possibly be related to Covid-19 Pandemic starting in March 2020. The article search in this study was completed in July 2022, so the decrease in the number of published articles in 2022 in Figure 1 should be ignored.

Countries' contributions should be considered in bibliometric research to comprehend the global distribution of research and to identify the leading countries in the area.

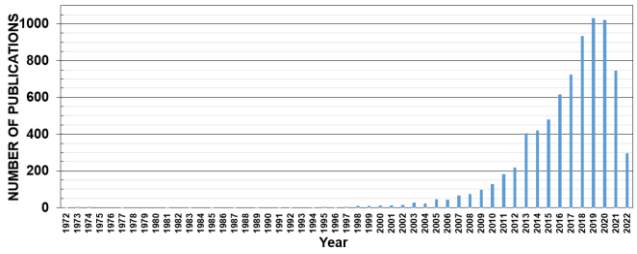

Figure 1. Number of publications about offshore wind from 1972 to 2022.

In Table 2, the top 10 contributing countries (corresponding author's country) in terms of the number of published papers on the topic of offshore wind can be seen. About 68% of 7600 articles belong to these 10 countries. Out of 7600 articles in the dataset, the highest number of articles (1424, 18.7%) is by China, followed by the USA (10.3%) and England (6.4%). The majority of the articles are in MEC (19.3% of 7600 articles), ECON (14.2%), ELEC (13%) groups/topics.

Table 2. The top 10 countries contributing to 7600 publications (percentage is out of 7600 publications).

Rank	Country	ECON	ELEC	ENV	HYD	MEC	GEO	OTHERS	Total
1	China	172	291	40	168	464	241	48	1424
2	USA	213	96	66	103	206	69	29	782
3	England	129	79	24	37	135	71	11	486
4	Norway	92	71	22	50	159	53	30	477
5	Denmark	112	102	17	25	93	43	6	398
6	Germany	97	81	28	30	105	43	10	394
7	South Korea	52	69	12	53	134	43	18	381
8	Spain	103	108	17	40	55	33	2	358
9	Scotland	78	56	6	34	46	10	5	235
10	Japan	33	37	9	50	72	19	9	229
		1081	990	241	590	1469	625	168	5164
		14.22%	13.03%	3.17%	7.76%	19.33%	8.22%	2.21%	67.95%

When we normalize the number of publications with the population [29], Norway, Denmark and the UK are the most contributing countries in terms of the number of publications normalized by population, on offshore wind topics: Norway (88 articles/one million people), Denmark (68), the UK (11), the United States (2.4). This may also be correlated with the cumulative installed offshore wind energy capacity indicating the experience in industry and in research.

3.2 Publications in offshore geotechnical engineering topics

When the articles in the GEO group are analysed (842 out of 7600 total number of articles, %11.1), the top 10 contributing countries in terms of the total number of published articles are summarized in Table 3. Out of 842 articles, the highest number of articles (28.6%) is written by researchers in China, followed by England (8.4%) and the United States (8.2%). After normalizing the total number of GEO publications with the population of the country [29], contribution ranking of countries per one million people is as Norway (9.8 articles/one million people), Denmark (7.3), the UK (1.2), the United States (0.21) and China (0.17). Norway is the most impactful country in terms of the number of published articles in the GEO group.

Table 3. Top 10 contributing countries in terms of the number of publications in GEO group.

Ranking	Countries	Number of Published Articles in GEO Group (Percentage among 842)
1	China	241 (28.6%)
2	England	71 (8.4%)
3	The United States	69 (8.2%)
4	Norway	53 (6.3%)
5	Denmark	43 (5.1%)
6	Germany	43 (5.1%)
7	South Korea	43 (5.1%)
8	Australia	37 (4.4%)
9	Spain	33 (3.9%)
10	India	31 3.7%
-	Total	664 (78.9%)

After examining the abstract, title and keywords of the articles in GEO group, they were grouped in 3 different ways:

- the type of the offshore wind turbine studied,
- the research method of the study and
- the loading condition studied.

Table 4. Number of GEO articles in terms of the offshore wind turbine types.

Type of the Offshore Wind Turbine	Number of Published Articles
Floating	295 (35%)
Fixed Bottom	469 (55.7%)
Both (Floating & Fixed Bottom)	17 (2%)
No Information	61 (7.3%)

35% of the GEO articles (295 out of 842) studied floating (Table 4) and 55.7% studied fixed bottom (monopile, suction bucket etc.) offshore wind turbines. Both types were studied in 2% of the articles and no information was found in the remaining articles.

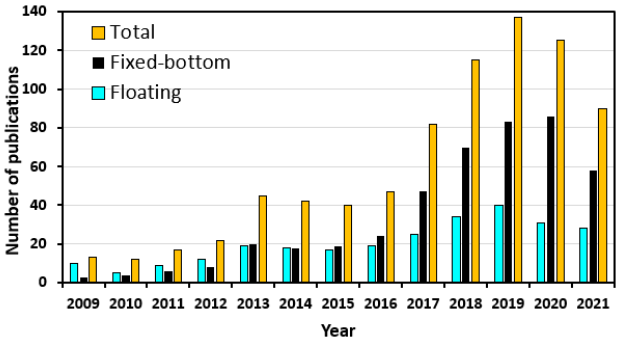

Figure 2. Among the GEO articles, number of publications on the type of wind turbines (studies that have both types and studies with no information are excluded).

In terms of the research method (Table 5), experimental methods (centrifuge test, physical modelling etc.) were used in 23.4% of the GEO articles, numerical methods (ABAQUS, PLAXIS 3D, FLAC3D, MPM etc.) in 45.6%, both experimental and numerical methods were used in 2.7% of the articles.

Table 5. Number of articles in terms of the research method.

Research Method	Number of Published Articles
Experimental	197 (23.4%)
Numerical	384 (45.6%)
Both (Experimental & Numerical)	23 (2.7%)
Probabilistic	39 (4.6%)
Seabed Soil Property	19 (2.3%)
Review	120 (14.3%)
Other	60 (7.1%)

In 4.6% of the articles, probabilistic approach (risk, reliability) was adopted, and in 2.3% seabed soil property/investigation was studied. While 14.3% of were review articles, methods other than the ones mentioned here were used in 60 articles (7.1%).

As for the loading conditions of offshore wind turbines, cyclic loading (wind, wave & current) was studied in 53.9% of 842 GEO articles; seismic loading due to earthquakes in 8.9%, and loading by floating sea ice was studied in 0.4%. Both cyclic & seismic loading and cyclic & ice loading were studied in 1.4% of the articles. For the remaining articles, no information was found.

GEO-related journal articles have been published more frequently in the journals shown in Figure 3. When we look at the individual journal articles having more than 100 citations (times cited in WoS all databases) the top-cited-articles are been published in the following journals (in order): Journal of Renewable and Sustainable Energy, Computers and Geotechnics, Journal of the Acoustical Society of America, Applied Ocean Research, Renewable Energy, Proceedings of The Institution of Civil Engineers-Geotechnical Eng., Journal of Geotechnical and Geoenvironmental Eng., Ocean Eng.

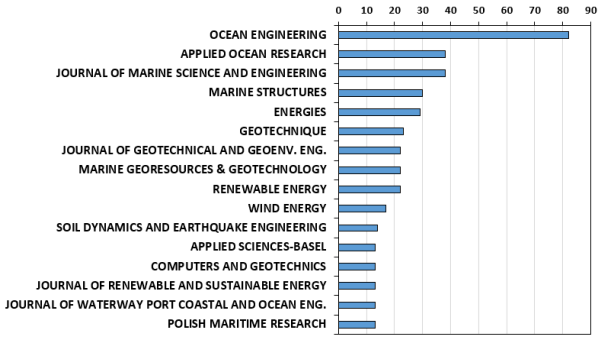

Figure 3. Journals in which GEO group articles are published in 1972 to 2021.

4 CONCLUSIONS

This bibliometric analysis gives a general idea of current research trends and future research needs in offshore wind energy based on the dataset including 7600 publications between 1972-July 2022. Norway, Denmark and the UK are the top contributing countries to total number of articles in offshore topics, as well in GEO-related topics.

Research on geotechnical engineering aspects of floating offshore wind is expected to increase in the future. Among the articles related to floating types, it is seen that drag embedded anchors, vertically loaded anchors, multiline anchors, pile driven plate anchors, dynamically embedded plate anchors, suction embedded plate anchors were studied. We foresee more studies on seabed anchor alternatives, buried cables in seabed, shared mooring lines and shared anchors etc.

There seems to be limited research which combines experimental and numerical modelling approaches. Research on risk, reliability-based probabilistic methods is expected to increase. Among the loading conditions, limited studies are available for seismic loading condition. These aspects are expected to be further investigated in the coming years.

ABSTRACT: This article addresses the issues related to the geotechnical design of a zoned embankment dam, about 50 m high, located in the centre-south of Portugal. It addresses, more specifically, the issues related to the research and characterization of borrow areas for the various natural construction materials and the geometric optimization of the dam to maximize the exploitation of the various materials within the future submerged area of the reservoir, thus minimizing the environmental impacts caused by open pit exploitation outside this area, or by transport from commercial exploitations located at great distances.

RÉSUMÉ: Cet article aborde les enjeux liées à la conception géotechnique d'un barrage en remblai zoné, d'environ 50 m de hauteur, situé dans le centre-sud du Portugal. Il aborde plus spécifiquement les défis liées à la recherche et à la reconnaissance de zones d'emprunt pour les divers matériaux naturels de construction et à l'optimisation géométrique du barrage, afin de maximiser l'utilisations des différents matériaux au sein de la future zone immergée du réservoir, réduisant ainsi les impacts environnementaux résultants de l'exploitation à ciel ouvert en dehors de cette zone, ou du transport depuis des exploitations commerciales situées à de grandes distances.

Keywords: Dam; construction materials; environment.

1 INTRODUCTION

The Pisão Dam is the main asset of the Crato Multi-Purpose Hydraulic Project, whose primary objective is the establishment, in the northeast region of Alentejo, of a new strategic water reserve. Having multiple purposes, this Project will allow the supply of water for human consumption, will enable the irrigation of around 5400 ha of agricultural fields and will have an estimated installed capacity for the production of electrical energy of about 150 MW in full operation. The energy will be produced through a set of photovoltaic plants, installed on land and over the stored water.

The first studies for the dam date back to the 60s and 70s of the last century. Since then, several geological and geotechnical studies have been carried out in different phases, with emphasis not only on the site of the dam and hydraulic structures, but also on the construction materials research.

Given the geometry of the valley at the dam site, characterized by a large amplitude, the option for an embankment dam was always the only one that seemed feasible, with the solution for the dam's typical cross section being entirely conditioned by the construction materials available at the site.

2 GEOLOGICAL AND GEOTECHNICAL FRAMEWORK

The dam will be located approximately 20 km west of Vila do Crato, implanted in Ribeira de Seda. At the dam's site, the river runs on the contact between geological formations of different strengths, which results in a quite asymmetrical valley. In fact, granite formations occur on the left bank, which, due to their great strength, gives rise to more vigorous reliefs with steep slopes, whilst, on the right bank, softer schist formations occur, resulting in a relatively wavy and soft relief. About 85% of the works are located in the right bank, involving the schist rock mass.

In the right bank, dominated by schist formations, the rock mass is covered by residual soils presenting

reduced thickness. The rock mass is often observed at the surface being these soils inexistent.

Below the residual soils, grey schists predominate. Although rarely, greywacke levels have also been detected. The rock mass presents a weathering profile corresponding to a thin horizon of weathered and disaggregated rock, quickly passing to a horizon of moderately to slightly weathered and fractured rock.

In the left bank, where granite formations occur, the residual soils are more abundant, and the weathering profile is more irregular.

3 GENERAL CHARACTERISTICS OF THE DAM

The Pisão Dam, with a volume of about 2 700 000 m^3 and a crest length of 1382 m, will have a zoned embankment solution (Figure 1), with a low permeability core made of fine clayey soils (1). The upstream and downstream shells (3) will be made of soil-rockfill mixture, with a coarse sand with fines prism (2) in the transition zone between the upstream shell and the core (1). Such prism will allow the gradual reduction of permeabilities from upstream to downstream, as well as a transition in terms of stiffness.

In geometric terms, the embankment dam cross section has a maximum height of around 54 m above the foundation and a crest width of 10 m. The upstream and downstream slopes will have an inclination of 1V:2.5H and 1V:2H, respectively. The downstream slope will include three berms, 3.0 m wide, located at elevations 208.8 m, 221.8 m and 236.8 m (Figure 1).

The internal drainage system consists of a sub vertical filter, 3.0 m wide, which extends downstream at the base, through a drainage blanket. At the bottom of the valley, the 1.5 m thick drainage blancket, extends to the downstream slope face, guaranteeing the exit of the seepage. This drainage blancket is extended laterally to the abutments, and includes outlets distributed along the right bank, due to the crossing of several secondary water lines.

At the downstream shell, a rockfill toe (E2) was defined which, in addition to improving the slope stability conditions, will protect the embankment from water flooding during spillway discharges. In addition, the upstream slope face will be protected from wave-induced erosion by a protective rockfill layer (E1), beneath which a filter layer (F1) will be placed.

4 BORROW AREAS AND MATERIAL CHARACTERIZATION

4.1 General Considerations

In the initial studies (late 60s / early 70s of the 20th century), the solution considered for the dam involved a homogeneous cross section, built with residual soils from granite rock mass. Later, at the beginning of the 21st century, a review of the type of dam was carried out, in light of technological advances in dam construction, resulting in adopting a zoned cross section, with a clayey core and soil-rockfill mixture for the shells.

Since then, construction materials studies have focused, above all, on researching clayey materials for the construction of the core. To this end, the research began by essentially being confined to the future reservoir area, as required by good practices. However, given the scarcity of soils in the region with suitable characteristics for use in the dam core, namely fines content and plasticity requirements, the research was extended to areas located outside the reservoir, being the main concern the quantity assessment of the available materials.

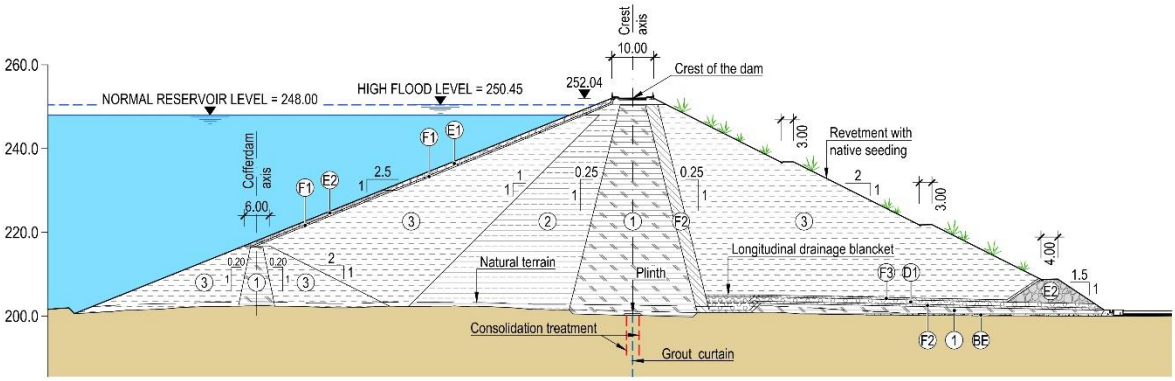

Figure 1. Typical cross-section of the da.m for the highest section (Aqualogus / TPF, 2023a).

4.2 Borrow areas

When defining the borrow areas, the main objective was to maximize the exploitation of the various materials within the future submerged area of the reservoir. Therefore, it was considered that the soil-rockfill mixtures for the shells would come from the excavations to be carried out on the right bank, whether resulting from the implementation of the bottom outlet or the creation of borrow areas inside the future reservoir, involving the highly weathered and highly fractured upper part of the rock mass as well as the residual soils cover. The coarse sand with fines prism would be made up of granitic residual soil from either the excavations for the spillway or the creation of borrow areas inside the reservoir area, on the left bank. The biggest challenge was then the identification of soils with suitable characteristics for placement in the core, and specially in sufficient quantity. With that in mind, geotechnical investigations surveys were carried out involving seismic refraction and excavation pits with sample collection. Along the different phases of the dam studies, since the late 60s / early 70s of the 20th century until 2021, a total of 57 seismic refraction tests, 48 excavation pits were executed and 90 samples were collected and submitted to laboratory testing.

Table 1 shows the distribution of the collected samples by borrow area.

Table 1. Samples submitted to laboratory testing (Aqualogus / TPF, 2023b).

Borrow area	Geological formation	Location referring to reservoir	Samples
E1	Schist	Inside	19
E2	Schist	Inside	32
E3	Ultrametamorphic rocks	Outside	17
E4	Granite	Inside	10
E3a	Schist	Outside	4
E3b	Schist	Outside	1
E3c	Schist	Outside	0
E3d	Schist	Partially inside	3
E3e	Ultrametamorphic rocks	Partially inside	4

4.3 Material characterization

Grain size distribution curves, Atterberg limits and specific gravity were determined, as well as the compaction and permeability characteristics. Table 2 presents the average values obtained in the laboratory tests.

Table 2. Average values of the index properties (Aqualogus / TPF, 2023b).

	< #200 (%)	PI (%)	w_{opt} (%)	$\gamma_{d,max}$ ($kN \cdot m^{-3}$)	G_s (.)	k ($m \cdot s^{-1}$)
1	33	10	13	18.9	2.68	10^{-9}
2	10	-	10	19.9	2.74	10^{-7}
3	12	-	9	20.0	2.67	10^{-7}

1 – Clayey soils; 2 – Sandy soils; 3 – Soil-rockfill mixtures

Regarding the mechanical properties of strength and stiffness, the materials were characterized through undrained consolidated triaxial tests (CU), with measurement of pore pressures. For soil-type materials, to be applied in the core (fine soils) and in the transition zone (coarse sand with fines prism), the specimens were tested in normal triaxial chambers (4''). In the case of soil-rockfill mixtures, it was necessary to use 230 mm chambers, to guarantee representation in relation to the maximum particle size of the mixture.

The specimens were remoulded complying with the optimal characteristics of the compaction test and were then consolidated to a pre-established stress. Finally, they were subjected to triaxial shear by increasing the deviatoric stress, q, until an axial deformation of 20% was reached.

The soils' strength (c' and ϕ') and stiffness design values were determined from the undrained triaxial tests' responses. Compatible secant drained Young modulus, E', was inferred for different levels of axial strain, namely for the axial strain associated with $q/p'max$, for 0.10% and 1% strain. The Poisson coefficient values were adopted after the literature values. Table 3 presents the considered design values.

Table 3. Design values for strength and stiffness properties (Aqualogus / TPF, 2023b).

	φ' (º)	c' (kPa)	E' (Mpa)	ν' (.)

5 MATERIAL AVAILABILITY AND DESIGN OPTIMIZATION

In any embankemnt dam, the most important element corresponds to the waterproofing element, which will ensure that there will be no relevant seepage through the body of the dam. In the case of the Pisão Dam, this element is materialized by the core, made up of clayey soils. Finding soil with the appropriate characteristics and in sufficient quantity for the construction of the dam core therefore became the main constraint of the material research studies.

Although initially, the site seemed very promising in terms of the presence of this type of soil since it is usually expected that schist rock masses give rise to clayey residual soils, what was found was a reduced quantity of these soils given the weathering profile of the rock mass. In fact, the schist rock mass presented a thin horizon of residual soil of about 1.0 m thickness on average (typical values between 0.5 and 1.6 m), or often inexistent. This profile was considered to lead to insufficient available volumes and important difficulties in the "clean" exploration of too thin layers of material, due to possible contamination either with top soil or with coarse material. Consequently, it was decided to search for borrow areas with better exploitation potential outside the future reservoir area, while at the same time to reduce to a minimum the need for clayey materials.

Fine materials were identified in greater abundance outside the area of the future reservoir in a radius of 1 to 3 km of the dam, corresponding to residual soil from ultrametamorphic rocks, specifically migmatite gneisses. This rock mass presented a more regular weathering profile and an average thickness of residual soils of about 1,3 m (typical values between 0.9 and 2.1 m).

Simultaneously, the core geometry was optimized, resulting in a thinner core of fine material with a minimum width of 6.0 m and 4V:1H slopes. The geometry optimization allowed the reduction in the need for fine soils from about 529 800 m^3 to 401 500 m^3.

6 CONCLUSIONS

The Crato Multi-Purpose Hydraulic Project, which includes the Pisão Dam, was considered an anchor of development by all the 15 municipalities of Alto Alentejo, by the population and by the Government, being an historical aspiration and demand dating back more than half a century.

Given this strategic importance, it became necessary to make decisions in the design stage that, although not the most desirable, would make the dam's construction viable, such as the exploitation of materials outside the future reservoir area.

However, given the thickness of exploitable material, it was considered that the implementation of current environmental recovery measures would straightforwardly reverse the impacts of this exploitation, returning the area in question to its usual use.

Numerical evaluation of the long-term performance of energy piles in hot-dominated climates

Évaluation numérique de la performance à long terme des pieux énergétiques dans les climats à dominante chaude

S. ten Bosch*, E. Ravera, L. Laloui
EPFL, Lausanne, Switzerland

ABSTRACT: Using energy piles to extract geothermal energy for heating needs has been the main focus of research in energy geostructures. In hot-dominated climates, the interest is to inject heat into the ground and extract energy for space-cooling purposes. This study evaluates the feasibility of energy piles in this operation mode through 3D numerical modelling for a case study targeted to provide 40% of the total cooling demand of a typical building in Dubai. The unbalanced energy demand causes an increase in the outlet temperature of the heat carrier fluid in the geothermal pipes and the radial soil temperature over time. Observation of long-term behaviour, however, indicates that the temperature increase is most significant in the initial years and stabilizes over time. The heat pump operating limit in terms of maximum temperature is respected over 50 years due to this stabilization behaviour. The results show that energy piles are highly effective in reducing carbon emissions and supplying renewable energy to buildings in hot climates, addressing a key societal challenge.

RÉSUMÉ: L'utilisation de pieux énergétiques pour extraire l'énergie géothermique à des fins de chauffage a été le principal axe de recherche dans le domaine des géostructures énergétiques. Dans les climats chauds, l'intérêt est d'injecter de la chaleur dans le sol et d'en extraire de l'énergie pour refroidir les bâtiments. Cette étude évalue la faisabilité des pieux énergétiques dans ce mode de fonctionnement à l'aide d'une modélisation numérique en 3D pour une étude de cas visant à fournir 40 % de la demande totale de refroidissement d'un bâtiment type à Dubai. La demande d'énergie déséquilibrée entraîne une augmentation de la température de sortie du fluide caloporteur dans les tuyaux géothermiques et de la température radiale du sol au fil du temps. L'observation du comportement à long terme indique toutefois que l'augmentation de la température est plus importante au cours des premières années et se stabilise avec le temps. La limite de fonctionnement de la pompe à chaleur en termes de température maximale est respectée sur 50 ans en raison de ce comportement de stabilisation. Les résultats montrent que les pieux énergétiques sont très efficaces pour réduire les émissions de carbone et fournir de l'énergie renouvelable aux bâtiments dans les climats chauds, ce qui permet de relever un défi sociétal majeur.

Keywords: Numerical modelling; energy piles; hot-dominated climates; cooling systems; geothermal energy.

1 INTRODUCTION

The pressing challenge of providing sustainable energy for a growing global population while reducing greenhouse gas emissions emphasizes the importance of sustainable energy sources. Space cooling is a major driver of residential energy consumption in hot climates, and its demand is expected to triple by 2050 (IEA, 2018). Dubai, UAE, is a region where cooling represents a substantial portion of energy use. The need for sustainable cooling sources here is underlined by a doubling of CO_2 emissions in the UAE over the past three decades.

Energy geostructures, such as energy piles, can be used as an innovative solution for space conditioning purposes. Energy piles utilize ground-embedded structures for heating or cooling and have demonstrated strong performance in various applications (e.g., Brandl, 2006; Laloui & Rotta Loria, 2019). However, research has primarily focused on its heating applications, with less attention to cooling use in hot-dominated regions. The impact of an unbalanced energy demand has been explored by Akrouch et al. (2020), Olgun et al. (2015) and Sutman et al. (2020), but never with an only-cooling demand in the setting of an arid region.

This study aims to assess the feasibility and long-term energy performance of using energy piles exclusively for cooling in hot-dominated climates, with Dubai as a representative case. The work employs 3D time-dependent numerical modelling to simulate cooling energy extraction, offering insights into system operation in arid regions.

2 METHODOLOGY

Numerical evaluation of a representative case study in Dubai is achieved using a 3D finite element model in COMSOL Multiphysics 5.6.

2.1 Dubai case study description

An energy pile foundation with 33 20m-length and 0.8m-diameter piles is envisaged for a building in the coastal belt region of Dubai. HDPE pipes in the pile have a U-shaped configuration. A sandy soil profile characterizes the project location, and a variation in thermal conductivity over the depth of the profile is included in the study.

It is targeted to provide 40% of the total cooling demand of this building through its energy foundation. The required daily cooling load per energy pile is shown in Figure 1. The limitation of the feasibility of this technology lies in the reversed heat pump characteristics, as also identified by Alshehri et al. (2021). The outlet temperature (T_{out}) of the heat carrier fluid (HCF) in the energy pile should not reach the capacity limit temperature for the heat pump over its lifetime. The reversed heat pump employed in this study has a cooling capacity of 0.68 kW per energy pile, an energy efficiency ratio of 5.07 and the maximum allowable outlet temperature of the HCF is 45°C.

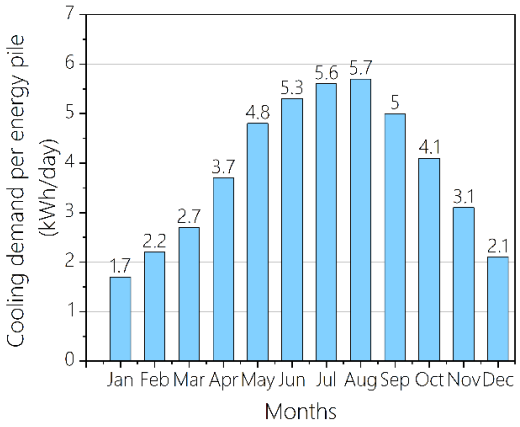

Figure 1. Monthly variation of daily cooling demand per energy pile.

2.2 Mathematical framework

This study employs a numerical modelling framework to simulate the energy piles, the ground and the geothermal pipes embedded within them. Conduction heat transfer characterizes the soil using an equivalent thermal conductivity approach, the concrete of the energy piles, and HDPE pipe wall domains. Similar frameworks have been effectively used in previous evaluations of energy geostructures (e.g., Rotta Loria, 2020) and it is thus not repeated here for concision.

The model simulates daily reversed heat pump operation, where cooling extraction continues until the calculated energy matches the daily energy demand. This approach, previously successful in prior work (Ravera, 2021; Sutman et al., 2020), is repeated for each simulated day. More information about the modelling framework can be found in Ten Bosch et al. (2024).

2.3 Numerical model description

The model, with its boundary conditions and mesh, is shown in Figure 2.

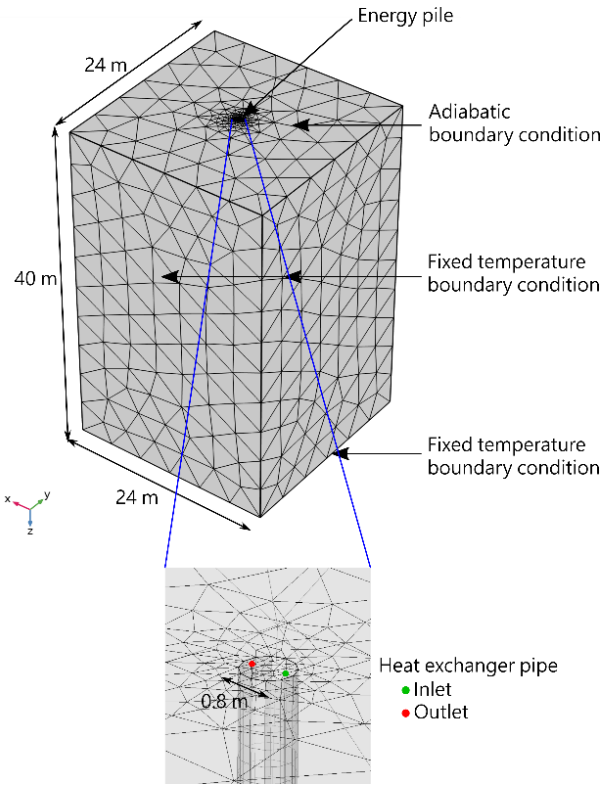

Figure 2. Setup of the numerical model for one energy pile in Dubai showing the applied boundary conditions and meshing.

Table 1. Thermal analysis model parameters.

Parameter	Value
HCF	water
Flow velocity	1.0 m/s
Ground thermal conductivity (variation over depth)	0-3 m: 0.939 W/(m·°C) 3-9 m:0.726 W/(m·°C) 9-13.5m: 1.192 W/(m·°C) >13.5m: 0.798 W/(m·°C)
Ground density	1537 kg/m^3
Ground specific heat	961 J/(kg·°C)
Pipe inner diameter	25.4 mm
Pipe surface roughness	0.0015 mm
Pipe wall thickness	3.25 mm
Pipe thermal conductivity	0.42 W/(m·°C)

Initial and boundary conditions include fixed temperature boundaries at the model's side and bottom, maintaining temperatures at the initial ground temperature of 30°C, representing Dubai's yearly average air temperature. Additionally, a thermal insulation boundary condition is applied at the model's surface. Model parameters that were used in the simulations are shown in Table 1.

3 DUBAI APPLICATION

3.1 One-year evaluation

The analysis of the system's behaviour over a year reveals fluctuations in the HCF outlet temperature. This one-year analysis is repeated with varying HCF flow velocities and internal pipe diameters, representing real-world conditions. The results are shown in Figures 3A, 3B. Daily temperature variations correspond to the activation and deactivation of the heat pump, driven by the cooling energy demand. Peak outlet temperatures coincide with higher cooling demands, notably in August. Despite these fluctuations, the HCF temperature remains within the heat pump's operating range for all model variations, indicating potential for energy-pile-based cooling.

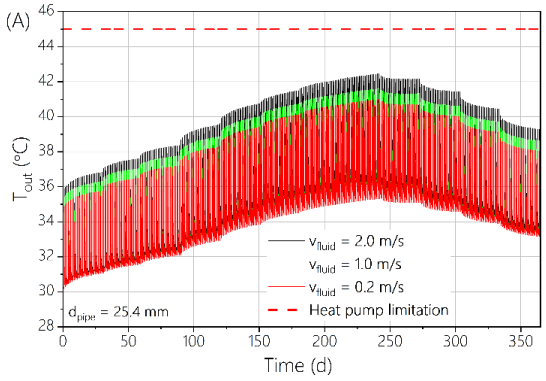

Figure 3A. One-year evaluation of the outlet temperature of the HCF fluid for variation of HCF flow velocity.

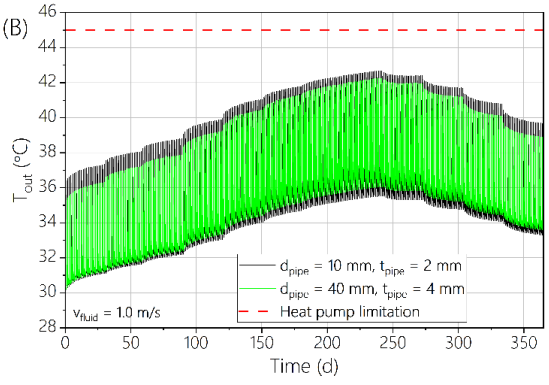

Figure 3B. One-year evaluation of the outlet temperature of the HCF fluid for variations of the pipe diameter.

Considering the sensitivity to the designs parameters, results indicate that lower flow velocities and wider pipe diameters reduce maximum outlet temperatures. Changing HCF flow velocities also affects operating costs and thus requires careful optimization.

3.2 Long term evaluation

A model with an enlarged soil domain (h = 40 m, x, y = 80 m) is used for a long-term case study evaluation to avoid boundary condition interference during the analysis.

Over a 50-year period, the system's energy performance is assessed, with Figure 4 illustrating the gradual increase in outlet water temperature. After an initial rapid response, the temperature increase stabilizes, remaining within the heat pump's capacity range.

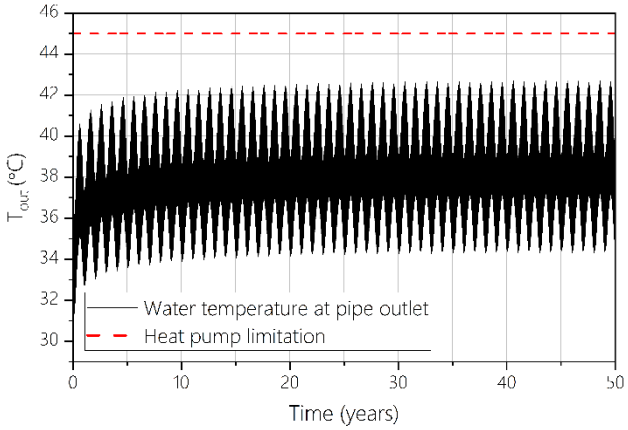

Figure 4. Long-term evaluation of the HCF outlet temperature for the Dubai case study.

Furthermore, the impact on the soil temperature around the energy pile could also be evaluated. The influence of 50 years of cooling energy extraction on soil temperature distribution at the surface level is presented in Figure 5, highlighting the highest temperatures near the pile location.

3.3 Discussion

The presented results are obtained with a single energy pile, thus, for buildings with a pile spacing exceeding the zone of influence, it is demonstrated that geothermal activation of the foundation can meet 40% of the building's energy demand. In cases where piles are closely spaced, interactions among piles should be considered. This overlapping influence can impact system performance. An assessment according to an infinite pile group model similar to Makasis & Narsilio (2022) over one year is used and indicates effects within a 10% increase of outlet temperature at the end

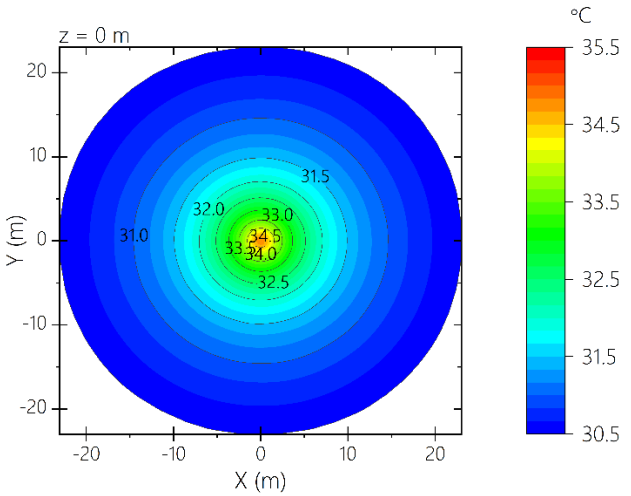

Figure 5. Ground temperature evaluation after 50 years of cooling energy extraction.

of one year for a pile spacing of 6.75 times the pile diameter using the Dubai case study settings.

Potential ground water flow is not considered in this study but is expected to have a positive influence through its cooling effect on the increasing soil temperatures surrounding the energy pile.

4 CONCLUSIONS

This work investigates the long-term behaviour of cooling energy extraction using energy piles in hot-climates. A 3D numerical model is used to assess a case study aiming to supply 40% of a typical building's cooling energy demand through the use of the energy foundation in Dubai. The unbalanced energy demand at this location causes an initial rise in heat carrier fluid and soil temperatures during operation of the energy pile. However, it is found that these increases stabilize over time, indicating the technology's viability even under such conditions. Furthermore, the numerical results for an isolated energy pile suggest it can meet 40% of the total cooling demand for the building over at least 50 years, respective heat pump functionality limitations regarding heat carrier fluid temperature.

ACKNOWLEDGEMENTS

Some of the used data inputs were inspired from measurements made available by E.construct.

Strength, microstructural, and leaching characteristics of phosphogypsum-fly ash mixtures

Caractéristiques de résistance, de microstructure et de lixiviation des mélanges de phosphogypse et de cendres volantes

Y. Thakur, A. Tyagi*, S. Sarkar
Department of Civil Engineering, Indian Institute of Technology Roorkee, India
**akanksha.tyagi@ce.iitr.ac.in*

ABSTRACT: Phosphogypsum (PG) is a waste product from the fertilizer industries producing phosphoric acid and phosphate fertilizers. On the other hand, fly ash (FA) is the by-product of thermal power plants. This paper presents a comprehensive study of the application of PG in combination with FA in road construction. The PG-FA mixtures are prepared in 70:30, 60:40, 50:50, and 40:60 ratios at 97% of maximum dry density (MDD) and corresponding water content. The California bearing ratio (CBR) of mixes is then evaluated after 4 days of soaking. The risk of contamination is also determined by performing Toxicity Characteristic Leaching Procedure (TCLP). In addition, Field Emission-Scanning Electron Microscopy (FE-SEM) is conducted to identify the microstructural changes and interaction of PG-FA mixtures. Results indicate that all the mix proportions have CBR values greater than 10%, while the PG:FA proportion of 50:50 was optimal. The TCLP test results suggest that the concentrations of various trace metals are within the threshold limits specified by USEPA (1992).

RÉSUMÉ: Le phosphogypse (PG) est un déchet provenant des industries d'engrais produisant de l'acide phosphorique et des engrais phosphatés. En revanche, les cendres volantes (FA) sont un sous-produit des centrales thermiques. Cet article présente une étude complète de l'application du PG en combinaison avec le FA dans la construction de routes. Les mélanges PG-FA sont préparés dans des rapports 70:30, 60:40, 50:50 et 40:60 à 97 % de la densité sèche maximale (MDD) et de la teneur en eau correspondante. Le rapport portant californien (CBR) des enrobés est ensuite évalué après 4 jours de trempage. Le risque de contamination est également déterminé en effectuant une procédure de lixiviation des caractéristiques toxiques (TCLP). De plus, la microscopie électronique à balayage par émission de champ (FE-SEM) est réalisée pour identifier les changements microstructuraux et l'interaction des mélanges PG-FA. Les résultats indiquent que toutes les proportions de mélange ont des valeurs CBR supérieures à 10 %, tandis que la proportion PG:FA de 50:50 était optimale. Les résultats des tests TCLP suggèrent que les concentrations de divers métaux traces se situent dans les limites spécifiées par l'USEPA (1992).

Keywords: Phosphogypsum; fly ash; CBR; microstructure; leaching.

1 INTRODUCTION

One of the major challenges in the field of road construction is the high demand for materials required for embankment and pavement construction. On the other hand, industries are producing a lot of waste that poses storage problems and high risks to human health and the ecosystem. For example, the phosphate and phosphoric industry generate enormous amounts of waste known as Phosphogypsum (PG). The annual production of PG is approximately 12-13 mt/yr in India, in which only about 40-50% of the PG generated is being used in the fertilizer industry, cement manufacturing, gypsum boards, and as road materials (Havanagi et al., 2018; Thakur et al., 2023a). Vast amounts of fly ash (FA) are generated as waste from thermal power plants and steel-based industries. FA has been utilized for the construction of road embankments in India for the last few decades. IRC:SP:58 (IRC, 2001) specifies the guidelines for constructing the FA embankments. However, no such guidelines exist for the use of PG for road construction. Hence, the bulk utilization of PG and FA in road construction will not only preserve natural materials but also safeguard valuable lands. The usage of PG is restricted due to the possible emission of heavy metals, fluoride, and radionuclides, as reported by several countries (Tayibi et al., 2009).

In a study conducted by Sharma and Walia (2017), it was found that the substitution of soil with 20% FA and 1-7% PG effectively met the IRC:37 (IRC, 2018) requirement of subgrade California bearing ratio

(CBR) of 2% to 10% to be used as embankment materials in flexible pavement. Havangi et al. (2018) observed the average CBR index of raw PG as 26%. The higher CBR value indicates the feasibility of using PG as a subgrade material. Recently, Thakur et al. (2023b) recently reported 4-days soaked CBR value of 31% for raw Indian PG. Ngo et al. (2022) investigated the effect of cement and lime content on various geotechnical properties, including compaction characteristics, unconfined compressive strength (UCS), modulus of elasticity, and CBR of a stabilized PG and FA mixture, in which PG was replaced with 10-20% FA and stabilized with 4-10% cement with or without the addition of lime. The UCS and CBR values remarkably improved with the increment of cement content (Ngo et al., 2022). A mixture of 80% PG, 10% FA, and 10% cement achieved a CBR value of approximately 10%, for the 7 days of curing, and more than 40%, after the 28 days of curing, at 95% and 98% relative compaction (Ngo et al., 2022).

In the last few years, extensive research has been carried out on PG-based mixes, such as PG-lime/PG-cement (Rezende et al., 2017), PG-FA/PG-FA-lime/ PG-FA-cement (Amrani et al., 2020; Meskini et al., 2021, Ngo et al., 2022), for their effective use in road construction material. However, no such studies are available on the Indian PG and FA mixtures.

Thus, this paper aims to investigate the potential utilization of Indian PG and FA mixtures for road construction by performing laboratory experiments, such as CBR. The results obtained from CBR are further explained using observations from Field Emission-Scanning Electron Microscopy (FE-SEM) images. In addition, Toxicity Characteristic Leaching Procedure (TCLP) tests are also conducted to evaluate the suitability of the PG-FA mix as subgrade material.

2 MATERIALS AND METHODOLOGY

2.1 Materials

The PG used in this study is collected from Paradeep Phosphate Limited, Paradeep, Orissa, India. FA is procured from a thermal power plant located at Hisar, Haryana, India. The particle size distribution curve of raw materials used in this study are shown in Figure 1. The PG and FA are classified as non-plastic silt based on the particle size distribution curve.

The chemical composition of raw materials was obtained from X-ray fluorescence (XRF). According to Thakur et al. (2023b), PG majorly comprises SO_3 (52-54%), CaO (42-44%), and small amounts of P_2O_5 (1-1.6%), and Al_2O_3 (0.11-0.17%). The FA majorly consisted of SiO_2 (56-59%), Al_2O_3 (25-32%), Fe_2O_3 (4-8%), and K_2O (1-1.28%) and was categorized as class F as per ASTM C-09 (ASTM, 2013).

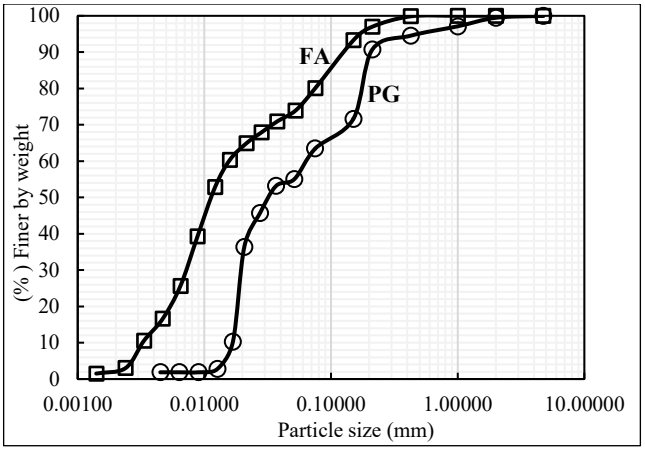

Figure 1. Particle size distribution curve of FA and PG (plot for PG taken from Thakur et al., 2023b).

2.2 Testing procedure

The California bearing ratio (CBR) is performed on different proportions of PG and FA mixtures, i.e.,70:30, 40:60, 50:50, and 60:40. All the samples are soaked under water for 4 days before conducting CBR test. The optimum mix satisfying the strength criteria is tested for TCLP. The mix proportions in this study are designated as 70PG30FA, 40PG60FA, 50PG50FA, and 40PG60FA.

2.3 Mixing procedure

To prepare the specimens, the required amounts of PG, FA, and water are weighed to 97% of maximum dry density (MDD) and corresponding moisture content. PG is replaced with different percentages of FA equivalent to 30, 40, 50, 60, and 70 % dry by weight, and then the required amounts of water are mixed. All prepared mixtures are kept in plastic bags for 24 hours for mellowing and homogeneity. Later, all prepared specimens are soaked in water for 4 days and then tested for CBR index.

2.4 Test performed

2.4.1 California bearing ratio (CBR)

The CBR test for all mix proportions is performed as per IRICEN, 2018. The samples are prepared at 97% MDD and their respective moisture content in mold diameter 152 mm and height 178 mm. All the samples are soaked under water for 4 days, then the soaked CBR test is carried out to evaluate the suitability of the mixture for road subgrade applications. The soaked CBR test is performed on PG-FA mixtures considering the adverse climate conditions on a pavement being subjected during heavy rainfall/flood.

2.4.2 Scanning electron microscopy (SEM)

For SEM analysis, samples were collected after the CBR test. A small flat piece of each specimen was then immersed into the ethanol to stop the any reactions further. Before conducting SEM, the specimens were dried in the oven at 60 ˚C for 24 hours. The specimen was coated with gold to avoid charging to the top surface. The samples' microstructure was examined using various magnifications and an acceleration voltage of 5 kV.

2.4.3 Leaching test

To assess the environmental performance of the PG-FA mixture, the TCLP test method 1311 (USEPA, 1992) test is carried out. This test is conducted only on the mixed proportion representing the optimum result (i.e., 50PG50FA). In the TCLP test, the PG-FA sample is extracted using the acetic acid solution with a pH of 4.93±0.05. This solution is prepared by adding 64.3 ml of 1M-NaOH with 5.7 ml of glacial acetic acid, then diluting to 1000 ml deionized water. The liquid-solid of 20:1 ratio is maintained for the extraction solution. Then the specimens are rotated for 18 hours at a speed of 30 rpm. After the rotation period, the leachate fluid is extracted and tested for trace element concentration using Microwave Plasma Atomic Emission Spectroscopy (MP-AES).

3 RESULTS AND DISCUSSION

3.1 California bearing ratio (CBR) results

Figure 2 illustrates the CBR test results performed on various PG-FA mixtures. All the mix proportions have values of CBR greater than 10%, which is a desirable value for sub-grade material as per IRC guidelines (IRC, 2018). Further, it is seen that the mixture containing an equal percentage of PG and FA reached the maximum CBR value, beyond which there is a significant decline (Figure 2). This reduction in CBR value may attributed to the non-cohesive nature of FA, which weakens the bond within a mixture and leads to a lower CBR value.

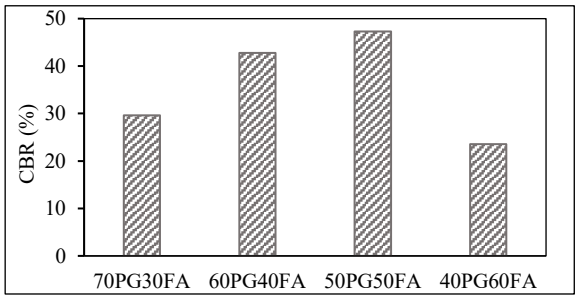

Figure 2. CBR value of different PG-FA mix at 4-day soaking corresponding to 97% relative compaction.

3.2 Microstructural characteristics

Figure 3 illustrates the SEM images of the specimens having minimum and maximum CBR values of 4 days soaking with 40,000× magnification. It is seen that the 40PG60FA specimen has a more visible pore. On the contrary, 50PG50FA shows a comparatively denser microstructure due to the formation of needle-like ettringites, which entrap the FA particles and lead to a denser microstructure. It is noted that the formation of ettringites provides early strength gain and is also known for their ability to expand. Therefore, the 50PG50FA specimen exhibits a higher CBR index than the 40PG60FA specimen. However, researchers also reported that the formation of large ettringite can cause distress and damage to the pavements (e.g., Lee et al., 2005). In this context, managing and preventing large amounts of ettringite is critical to ensure the performance and durability of a pavement. This may include careful material selection, appropriate mix design, and effective construction practices to lessen the negative impacts of ettringites.

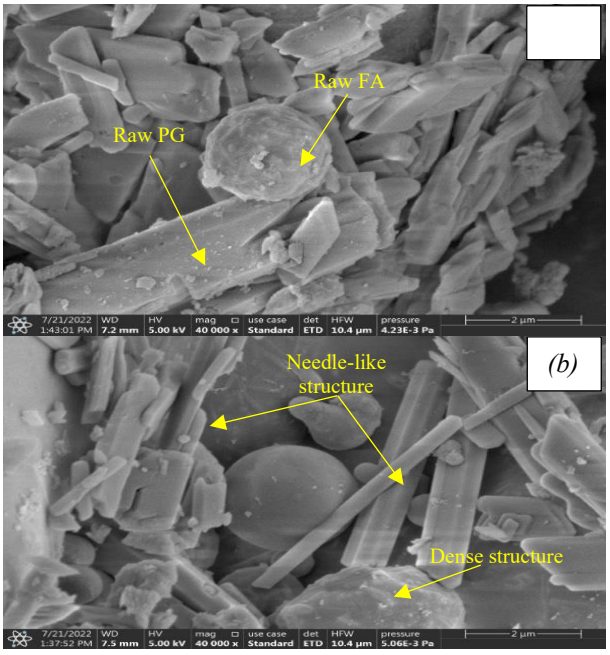

Figure 3. SEM image of (a) 40PG60FA, and (b) 50PG50FA mixes after 4 days soaked CBR test.

3.3 Leaching characteristics

Trace elements are identified by Microwave Plasma Atomic Emission Spectroscopy (MP-AES), with concentrations ranging from 0.01 mg/l to 0.70 mg/l. The selected elements are compared with the threshold limit established by the USEPA (USEPA, 1992). Table 1 shows that the obtained concentrations are below the threshold limit, which suggest that the PG-FA mixture can be used as a road subgrade material from this perspective.

Table 1 Trace element concentrations for 50PG50FA mixture.

Trace metal	Concentration (mg/l)	Threshold limit, mg/l (USEPA 1992)
Zn	0.45 ± 0.10	2.0
Cu	0.70 ± 0.05	-
Ni	0.11 ± 0.05	-
Co	Nd	-
Pb	Nd	5.0
Cr	0.37 ± 0.05	5.0
Cd	Nd	1.0
As	0	5.0
Mo	0.01 ± 0.05	-
V	Nd	-

**Nd= not detected*

4 CONCLUSIONS

The main findings of the present experimental study on PG-FA mixtures are given below:

- All the PG-FA mixtures achieved higher CBR values than the desirable value for sub-grade material, i.e., 10%. The high CBR index was obtained for equal PG and FA proportion (i.e., 50PG50FA). Further increment in FA content led to the decline in the CBR index, attributed to its non-cohesive nature.
- The 40PG60FA specimen has more visible pores, while the 50PG50FA specimen has a denser microstructure due to needle-like ettringites, resulting in a higher CBR index.
- From the TCLP test results, it can be seen that the concentrations of various trace metals are within the threshold limits specified by USEPA (1992).

Advances in groundwater recharge during construction dewatering

Avancées dans la recharge des nappes phréatiques lors de l'assèchement des chantiers

ABSTRACT: Abstraction of groundwater for consumptive use, such as for drinking water, agriculture, and industrial purposes, regularly requires the granting of a permanent abstraction licence from environmental regulatory bodies. Temporary abstraction of groundwater required for construction, however, has not historically required an abstraction licence. More recently, due to the conservation of groundwater in Europe now being a major challenge, it is becoming more common in European countries that licensing for the temporary abstraction of groundwater during construction dewatering, known as groundwater control, is now required from the environmental regulators of each country. Due to this requirement for licensing, the development of effective techniques for reducing the overall loss of groundwater has become more important. In particular, such conservation techniques include increased use of artificial recharge of groundwater back into the same strata from which it was abstracted. This paper presents three case studies describing a number of groundwater abstraction and recharge systems implemented on major infrastructure construction projects in the United Kingdom.

RÉSUMÉ: Le captage d'eau souterraine à des fins de consommation, par exemple pour l'eau potable, l'agriculture et l'industrie, nécessite régulièrement l'octroi d'un permis de prélèvement permanent auprès d'organismes de réglementation de l'environnement. Toutefois, le prélèvement temporaire d'eau souterraine nécessaire à la construction n'a pas toujours nécessité de permis de prélèvement. Plus récemment, en raison de la conservation des eaux souterraines en Europe qui est maintenant un défi majeur, il est devenu de plus en plus courant dans les pays européens qu'une licence pour le prélèvement temporaire d'eau souterraine pendant l'assèchement des constructions, connue sous le nom de contrôle des eaux souterraines, soit désormais exigée des régulateurs environnementaux de chaque pays. En raison de cette exigence de licence, le développement de techniques efficaces pour réduire la perte globale d'eau souterraine est devenu plus important. En particulier, ces techniques de conservation comprennent l'utilisation accrue de la recharge artificielle des eaux souterraines dans les mêmes strates d'où elles ont été extraites. Cet article présente trois études de cas décrivant un certain nombre de systèmes de captage et de recharge des eaux souterraines mis en œuvre dans le cadre de grands projets de construction d'infrastructures au Royaume-Uni.

Keywords: Groundwater control; water conservation; construction dewatering.

1 INTRODUCTION

Total global groundwater abstraction was estimated to be circa 1000 km^3/annum in 2010; 72 km^3/annum of which was within Europe (Margat and van der Gun, 2013). Although significantly less than estimated global natural recharge (Dillion, Stuyfzand, and Grischeck, 2019), the concentration of abstractions in urban and dry areas has led to substantial groundwater quantity and quality deterioration in a number of regions.

Where abstraction exceeds recharge, water table lowering results in a reduction of baseflow to surface water features, ground subsidence and deterioration of water quality through mechanisms such as saline intrusion and contamination mobilization.

The rapid rise in global groundwater abstraction over the past century has resulted in groundwater resource sustainability concerns. This in turn has led to an increased drive to advance and adopt intentional artificial recharge systems, also referred to as managed aquifer recharge: MAR (Dillion, Stuyfzand, and Grischeck, 2019). This focus has generally been on long term and permanent operations, as opposed to temporary works such as construction dewatering.

Although not regularly utilised in the United Kingdom, artificial recharge during temporary construction dewatering operations is not a new concept (Bock and Markussen, 2007; Cashman and

Preene, 2013; Powrie and Roberts, 1995; Preene, Roberts, and Powrie, 2016). The additional monetary costs of implementing artificial recharge have historically been a deterrent to construction companies, unless there is a site-specific requirement.

However, in England and Wales, the Water Abstraction and Impounding (Exemptions) Regulations 2017 (Statutory instrument, 2019) came into force in January 2018. These regulations made construction dewatering a licensable activity (abstraction during engineering works was exempt from abstraction licensing prior to this date).

With construction dewatering abstraction now regulated by the Environment Agency (England) and Natural Resources (Wales), contractors are having to revise and refocus their approach to groundwater control and management.

A focus on minimising the environmental impact of construction dewatering operations, to enable a smooth licensing process, is becoming a more economically viable option. The introduction of the regulations has resulted in recharge and cut-off systems, that were previously not contemplated due to cost, now being considered more regularly.

With artificial recharge systems being increasingly designed and utilised as part of temporary construction dewatering operations, this paper aims to document the authors' experience of implementing temporary dewatering recharge systems, together with key advantages and disadvantages. Three recent case studies are also presented.

2 GROUNDWATER CONTROL RECHARGE SYSTEMS

2.1 Recharge system design

Groundwater recharge during temporary construction dewatering involves the recirculation of abstracted groundwater back into the same geological strata by reinjection (via wells) or infiltration (via trenches or shallow wells) (Preene and Fisher, 2015), generally without any intervening use. The recharge system needs to be at an appropriate distance which is logistically feasible, whilst not close enough to prevent the dewatering system from maintaining the water table below the target level.

If designed and implemented appropriately, the groundwater quality remains constant, drawdown at distance is reduced, with negligible net water abstraction from the aquifer.

Abstraction wells need designing to enable water table lowering to the target level, taking into account the reduced radius of influence due to artificial recharge. Wells need to be designed with appropriate filtration to prevent mobilization of ground fines which could clog the recharge wells or cause ground loss.

Recharge wells need careful designing to allow groundwater to readily discharge into the aquifer without causing localized flooding around the well. Wells need to have sufficient slotted length, and a free-flowing annulus filter pack. This is to mitigate water quality issues from clogging (Cashman and Preene, 2013). This becomes more critical the longer the duration of the dewatering operation.

Appropriate pipework is installed from the abstraction wells to the recharge wells. Closed pipework systems are generally utilised to reduce the clogging risks associated with the groundwater being exposed to the atmosphere (e.g. iron ochre precipitation, gas binding etc.). Discharge to recharge wells can be via gravity, or under pumped pressure. Settlement/inspection tanks, sample taps, and/or flowmeters may be installed within the connecting pipework depending on the site conditions and requirements.

A construction dewatering groundwater recharge concept is illustrated in Figure 1.

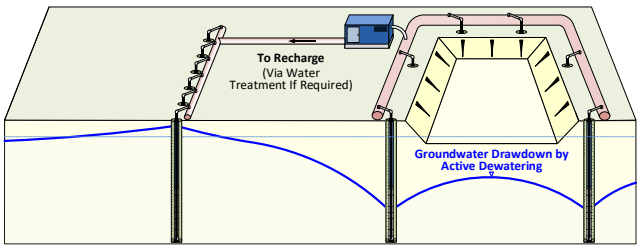

Figure 1. Concept groundwater control recharge system.

2.2 Benefits of utilising a recharge system

The primary benefits of utilising a recharge system on a temporary construction dewatering project are to adhere to legislation, protect surrounding infrastructure by mitigating settlement risk, reduce water disposal costs, conserve water and to protect vulnerable water features from drawdown impacts.

Drawdown at distance is also reduced, preventing the alteration of head gradients, which could lead to reduction in baseflow to surface water systems, deterioration of existing abstractors, and contamination/saline interface migration. A reduction in drawdown also mitigates the risk of settlement from pore water pressure reduction.

With an appropriate recharge system specified, obtaining the relevant abstraction license and discharge permit can be simplified as environmental risks are minimized. This reduces the risk of delays to the project programme.

2.3 Disadvantages of utilising a recharge system

Historically, the main disadvantage to contractors of recharge systems is the cost associated with both their installation and implementation, including their design costs. Access to suitable land to locate recharge wells can be a constraint, particularly in urban areas.

Furthermore, recharge systems are not always a feasible groundwater management strategy, as they are dependent on the hydrogeological conditions encountered. In addition, the recharge system may need to be implemented in tandem with other groundwater control methodologies such as cut-off walls, to work effectively.

Where recharge is feasible, the advantages of a recharge system can only be realised if the groundwater control system is appropriately designed and monitored by competent and experienced personnel (due to the additional risks as documented previously).

Without appropriate design, recharge systems can be overwhelmed resulting in localised flooding around the recharge wells, or the target drawdown not being met. In addition, as groundwater is being directly recharged into the aquifer, it is vital that the system is protected to prevent the possibility of contaminants entering the groundwater body.

3 GROUNDWATER RECHARGE CASE STUDIES

3.1 Tunnel boring machine drive pit, England

The River Humber gas pipeline replacement is a major infrastructure project to replace an existing gas pipeline which stretches circa 5 kilometres beneath the River Humber; a large tidal estuary on the eastern coast of Northern England.

To construct the pipeline, a slurry tunnel boring machine (Figure 2) was driven from the southern bank of the Humber. The depth of the tunnel drive pit, together with a relatively shallow water table (circa 1 m below ground level), required a temporary groundwater control system.

During the Development Consent Order stage (planning permission for developments categorized as Nationally Significant Infrastructure Projects in the UK), the sensitivity of the chalk aquifer on the southern bank of the Humber to any dewatering was identified. The primary concerns of the Environment Agency were (i) the risk of the saline interface mobilizing inland, and (ii) the regional water resource status. The Catchment Abstraction Management Strategy (CAMS) status of the south Humber bank is 'no water available for abstraction except at extremely high flows. Groundwater resources in the Lincolnshire Chalk are fully committed to existing users and the environment' (Environment Agency, 2013).

Figure 2. Tunnel boring machine used to construct the Feeder 9 gas pipeline.

The geology of the site comprised low permeability alluvial and glacial deposits (Superficial Deposits) to circa 10 m below ground level. These deposits were underlain by the Flamborough Chalk, which was highly weathered in the top several metres and recovered as a chalk gravel, and is termed by Chalk Bearings. This highly weathered stratum was highly permeable with sub-artesian groundwater encountered during the site investigation. This stratum was underlain by the intact Fractured Chalk, of significantly less permeability than the weathered chalk (Figure 3).

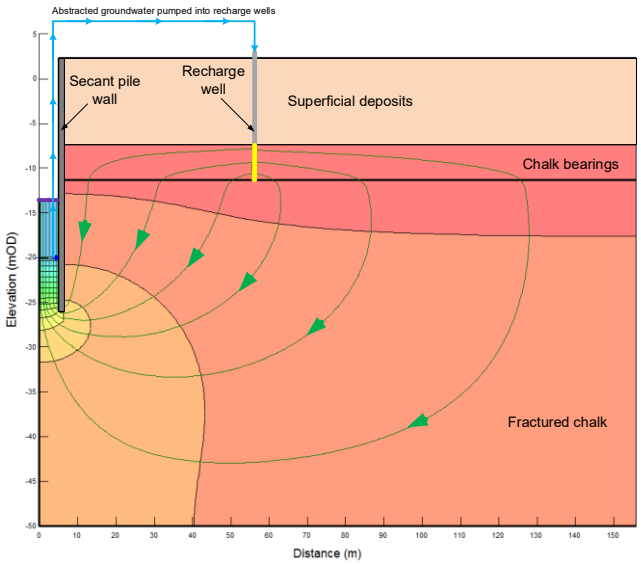

Figure 3. Finite element modelling of dewatering and recharge system for Feeder 9 gas pipeline.

To mitigate the risks, a groundwater control strategy utilising a partial cut-off and recharge system was developed (Figure 4). This resulted in abstraction

being non-consumptive, and prevented drawdown towards the River Humber, so mitigating saline water intrusion.

Figure 4. Pressurised wells to recharge abstracted groundwater back to the aquifer.

As the weathered chalk was very high permeability, a cut-off wall was required to penetrate through these deposits. Full cut-off of the weathered and underlying fractured chalk strata was originally considered; however, this was deemed impractical due to the fractured chalk extending circa 40 m to 50 m below ground level. Internal dewatering was specified within the Drive Pit (borehole pumps within designed wells). These internal wells abstracted groundwater from the more competent underlying fractured chalk.

Abstracted groundwater was then recharged back into the weathered chalk outside the Pit, reducing the radius of influence of the groundwater control operation and reducing the net abstraction from the aquifer to almost zero. The recharge system was fully enclosed, preventing the groundwater from coming into contact with the atmosphere, which helped prevent dissolved iron in the groundwater from precipitation and discolouring the groundwater.

Further project detail is described in Proceedings of the Chalk 2018 Conference (Goodfellow & Thomas, 2018; Holmes, Roberts, & Lee, 2018).

3.2 Microtunnel reception shaft Glasgow, Scotland

During construction of a Microtunnel reception shaft in Scotland, larger and more frequent boulders were encountered than expected.

These unexpected ground conditions resulted in the construction methodology being changed from jacked caisson to underpinning. The previous construction methodology could be undertaken in the wet, however the new methodology would require active dewatering.

Concerns were raised by key stakeholders about the potential risk of settlement from dewatering as the shaft was in close proximity to both a live railway, and bridge piers on frictional piles for a major road bridge spanning the River Clyde (Figure 5).

Figure 5. Photo of micro-tunnel reception shaft located close to the bridge piers.

The geology at the site generally comprised silty sands and gravels, overlying glacial till containing cobbles and boulders (Figure 6). Stakeholders were concerned with two main mechanisms for ground settlement at the site, settlement from ground loss, and settlement from a reduction in pore water pressure in shallow deposits.

To mitigate the concerns of stakeholders, a groundwater control system that included recharge was designed to minimize drawdown at a distance, as well as reduce water ingress into the shaft which could mobilise the soil.

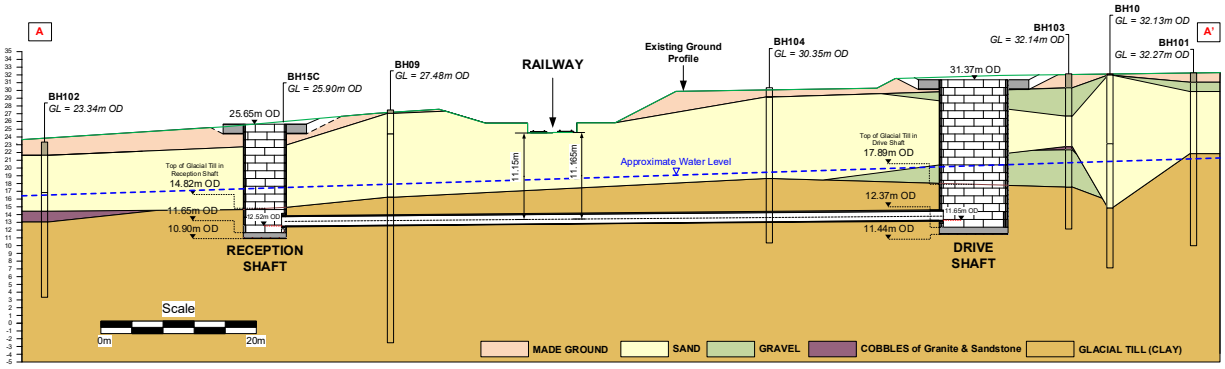

Figure 6. Conceptual model at the location of the reception shaft & drive shaft.

Site logistical constraints required recharge wells constructed within relatively close proximity to the shaft, and as such an assessment was required to confirm the system's feasibility.

Finite element modelling was undertaken to ascertain the flow rates required to minimize groundwater ingress into the shaft, and to prevent excessive drawdown below the railway and bridge piers by recharging into wells between the shaft and sensitive structures.

The finite element model head contours (Figure 7), demonstrated that a recharge system was feasible, and would prevent drawdown of more than 500 mm at the bridge piers and railway track.

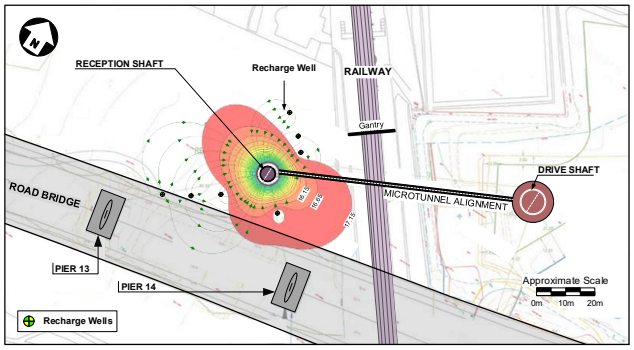

Figure 7. Finite element simulation of the dewatering and recharge system.

Figure 8 demonstrates the well design with slot sizes and filter material specified to prevent ground ingress into the wells, to mitigate ground settlement. Figures 9 and 10 depict the wellhead of a pumping well and recharge well respectively.

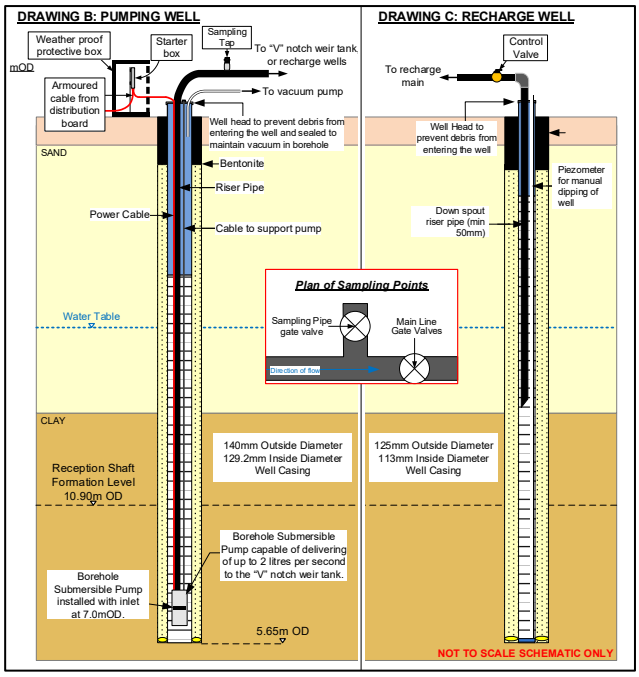

Figure 8. Specification of pumping and recharge wells.

Figure 9. Pumping well.

Figure 10. Recharge well.

3.3 The Commonwealth Games Aquatics Centre, Sandwell, Birmingham

The 2022 Commonwealth Games Aquatics Centre in Sandwell, Birmingham, was under construction over the period 2018 to 2022 (Figure 11), and required excavation for the competition pool, dive pool, plant room, down to a depth of 7 m below ground level.

The dewatering operation would have been less complex if the abstracted groundwater could be discharged directly to a watercourse. However, this approach would have resulted in the loss of groundwater from the aquifer resource in the order of 250 million litres.

Figure 11. The Birmingham Commonwealth Games Aquatic Centre during construction.

Due to the over-abstraction of groundwater from the aquifer underlying Birmingham (the Chester Formation), the Environment Agency specified a "net zero" abstraction rate during the construction of the Commonwealth Games Aquatics Centre Project. This meant that one hundred per cent of the groundwater abstracted during the construction period was required to be recharged back to the same aquifer from which it was abstracted.

The Aquatic Centre system required over 120 drilled suction abstraction wells and 50 recharge wells; with each well individually specified so that groundwater abstraction and recharge were targeted at the appropriate strata. Figure 12 presents the location of the numerous abstraction and recharge wells, and the cross-sectional output of the two-dimensional mixed confined-unconfined aquifer model GEMOS (Authors' Software).

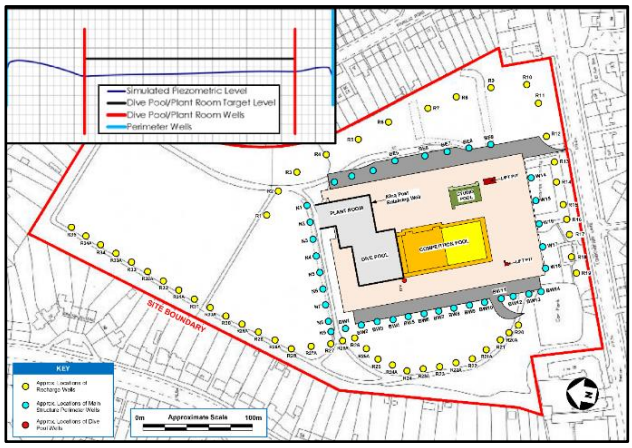

Figure 12. Location of abstraction & recharge wells during construction.

It was essential to abstract clear filtered groundwater (Figure 13), to prevent silts from being removed from the ground, and so allowing recharge of clear water to avoid frequent blockage. Note that regular maintenance and cleaning of the recharge wells was still required.

Figure 13. Abstraction of clear groundwater.

The recharge system required the pressurisation of the water with a circa 3 m head above ground level at each recharge wellhead. This was achieved by pumping the abstracted groundwater uphill to a water holding tank (Figure 14) at an elevated location. This then fed the recharge pipes to maintain a pressure of 30kPa to overcome the artesian head in the aquifer.

Figure 14. Water holding tank before discharging to the multiple-well recharge system.

ABSTRACT: Engineering systems are described for stormwater attenuation and enhanced infiltration, including the construction of trenches containing perforated attenuation pipes with a gravel surround, integrated with large numbers of drilled vertical infiltrators installed through the base of the trenches. Adding the pressure head of water in the attenuation trenches to the negative suction pressure in the unsaturated vadose zone, provides the differential pressure to force the water into the ground surrounding the infiltrators. The vertical infiltrators often encounter anisotropic ground strata where the horizontal permeability is much greater than the vertical permeability. Stormwater Attenuation and Enhanced Infiltration Systems have been used for many years in the United Kingdom to mitigate flooding and erosion, and to provide recharge to groundwater resources. With groundwater resources similarly in decline in Portugal, together with more frequent flooding conditions during intense rainfall, similar collection and enhanced infiltration systems could also be most beneficial to the hydrogeology and weather conditions of Portugal. Using this system, stormwater infiltrating into the vadose zone eventually find its way down to the water table, and so mitigate drought conditions by supplementing the aquifer water resources.

RÉSUMÉ: Des systèmes d'ingénierie sont décrits pour l'atténuation des eaux pluviales et l'infiltration accrue, y compris la construction de tranchées contenant des tuyaux d'atténuation perforés avec un entourage de gravier, intégrés à un grand nombre d'infiltrateurs verticaux forés installés à travers la base des tranchées. L'ajout de la pression de l'eau dans les tranchées d'atténuation à la pression d'aspiration négative dans la zone vadose non saturée, fournit la pression différentielle pour forcer l'eau dans le sol entourant les infiltrateurs. Les infiltrateurs verticaux rencontrent souvent des strates de sol anisotropes où la perméabilité horizontale est beaucoup plus grande que la perméabilité verticale. Les systèmes d'atténuation des eaux pluviales et d'infiltration améliorée sont utilisés depuis de nombreuses années au Royaume-Uni pour atténuer les inondations et l'érosion, et pour recharger les ressources en eaux souterraines. Les ressources en eaux souterraines étant également en déclin au Portugal, ainsi que des inondations plus fréquentes lors de pluies intenses, des systèmes similaires de collecte et d'infiltration améliorés pourraient également être très bénéfiques pour l'hydrogéologie et les conditions météorologiques du Portugal. Grâce à ce système, les eaux pluviales qui s'infiltrent dans la zone vadose finissent par se frayer un chemin jusqu'à la nappe phréatique, et atténuent ainsi les conditions de sécheresse en complétant les ressources en eau de l'aquifère.

Keywords: Stormwater attenuation; enhanced groundwater infiltration.

1 INTRODUCTION

Climate change and global warming are affecting all countries of the world, with more extreme weather events happening with greater frequency (Stott, 2016). In the United Kingdom (UK), one major impact of global warming has been the increase in hotter periods combined with an increasing frequency of high-intensity rainfall events (Kay et al., 2011, Schaller et al., 2016). With more of the UK being covered with urban developments, roads and industrial parks, the available open land to enable natural infiltration to the ground is receding (Charlesworth and Booth, 2016).

Over time this means less water is being recharged back into the ground and the major aquifers. As a consequence, the UK Government has enforced where possible the need for a developer to construct a Sustainable Drainage System (SuDS) to mitigate peak flooding that occurs from rapid runoff from hard impermeable surfaces such as roofs, roads, car parks

or other paved areas (Fletcher et al., 2015).In 2010, the UK Government published Building Regulations with Part H (Building Regulations, 2015).

Within these Regulations, Part H3 (3) describes the design of systems to manage the drainage of rainwater with the following priority:

a) An adequate soakaway or some other adequate infiltration system; or where that is not reasonably practicable,
b) A watercourse; or where that is not reasonably practicable,
c) A stormwater sewer; or where that is not reasonably practicable,
d) A foul sewer.

The building regulations guidance presented above clearly states that the priority is to discharge collected groundwater to an adequate soakaway or some other adequate infiltration system. In response to these regulations a Stormwater Attenuation and Enhanced Infiltration System (SAEIS) has been developed to provide an efficient method to collect, attenuate and infiltrate stored water into soils of variable permeability at depth. This system has been designed to infiltrate water at greater depths (typically in the range of 3 m to 12 m deep) than conventional soakaways which means this system is more suitable in areas where low permeability anisotropic soils such as laminated sandy and silty clays are more prominent (Jarvis et al., 1984).

By enabling infiltration at depth into laminated silt or sand lenses within clay soils, an enhanced infiltration system helps to mitigate local surface water flooding by reducing the flow of water to watercourses and sewers. This in turn helps to lower the peak water levels in local rivers following storm events, as illustrated in Figure 1 for a non-attenuated and attenuated concept storm hydrograph.

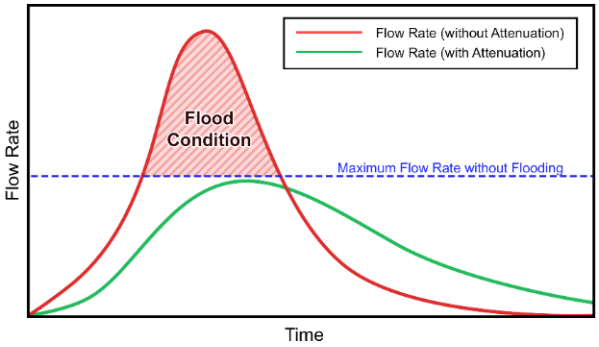

Figure 1. Illustration of two storm event hydrographs for non-attenuation and attenuation conditions respectively.

This paper describes the mathematical modelling applied to demonstrate the impact of attenuation and enhanced infiltration systems, by simulating the seepage of stormwater from the infiltrators into the surrounding anisotropic strata of mixed medium and low permeability, common in the United Kingdom.

With storm flood conditions also occurring more frequently in areas of Portugal over recent decades, enhanced infiltration techniques have the potential to mitigate the worst impact of such flooding events. Furthermore, the resulting enhanced infiltration of storm rainwater back to the unsaturated vadose zone will also serve to contribute to the mitigation of drought conditions, as the infiltrated rainwater will eventually find its way downwards to the water table.

2 STORMWATER ATTENUATION AND ENHANCED INFILTRATION SYSTEM

The enhanced infiltration system has been designed to attenuate and infiltrate large volumes of rainwater following storm events. The schematic in Figure 2 depicts how the system collects stormwater, and then how it is attenuated and infiltrated into the ground.

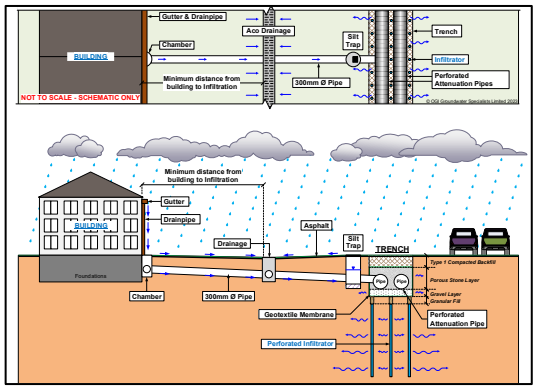

Figure 2. Attenuation and Enhanced Infiltration System.

Stormwater that lands on buildings and paved surfaces such as car parks, then enters the drainage system through a series of gutters and drains. Water then flows through a series of underground drains towards a silt trap where fine particles can settle out from the water to mitigate clogging of the infiltration system. Water then flows into a series of attenuation trenches set a minimum of 5.0 m away from any buildings. The trenches are typically in the order of 1.8 m wide and 1.7 m deep Figure 3).

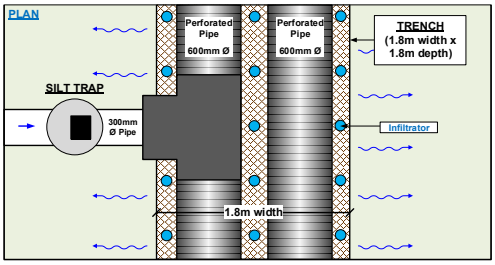

Figure 3. Schematic of the Attenuation and Enhanced Infiltration system in plan.

Each trench normally contains one or two large diameter perforated pipes, designed to provide a high storage volume to attenuate collected rainwater following a storm event. The trench is backfilled around the perforated pipes with gravel or angular stone. At the base of each trench, the pipes typically sit on a layer of 10 mm pea gravel. Gravel or stone is then backfilled around the pipes and typically to 300 mm above the crown of the pipes. Surrounding this gravel & pipe attenuation structure is a specialist nonwoven green geotextile developed to promote the growth of a microbic biofilm to absorb and digest any hydrocarbon. The nonwoven geotextile also provides stabilising of the sub-base construction. Above the attenuation structure is placed graded stone, which is compacted to provide greater bearing capacity.

Pre-drilled beneath the attenuation trenches are a series of specially designed vertical infiltrators (Figures 2 and 4), which aid the infiltration of water into the soil. Each infiltrator comprises a 90mm drilled borehole, then installed with a device that is designed to accelerate the transmission of water into the ground. The top of each infiltrator is set normally 300 mm below the base of the trench as depicted in Figure 4. The length of infiltrators normally varies between 3 m and 12 m, depending on the geology and volume rate of water that needs to be infiltrated.

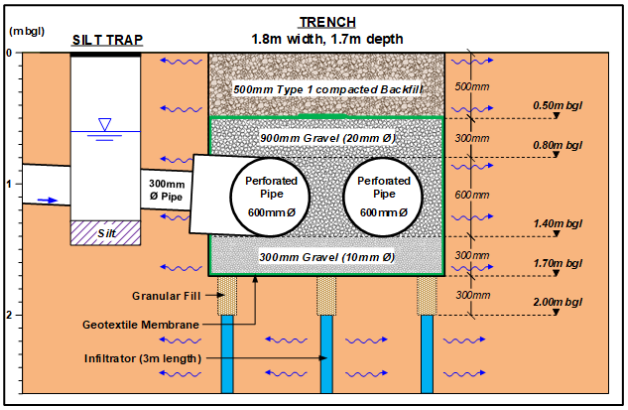

Figure 4. Attenuation and Enhanced Infiltration section.

The attenuation and enhanced infiltration system depicted above has been successfully implemented to discharge collected water at over 500 sites in the UK. The system provides an elegant and energy-efficient solution to the flooding challenges at each location.

The system has proved particularly successful in draining waterlogged sports fields, including rugby fields, cricket pitches and horse racing tracks. However, the main area of growth currently is for new-build housing and commercial construction, where city councils are legislating for 100% of the collected rainfall to be reintroduced back to ground.

To illustrate the application of this attenuation and enhanced infiltration system, Figures 5, 6 and 7 present the application at an industrial unit and car park in the northeast of England. The silty-clay ground was initially considered to be unsuitable to soakaway stormwater; but after installation, the 180m of trench, together with circa 500 infiltrators, was sufficient to manage the rainwater over a 4 Ha.

Figure 5. Perforated pipes within attenuation trenches.

Two horizontal perforated pipes are installed and then backfilled with gravel to 300 mm above the crown of the pipes. Nonwoven green geotextile wrapping of the gravel is then completed before a graded stone is infilled and compacted on top of the geotextile to provide greater bearing capacity before the construction of an asphalt finish for vehicle use.

To mitigate the potential of silts from entering the trench attenuation system, there are many silt traps and chambers constructed to intercept the silts. These structures are regularly cleaned as part of a planned maintenance program.

To degrade any possible hydrocarbon collected, the attenuation trench comprising pipes and gravel is wrapped with a specialist green nonwoven geotextile (Figure 6) before compaction of the grading layer.

Figure 6. Final backfilling of attenuation trench and wrapping with green nonwoven geotextile.

The combination of the nonwoven geotextile of a green fibre structure, with the pea gravel backfill, adds treatment for hydrocarbon contamination by

promoting the growth of a microbic biofilm which absorbs and digests the hydrocarbon.

3 RAINWATER INFILTRATION THEORY INTO UNSATURATED GROUND

Rainwater infiltration into unsaturated ground above the water-table is complex to simulate. When water fills the attenuation volume within the trenches, this water also fills the infiltrators beneath. This results in a high differential pore water pressure between the water-filled infiltrator, and the natural suction pressure in the surrounding unsaturated ground.

(i) The pressure in the infiltrators will be governed by the elevation of the water head in the attenuation storage (Figure 7). For example, if the water level fills the trenches to 600 mm above the base of the trench, and the infiltrators are installed to 3.3 m below the base of the trench, there will be a pressure of circa 38 kPa at the tip of the infiltrator.

(ii) The initial negative pore water pressure in the unsaturated ground surrounding the infiltrator (i.e., less than atmospheric pressure), is also commonly referred to as soil suction. In fine-grained soils, suction pressure can be high-negative, with values of -50 kPa regularly produced.

(iii) Combining these two conditions can result in circa 88 kPa in differential pore-water pressure between the positive pressure at the infiltrator tip and the negative suction pressure in the surrounding unsaturated soil. This results in the pressure in the infiltrator "pushing" the water into the surrounding ground, and the unsaturated ground also effectively "pulling" the water from the water-filled infiltrator.

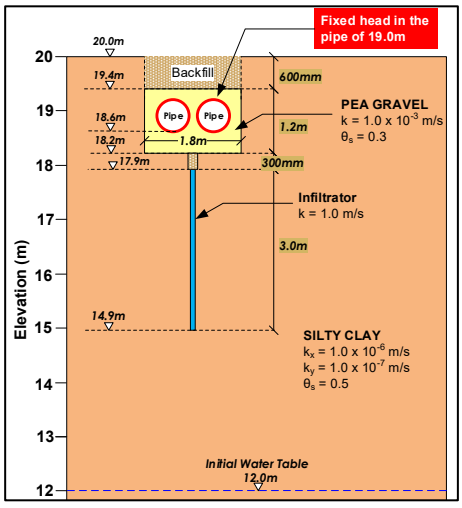

Figure 7. Conceptual model of a single infiltrator with ground properties used in the mathematical modelling.

Experience from the UK has demonstrated that the performance of a stormwater attenuation and enhanced infiltration system far exceeds the rate of infiltration from a normal and traditional soakaway trench, i.e. without the addition of drilled infiltrators.

This performance is regularly met with surprise by those who have traditionally viewed that a soakaway does not work sufficiently in silt or clay soils. However, when the concept of high anisotropy that occurs in a laminated soil, together with the fact that an unsaturated soil "pulls" the water from the infiltrator, especially when mathematical models are used to simulate and validate the performance, this innovative system is now becoming increasingly accepted in the construction industry.

Although over 500 enhanced infiltration systems have been installed in the UK, there is still always resistance to a new technique. The main opposition to the use of the system to dispose of stormwater is the view by some that this high water infiltration rate into low permeability ground is considered not feasible, despite the system having been tested and demonstrated to work in practice.

For this reason, more "science" has been required to demonstrate how it is indeed technically feasible to infiltrate high water flow rates into soils of low to medium permeability. To achieve this requirement, the authors built a non-linear finite element model to demonstrate that a carefully constructed and tested system can be proven to work scientifically.

4 FINITE ELEMENT MODELLING OF ENHANCED INFILTRATION

The movement of the collected stormwater through the infiltrator into the ground has been modelled by French and Thomas (Authors) using the GeoStudio finite element software SEEP/W (Geostudio, 2012).

The finite element model requires "discretisation" of the ground domain surrounding the infiltrators into tens of thousands of smaller zones called "elements" to geometrically simulate the groundwater behaviour using the radial version of the equation below:

$$\frac{\partial}{\partial x_i}\left(k_{rw}K_{ij}\frac{\partial h}{\partial x_j}\right) = \left(S_w S_s + \varphi\frac{\partial S_w}{\partial \psi}\right)\frac{\partial h}{\partial t} - Q_w \quad (1)$$

where k_{rw} is relative permeability, K_{ij} is Hydraulic Conductivity Tensor, h is hydraulic head, φ is porosity, S_w is water saturation, S_s is Specific Storage, ψ is pressure head, and Q_w is a point water source.

The non-linear functions used in the modelling for (i) Volumetric Water Content, and (ii) Hydraulic Conductivity, which are dependent on soil suction, are presented in Figures 8a and 8b.

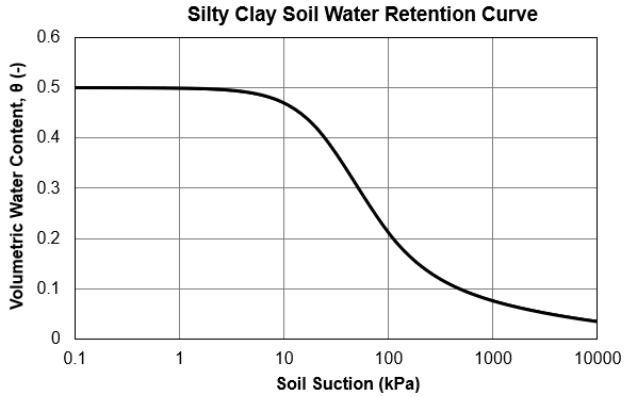

Figure 8a. Soil-water retention function curve.

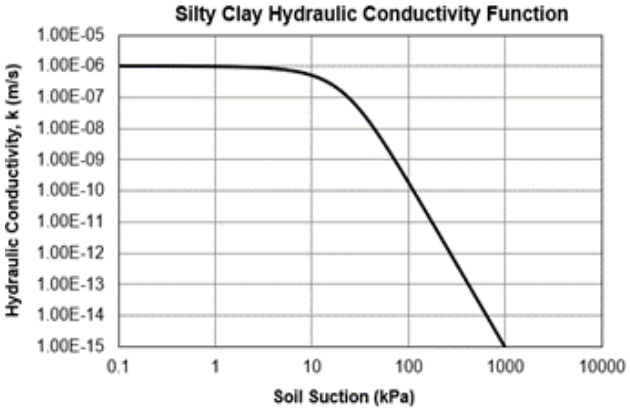

Figure 8b. Hydraulic conductivity function vs soil suction.

The finite element model then enables different properties and boundary conditions to be input in a range of locations for which the governing flow equation is solved, and heads output.

From these outputs, other information can be calculated such as pore pressure, degree of saturation and groundwater velocity.

An axisymmetric finite element computer model has been utilised to simulate two-dimensional radial steady-state flow of collected water into the vadose (unsaturated soil) zone surrounding an infiltrator.

For this scenario, a saturated sump and infiltrator have been simulated using SEEP/W. The simulated soil is based on a typical anisotropic silty clay, common to the northeast of England.

Input horizontal permeability is 1.0 x 10^{-6} m/s and vertical permeability 1.0 x 10^{-7} m/s. To simulate the unsaturated behaviour of the soil, SWRC (soil water retention curve) along with a hydraulic relative conductivity function have been selected based on typical functions for silty clays, (Figures 8a and 8b).

A fixed head boundary condition is applied to the sump, and a high permeability infiltrator is specified, to simulate the flooded sump and infiltrator.

Figure 9 presents simulated groundwater head contours (ranging from 18 m to 6 m) and the flow lines (shown by the green lines with arrows).

The dashed blue line represents the position of the water table (which is the position where pore water pressure equals 0.0 kPa and saturation equals 100%).

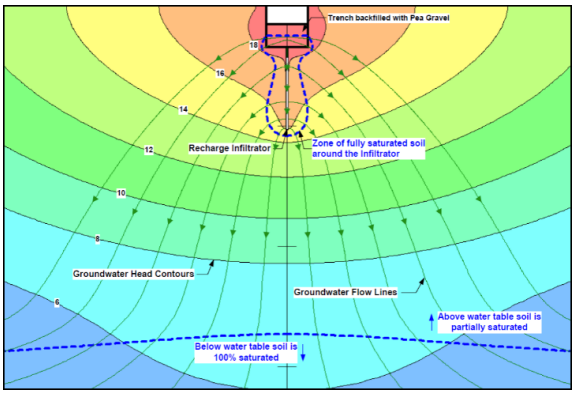

Figure 9. Simulated head contours and flow paths.

Groundwater flow velocity is driven by a gradient of hydraulic head (Darcy's Law); which explains the pattern of groundwater flow that can be seen in Figure 9. The head changes from 19.0 m at the sump to 15.0 m at the bottom of the infiltrator. This 4.0 m head differential drives the water down through the vertical infiltrator, as depicted by the green arrows.

Another driver is that the pore pressure in the unsaturated vadose zone above the water table will be negative, i.e. under suction. This means there is a greater differential head produced between the positive pressure in the infiltrators, and the negative pore-water pressure in the unsaturated vadose zone.

The collected and filtered water then enters the soil at depth, and then flows into the horizontal silt or sand layers of higher permeability. This horizontal flow into the soil results in a zone of fully saturated soil immediately surrounding the infiltrator within the upper blue water-table line in Figure 9.

Enhanced saturation enables greater groundwater flow into the surrounding soil as this increases the permeability. Radially from the infiltrator beyond the saturated zone, saturation decreases, increasing soil suction, but also reducing the effective permeability.

Whilst a reduction in the permeability of the soil occurs in the unsaturated zone, the soil suction pressure gradient, combined with the head gradient in the infiltrator, is sufficient to drive the collected water into the vadose zone surrounding the infiltrator.

The concept of transient stormwater attenuation and enhanced infiltration during and after a rainstorm event is depicted in Figure 10. Surface water during a storm event is directed to the drains and attenuation trenches. After cessation of the storm, this collected and attenuated stormwater will dissipate from the infiltrators into the surrounding unsaturated soil, and will then slowly percolate down to the water table, so ultimately restoring aquifer water resources.

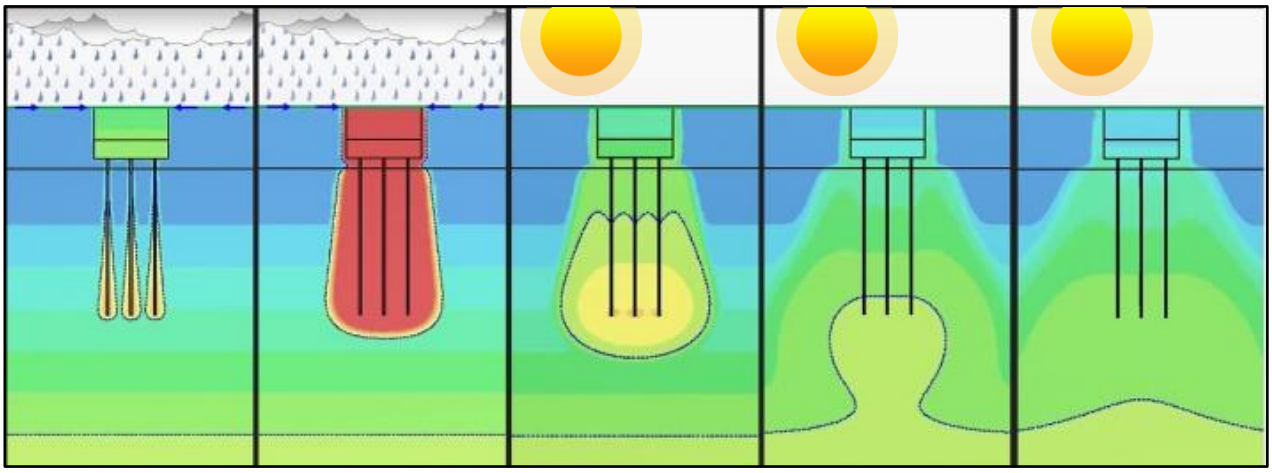

Figure 10. Various stages of attenuation and enhanced infiltration during and following a storm event.

5 CONCLUSIONS

A Stormwater Attenuation and Enhanced Infiltration System enables collection, attenuation and infiltration of stormwater back to the ground, thus mitigating surface flooding. This paper describes how this innovative attenuation and infiltration system functions in practice, and then demonstrates by mathematical modelling how water flows through the system and infiltrates water into the soil at a far greater rate than can be achieved using a conventional soakaway system. Soil characteristics used in this study are based on a typical laminated anisotropic silty clay.

Mathematical modelling conducted by the authors demonstrates that infiltration systems can be effective in both medium and low permeability ground, benefitting from the anisotropy of the ground where horizontal silt and sand bands exist within otherwise clay soil, as it enables the infiltration of stormwater at depth into more permeability soil layers.

Where stormwater has traditionally been sent to watercourses and sewers, the application of effective infiltration systems has a significant benefit by mitigating the risk of localised flooding, together with replenishing water resources. This opens the option of using enhanced infiltration systems anywhere in the world where shallow soakaway systems were once not originally thought suitable.

Stormwater attenuation and enhanced infiltration exemplify true low-carbon sustainability, contributing to the United Nations Department of Economic and Social Affairs for Sustainable Development Goal 6: ***Ensure availability and sustainable management of water and sanitation for all.***

ABSTRACT: Ground source heating and cooling is well established in many parts of the world providing a highly efficient source of low carbon heating and cooling. Given its efficiency, it is more economical to run a heat pump almost continually maintaining the minimum base heat/cool load, than it is to install a much bigger heat pump capable of reaching peak load for only short durations. For this reason, a heat pump system is most efficiently operated when integrated with other traditional or alternative energy sources to produce a hybrid system. This approach can be further enhanced by the application of other technologies, such as energy from low-carbon waste heat which can significantly improve the efficiency of heat pumps. Similarly, capturing cold night air in winter can be used to cool the ground to cool buildings in the summer in hot cities such as Lisbon. Two systems are presented to demonstrate the effectiveness of using the ground to store heat and cool energy to highlight the practical issues which may be encountered during design and installation.

RÉSUMÉ: Le chauffage et le refroidissement géothermiques sont bien établis dans de nombreuses régions du monde, fournissant une source très efficace de chauffage et de refroidissement à faible teneur en carbone. Compte tenu de son efficacité, il est plus économique de faire fonctionner une pompe à chaleur en maintenant presque continuellement la charge minimale de chauffage/refroidissement de base, que d'installer une pompe à chaleur beaucoup plus grande capable d'atteindre la charge maximale pendant de courtes durées seulement. Pour cette raison, un système de pompe à chaleur fonctionne plus efficacement lorsqu'il est intégré à d'autres sources d'énergie traditionnelles ou alternatives pour produire un système hybride. Cette approche peut être encore améliorée par l'application d'autres technologies, telles que l'énergie à partir de chaleur résiduelle à faible teneur en carbone, qui peut améliorer considérablement l'efficacité des pompes à chaleur. De même, la capture de l'air froid de la nuit en hiver peut être utilisée pour rafraîchir le sol afin de rafraîchir les bâtiments en été dans les villes chaudes comme Lisbonne. Deux systèmes sont présentés pour démontrer l'efficacité de l'utilisation du sol pour stocker la chaleur et refroidir l'énergie afin de mettre en évidence les problèmes pratiques qui peuvent être rencontrés lors de la conception et de l'installation.

Keywords: Ground source energy; heat pumps; low carbon heating and cooling.

1 INTRODUCTION

The worldwide drive towards cutting greenhouse gases and improving energy efficiency is underway. In recent years, this has resulted in the development of various new renewable technologies to generate electricity, and to produce sustainable low-carbon air and ground source systems for heating and cooling.

In the United Kingdom (UK), heating is the largest energy-consuming sector, accounting for over a third of greenhouse gas (GHG) emissions (UK Parliamentary Office of Science and Technology, 2016). In 2017, domestic heating accounted for 57% of the UK's greenhouse emissions from heating, with 20% from non-domestic (commercial) consumers, and the remainder from the industrial sector (Department for Business, 2018).

Across Northern Europe and North America, heat pump technology is used to both heat and cool buildings (Omer, 2006). However, in the UK, where gas has been traditionally used to heat homes, there is a resistance to replace a fully gas heated building with one 100% heated from ground source.

Recent advancements in technology have resulted in the design of heating and cooling systems that use ground source systems for the predominant source of heating, but with gas boilers stepping in to provide a top-up during times of extreme heating demand, and chillers being activated at times of peak cooling demand, which provides a valuable back-up system.

This paper examines the design of ground source heating and cooling systems, and describes the basic principles of a ground source system with a top-up/back-up system. Case studies are presented to show working examples of integrated ground source systems. The paper also explores how heating and cooling ground source systems can use the residual heat and coolth to operate more efficiently by storing the heat/cool energy in the ground, and so improving the efficiency of the system all year round.

Where ground source heating and cooling systems are used to replace traditional fossil fuels (i.e. gas, oil) there will be reduced carbon emissions. Using a GSHP system with a coefficient of performance (CoP) of 4.0 as an example, 75% of the thermal energy to the building is zero carbon energy abstracted from the ground. This means that there is an immediate four-fold reduction in carbon emissions. Furthermore, if the electricity used for powering the heat pump is sourced from zero-carbon energy such as wind power or photo-voltaic, then the complete system can be zero carbon.

2 TYPICAL HEAT DEMANDS OF A HEATING SYSTEM

The demand for heat in a building over a calendar year is not uniform. Clearly, there is a higher demand for heat during the winter months, than in the summer months. Additionally, heat demand varies throughout the day, during the night, and on weekends. With this, there are colder periods of weather which cannot be predicted. As a consequence of the weather variations, together with the variability of building usage and occupation, the heat demand from the heating system is highly variable.

Traditionally, a gas boiler system is sized for the maximum predicted demand, together with additional capacity. This approach is economic in that the installation cost of a gas boiler of, for example, 200 kW, is only slightly more than the installation cost of a 100 kW gas boiler. The main cost to the building is in the running costs of gas consumption per kWh. However, for a ground source system, the main costs are in the heat collection network, which comprises drilling, heat collectors, manifolds, etc. For this reason, a 200 kW ground source system can be almost twice the cost of a 100 kW ground source system.

It is for this reason that attention must be given to the most efficient sizing of the ground source system, including the size of the ground heat collection array.

In the design of a ground source heating system, it is recognised that specifying for the peak heat loading is highly inefficient regarding costs, and even carbon emissions. As an example, Figure 1 depicts a two-week period of predicted heat demand for a new hospital in the northeast of England. This figure demonstrates that if the peak building heat requirement is 1167 kW, then installing a 700 kW ground source heating system only provides 60% of the peak heating. However, the red area of the graph is the energy in kWh that is the shortfall, but the red area is substantially less than the green area, which is the total heat energy that can be provided by the ground source system. This means that the most effective system is one in which the main annual heat load is provided by the ground source, but with a top-up of peak heat, provided by a more traditional electric or gas system.

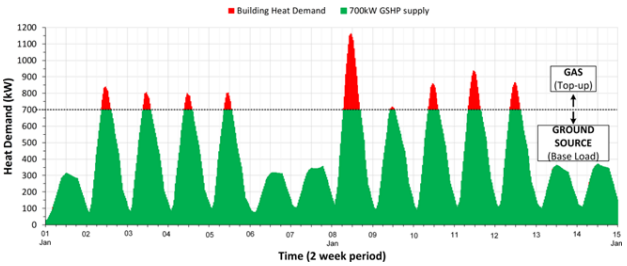

Figure. 1. Heat demand (kW) and ground source heat pump (700 kW) heat supply for a hospital.

The heat load demand for every building is always different, and the peak demand requires specification by a specialist. However, as depicted in Figure 2, the percentage of "full-load hours" of the heating demand, over an annual 8766 hours, is relatively consistent from building to building.

Based on the above, an efficient and pragmatic approach is to combine the technologies as follows:

1. Construct a ground source system to satisfy the bulk (circa 95%) of the total heat demand for a typical year, in kWh;
2. Choose the heat pump sized to maximise efficiency up to circa 60% of peak supply in kW;
3. Augment the ground source system with a gas/oil/electric boiler which provides a top-up heat supply at the point of the need. Typically, this top-up system need only provide 5% of annual demand, but can provide 100% if a back-up is required.

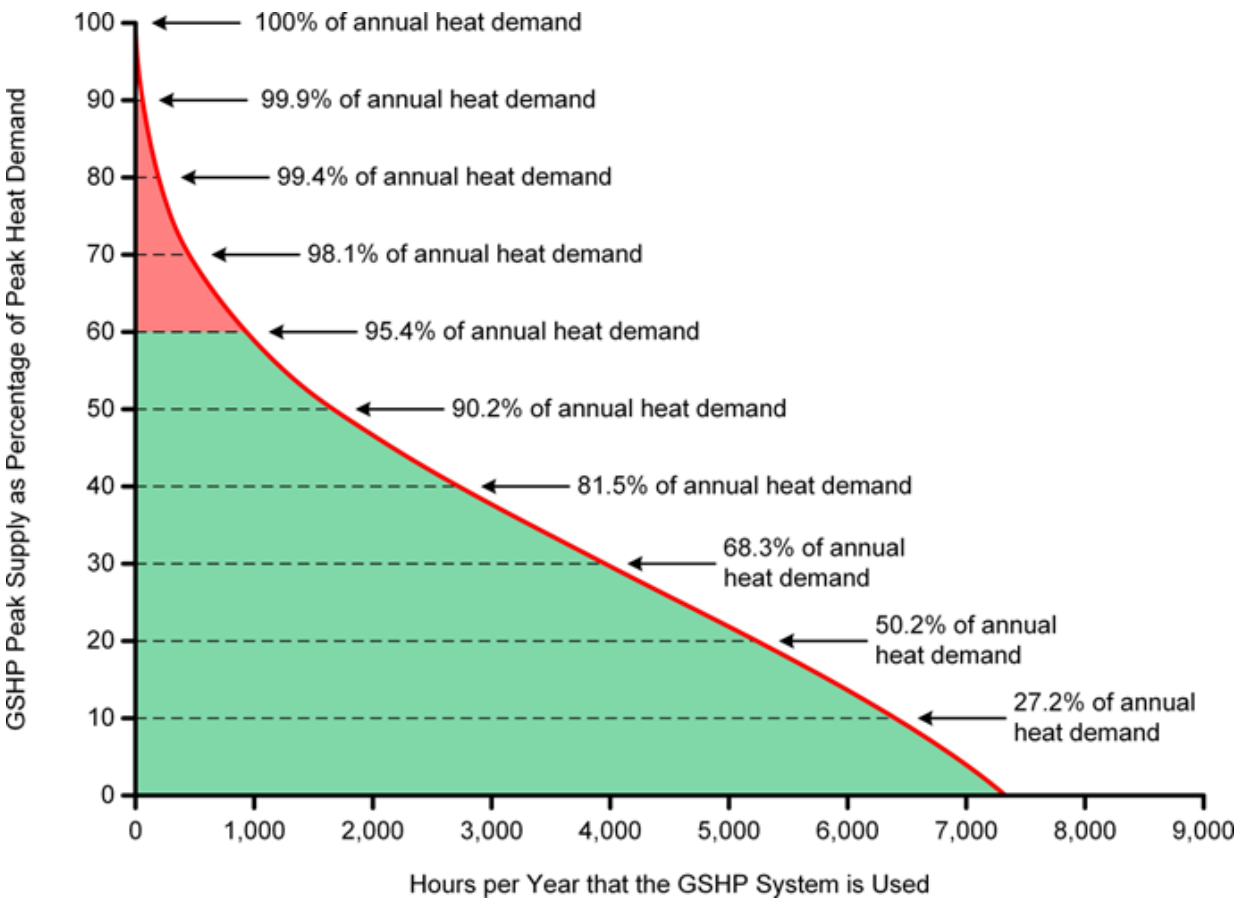

Figure 2. Graph depicting heat pump annual full load hours.

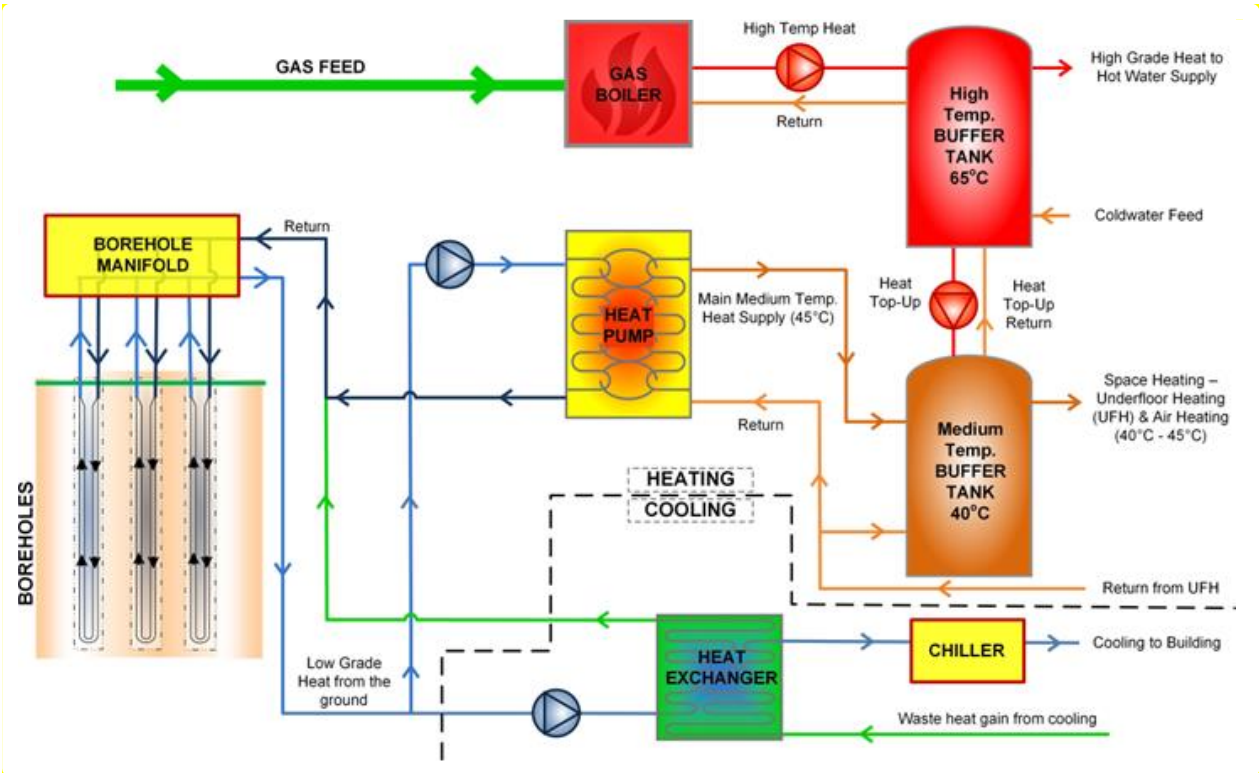

Figure 3. Schematic of ground source heating and cooling system integrated with gas boiler and electric chiller.

3 TOP-UP/ BACK-UP HEATING SYSTEM

The energy source used for top-up heating can be from a range of sources. Traditionally, this could be from natural gas, oil, LPG or electric immersion heaters. In addition, whilst heat pumps are very reliable, it can be good practice to use the top-up system as a backup (Thomas, et al. 2019). Then if there is a temporary impact on the ground source system, continued heating can be provided by the top-up system acting as backup. As the requirement for reducing carbon emission is becoming more in demand, hybrid systems depicted in Figure 3 are regularly installed to bring down the overall costs of such low-carbon heating systems.

4 CASE STUDY

The following describes details of a system designed and constructed in the north of England that has been selected to illustrate the cost and carbon reductions of a combined ground source heating and cooling system.

In 2008, a ground source heating and cooling system was designed for the new-build Stanley Primary Care Centre in County Durham, UK.

The NHS (National Health Service) Care Centre building provides an extensive range of modern medical services under one roof, including GP practices, dentistry, x-ray diagnosis and facilities to conduct minor operations. This is stated here to demonstrate that it was an essential pre-requirement for a reliable, cost-effective and low-carbon heating system to be constructed. The ground source heating system at Stanley, utilised two heat pumps, to provide heating water at 45°C used to feed the underfloor heating system and the electric fan coil ventilation system. The system generates 80 kW of peak heating, provided by two NIBE 40 kW “Fighter 1330” heat pump units. On occasions of high heating demand, the system is supplemented by integrated gas boilers, which provide up to 50 kW of heat. The gas boilers also provide heat to the building's DHW through a plate heat exchanger to the buffer vessel. The top-up system is controlled by the Building Management System (BMS) following a request for additional heat from the heat pumps.

Heat is collected from the ground via a total of 22 No. vertical boreholes and connecting trenchwork (19 No. boreholes drilled to a depth of 100 m and 3 No. boreholes drilled to a depth of 50 m). The majority of the boreholes were drilled beneath the building footprint, before construction (Figure 4).

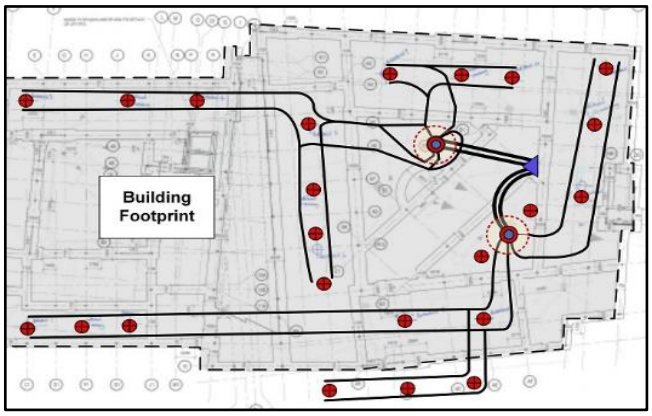

Figure 4. Stanley centre ground source collectors.

The trenches to accommodate the horizontal pipework were excavated and installed following the construction of the building superstructure.

The ground conditions beneath the site comprised interbedded sandstone, shales, and mudstone. Heat modelling was undertaken using in-house thermal software during the preliminary design stage to assess the heat replenishment of the ground (Figure 5).

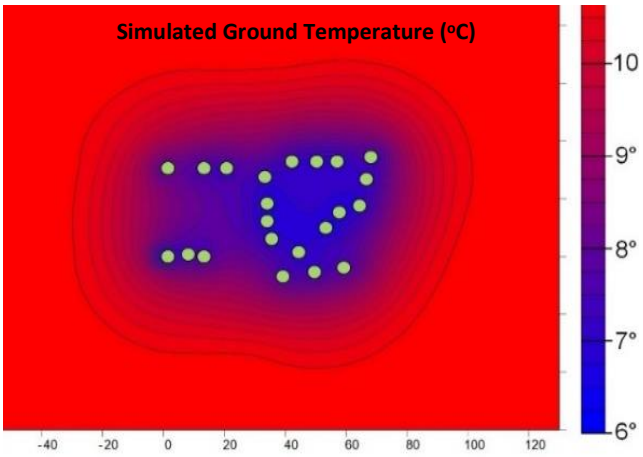

Figure 5. Thermal modelling of the ground collectors.

Each borehole has double loop collectors flow and return pipes. These are connected via underground horizontal 32 mm HDPE flow and return pipes installed within backfilled trenches to two manifold chambers. Each manifold leg is connected to a 63 mm flow and return header pipe that connects to the heat pumps located within the plant room. Manifold chambers are buried beneath ground level within the central courtyard areas of the building (Figure 6).

In summer months, the system provides 80 kW of chilled water which is stored in a chilled water accumulator. The system can do this ’passively’ (i.e. where heat transfer fluid is circulated through the ground collectors by a circulation pump but where the heat pump does not operate) or ’actively’, where the cooling water is generated by the heat pump.

Figure 6. Manifold chamber installed in the courtyard.

The heat pumps, water tanks and gas boilers are housed in the plant room on the third floor (Figure 7).

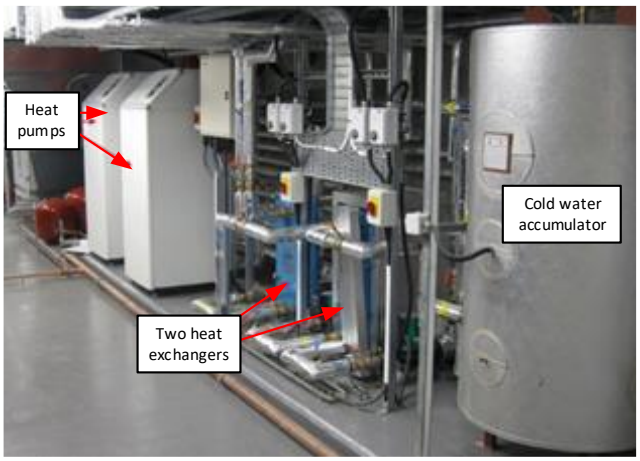

Figure 7. Stanley heat pumps, manifolds, chiller tanks.

5 FCT FUNDED PROJECTS, PORTUGAL

There has been a growing interest in the scientific and technical communities in the study of shallow geothermal systems and the assessment of their sustainability under the prevailing conditions in Southern Europe, particularly for the authors of this work, within the climatic conditions occurring in Portugal (Aljundi, et al. 2023). Between 2017 and 2021, the Portuguese National Library for Civil Engineering (LNEC) and the University of Aveiro (UA) collaborated on a research project funded by the Portuguese Foundation for Science and Technology (FCT), – ref. PTCDT/ ECM-GEO/0728/2014. In this project, the integrated behaviour of geothermal systems (primary and secondary circuits) was studied and modelled. Buildings at UA, whose climate control relies on different options of superficial geothermal systems, were used as prototypes. The project involved soil thermal characterization (Vieira et al. 2017), leading to the team gaining significant expertise. It also included extensive dynamic building modelling activities incorporating the analysis of the Shallow Geothermal System (SGE). This activity contributed to the formation of a successful collaborating working group, which is continuing and expanding.

More recently, as part of a new project, also funded by FCT – ref. PTDC/ECM-GEO/0728/2021, including in the team the Lisbon City Council (CML) and experts from the UK, there is an ongoing study on the geothermal potential of the city of Lisbon. This study has included a preliminary assessment of the thermal conductivity of the geological formations occurring in the city of Lisbon. This is presented in Figure 8, which includes the location of three testing boreholes: 1, 2, 3.

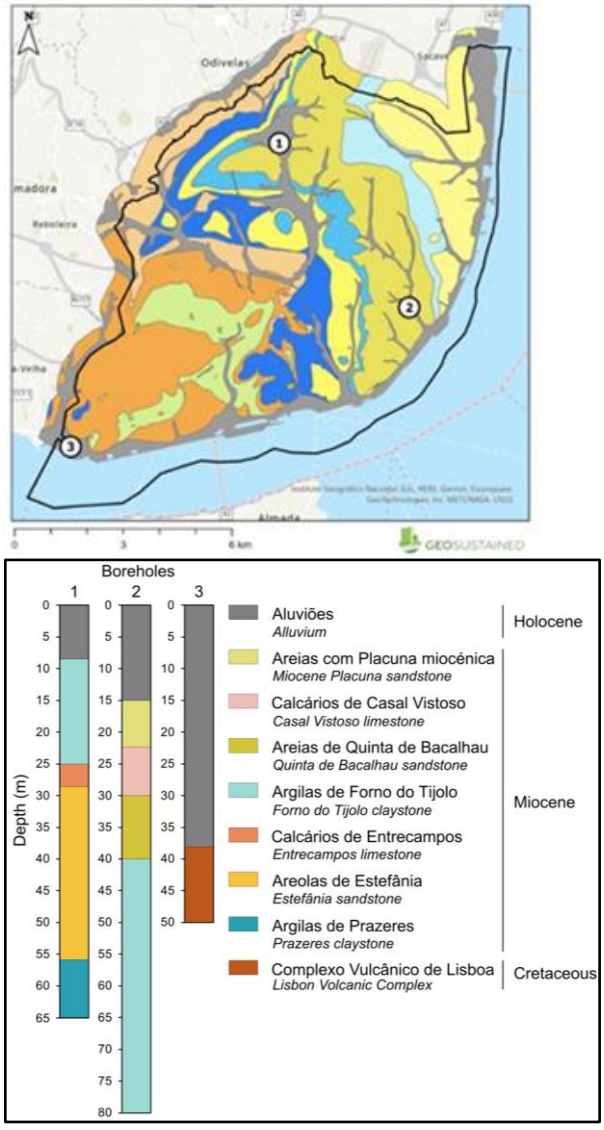

Figure 8. Lithology encountered in boreholes 1, 2, 3.

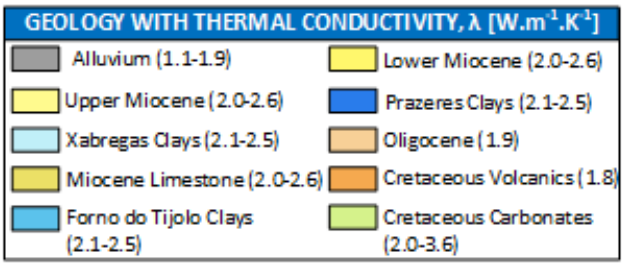

Figure 9. Lisbon thermal conductivity map, with values assessed and compiled by Vieira et al. (2023).

This comprehensive study encompasses the appraisal of the thermal characterization of the city's main geological formations, and the installation of temperature monitoring sensors at various locations in the city, allowing an understanding of the seasonal evolution of temperature to considerable depths.

The appraisal is based on bibliographic correlations that are already in the process of being validated with laboratory studies (Inácio et al, 2023; Vieira et al. 2023), as depicted in Figures 8 and 9.

Subsequent integrated studies will analyse the sustainability of these systems for different types of buildings and different SGE solutions. The entire group recognizes the importance of these studies in preparing and planning the city's evolution and addressing new challenges, particularly in the context of global warming, whose predictions indicate severe impacts on the city of Lisbon.

6 CONCLUSIONS

When designing a ground source heating and cooling system, it is ideal if there is a balance between the abstraction of heat from the ground when heating the building in the winter, and the return of the heat to the ground when cooling the building in the summer.

Similarly, the same type of ground energy balance is applied to a cooling system, whereby the ground cooling system can provide the dominant reduction in temperature through the year in kWh, with a traditional A/C unit providing a top-up system in peak demand.

When designing a balanced system for hot cities such as Lisbon, the sustainability of the ground must be considered, especially to prevent the ground temperatures from rising uncontrollably. This can be mitigated by capturing cold air during winter nights, then via heat exchangers, providing cool energy to the ground in preparation for the summer cooling period.

Meticulous testing and pilot projects are required to implement this approach sustainably. For this reason, it is encouraging to see many organisations working together to achieve this goal. This collaboration has already commenced with LNEC, the Câmara Municipal de Lisboa (CML) and UA, supported by UK-based OGI Groundwater Specialists, undertaking a research project (Project GeoSustained) to establish the thermal properties of the ground beneath the city, together with the measurements of transient ground temperatures from boreholes drilled to 80 m in depth.

Work has now started with engineers and scientists from Portugal and the UK building upon the current research to develop innovative low-carbon ground source heating, and particularly cooling systems specifically designed for the specific geology and cooling demands of the buildings in the city of Lisbon.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the recent collaboration between leading scientific, engineering and governmental organisations in Portugal and the UK, and to FCT (Portuguese Foundation for Science and Technology) under the Project GeoSustained (PTDC/ECICON/1866/2021).

Finite element modelling of wave loading on a multi-layered gassy soil seabed using complex number theory

Modélisation par éléments finis de la charge des vagues sur un fond marin à sol multicouche à l'aide de la théorie des nombres complexes

S.D. Thomas*
OGI Groundwater Specialists Ltd, City of Durham, UK
**stephen.thomas@ogi.co.uk*

ABSTRACT: Ocean wave loading on a gassy soil seabed, results in harmonic changes in stresses, displacements and pore water pressures over depth. For a multi-layered seabed soil with homogeneous properties within each layer, the behaviour of the dependent variables of displacement and pore pressure can be represented by a harmonic function in both horizontal space (x) and time (t). The amplitude of the horizontal & vertical displacement and pore-water pressure will vary over depth, dependent on the particular distribution of the multi-layered properties, together with the wave loading amplitude, wave number and angular velocity, together with the boundary conditions at the seabed, i.e. permeable or impermeable. To simulate the behaviour of the seabed in harmonic wave conditions, this paper presents a series of governing equations based on Biot theory for poro-elastic soil. These equations have been modified to represent the harmonic behaviour using real & imaginary complex number theory. The Finite Element Galerkin formulation combined with Green's Theorem is applied to these harmonic equations which result in six degrees of freedom per node, i.e. x-displacement, z-displacement and pore-water pressure, in both real (in-phase) & imaginary (out-of-phase) conditions. The harmonic finite element model can be used to match measured pore water pressure amplitude decay at various depths within a seabed, when subject to wave & tide loading.

RÉSUMÉ: La charge des vagues océaniques sur un fond marin gazeux entraîne des changements harmoniques dans les contraintes, les déplacements et les pressions de l'eau interstitielle en profondeur. Pour un sol de fond marin multicouche avec des propriétés homogènes au sein de chaque couche, le comportement des variables dépendantes du déplacement et de la pression interstitielle peut être représenté par une fonction harmonique à la fois dans l'espace horizontal (x) et dans le temps (t). L'amplitude du déplacement horizontal et vertical et de la pression de l'eau interstitielle variera en fonction de la profondeur, en fonction de la distribution particulière des propriétés multicouches, ainsi que de l'amplitude de charge des vagues, du nombre de vagues et de la vitesse angulaire, ainsi que des conditions aux limites du fond marin, c'est-à-dire perméable ou imperméable. Pour simuler le comportement des fonds marins dans des conditions de vagues harmoniques, cet article présente une série d'équations régulatrices basées sur la théorie de Biot pour les sols poro-élastiques. Ces équations ont été modifiées pour représenter le comportement harmonique à l'aide de la théorie des nombres complexes réels et imaginaires. La formulation de Galerkin par éléments finis combinée au théorème de Green est appliquée à ces équations harmoniques qui se traduisent par six degrés de liberté par nœud, c'est-à-dire le déplacement x, le déplacement z et la pression de l'eau interstitielle, dans des conditions réelles (en phase) et imaginaires (hors phase). Le modèle d'éléments finis harmoniques peut être utilisé pour faire correspondre la décroissance mesurée de l'amplitude de la pression de l'eau interstitielle à différentes profondeurs dans un fond marin, lorsqu'il est soumis à une charge de vagues et de marée.

Keywords: Wave loading; marine sediment; gassy soil; multi-layer; finite element modelling.

1 INTRODUCTION

This paper describes a Finite Element formulation of the differential equations that govern the wave-induced stresses, displacements and pore-water pressures in a multi-layered or anisotropic poro-elastic soft gassy soil seabed when subject to surface harmonic wave loading.

The harmonic stress, displacement and pore-water pressure behaviour of a gassy soil can be simulated under conditions that soil properties are homogeneous in the horizontal x and y directions, but can be variable, as in a multi-layered soil, in the vertical z-direction.

Under the condition that the total stress and water pressure loading on the seabed is harmonic in both timeand x-direction, that is a combination of a cosine and sine loading, the behaviour of each dependent variable is also harmonic in both time and the x-direction, and is governed by the wave period and wavelength of the loading wave; multiplied by the peak amplitude of the dependent variable. This is based on the equations by Yamamoto et al. (1978) and Madsen (1978).

When a combination of cosine and sine components of each dependent variable is replaced with complex

number theory, this enables application of the Galerkin Finite Element formulation combined with Green's Theorem, to the equations in the vertical dimension. This requires solving six degrees of freedom per node.

2 DIFFERENTIAL EQUATIONS FOR MULTI-LAYER & ANISOTROPIC PORO-ELASTIC SOIL CONDITIONS

Based on the Biot (1941) equations that govern the displacement, stresses and pore water pressures in a poro-elastic soil, as modified by Thomas (1987) for a Double Compressibility Gassy Soil, the equations of equilibrium in the x-direction, equilibrium in the z-direction, and continuity principles incorporating Darcy's Law of pore-fluid flow through a deformable poro-elastic medium, the following differential equations can be written for small strain conditions:

$$(\lambda + 2G)\frac{\partial^2 w_x}{\partial x^2} + G\frac{\partial^2 w_x}{\partial z^2} + \lambda\frac{\partial^2 w_z}{\partial x \partial z} + G\frac{\partial^2 w_z}{\partial z \partial x} - B\frac{\partial u_w}{\partial x} = 0 \quad (1)$$

$$(\lambda + 2G)\frac{\partial^2 w_z}{\partial z^2} + G\frac{\partial^2 w_z}{\partial x^2} + \lambda\frac{\partial^2 w_x}{\partial z \partial x} + G\frac{\partial^2 w_x}{\partial x \partial z} - B\frac{\partial u_w}{\partial z} = 0 \quad (2)$$

$$\frac{\partial}{\partial x}\left[\frac{k_{xx}}{\gamma_w}\frac{\partial u_w}{\partial x} + \frac{k_{xz}}{\gamma_w}\frac{\partial u_w}{\partial z}\right] + \frac{\partial}{\partial z}\left[\frac{k_{zx}}{\gamma_w}\frac{\partial u_w}{\partial x} + \frac{k_{zz}}{\gamma_w}\frac{\partial u_w}{\partial z}\right] = C\frac{\partial u_w}{\partial t} + B\frac{\partial}{\partial t}\left[\frac{\partial w_x}{\partial x} + \frac{\partial w_z}{\partial z}\right] \quad (3)$$

where w_x and w_z are the soil displacements in the x-horizontal and the z-vertical directions respectively, t is time, u_w the pore-water pressure within the soil matrix, k_{ij} the coefficient of permeability tensor, λ the Lame's constant and G the shear modulus. The gassy soil parameters B and C are derived from gassy soil theory (Thomas, 1987) as follows:

$$B = K^o/(K^o + K") = (1 + K"/K^o)^{-1} \quad (4)$$

$$C = (K^o + K")^{-1} + (1 - H)c_w n_w \quad (5)$$

The parameter K^o is the component of undrained bulk modulus governed by compression of the discrete gas bubbles, caused by an increase in total stress. Contributing to undrained compressibility is also water compressibility, c_w, water porosity, n_w, and Henry's constant H. The parameter $K"$ is the component of drained bulk modulus governed by consolidation of the saturated soil matrix. This results in two independent strain components, (i) caused by an increase in the total stress σ^o, and (ii) caused by an increase in the operative stress $(\sigma^o - u_w)$.

The modified equilibrium equations for a poro-elastic gassy soil are based on a Double Compressibility Model (Thomas, 1987) where the compression of the discrete gas bubbles is governed by the increase in the pressure of the gas bubbles, which in turn is governed by the average total stress within the soil. The compression of the surrounding saturated soil matrix, however, is governed by the difference between the total stress and the pore water pressure.

This difference between total stress and pore water pressure $(\sigma^o - u_w)$ is normally known as *effective stress* (Terzaghi, 1944). However, for a gassy soil, effective stress does not, on its own, govern the total volume change. For gassy soil, this difference between the mean total stress on a soil sample and the water pressure has been coined, the *operative stress* (Sills et al, 1991). This results in two independent components of strain caused by (i) an increase in the total stress σ^o, and (ii) an increase in the operative stress $(\sigma^o - u_w)$,

$$\epsilon^o = \Delta V^o/V = \Delta\sigma^o/K^o \quad (6)$$

$$\frac{\epsilon = \Delta V}{V} = \Delta\sigma"/K = (\Delta\sigma^o - \Delta u_w)/K \quad (7)$$

where ϵ^o is the volumetric strain due to the compression of the discrete gas bubbles caused by an increase in total mean stress $\Delta\sigma^o$, with $\epsilon"$ as the volumetric strain due to the compression of the soil matrix caused by an increase in operative stress $\Delta\sigma"$.

The main principle of the Double Compressibility Model (Thomas, 1987) for a gassy soil is that these two components of volumetric strain for a gassy soil, ϵ^o and, $\epsilon"$, can be added directly together to provide the total volumetric strain, as follows:

$$\epsilon = \epsilon^o + \epsilon" = \Delta\sigma^o/K^o + \Delta\sigma"/K" = \Delta\sigma^o/K^o + (\Delta\sigma^o - \Delta u_w)/K" \quad (8)$$

from which the change in total stress can be defined in terms of strain and pore pressure as:

$$\Delta\sigma^o = (\epsilon + \Delta u_w/K")/(1/K^o + 1/K") \quad (9)$$

3 HARMONIC APPROXIMATION OF GOVERNING EQUATIONS

For wave loading on the seabed when travelling in the x-direction along the surface of the seabed as depicted in Figure 1; under poro-elastic conditions, based on the equations by Yamamoto et al. (1978) and Madsen (1978), any variable ψ which is dependent on x, z and

t can be defined by a variable dependent in z only, multiplied by a harmonic function dependent on *x & t*:

$$\psi(x,z,t) = \psi_c + i\,\psi_s \tag{10}$$

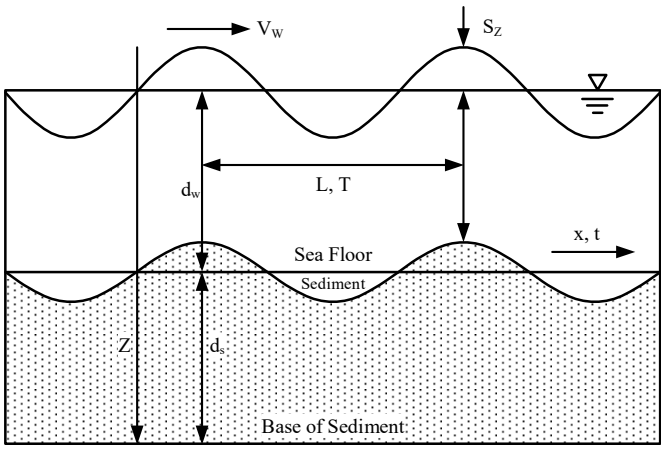

Figure. 1. Harmonic wave loading on a seabed sediment.

where:

$$\psi_c = \overline{\psi}(z)\cos(ax - \omega t) \tag{11}$$

$$\psi_s = \overline{\psi}(z)\sin(ax - \omega t) \tag{12}$$

and where $\overline{\psi}(z)$ is the peak variable function amplitude at depth z, from which:

$$\overline{\psi}(z) = \sqrt{\psi_c^2 + \psi_s^2} \tag{13}$$

$$\frac{\partial \psi}{\partial x} = +ia\psi = +ia\psi_c - a\psi_s \tag{14}$$

$$\frac{\partial \psi}{\partial t} = -i\omega\psi = -i\omega\psi_c + \omega\psi_s \tag{15}$$

where $\overline{\psi}$ is the amplitude of the harmonic variable at depth z, with a the wave number $2\pi/L$, with ω the angular velocity $2\pi/T$, and with L the wavelength and T the wave period.

This results in the harmonic displacements and pore-water pressure inhomogeneous, anisotropic soil sediment, being represented as follows:

$$w_x(x,z,t) = w_{xc} + iw_{xs} = \overline{w}_x(z)[\cos(ax - \omega t) + i\sin(ax - \omega t)] \tag{16}$$

$$w_z(x,z,t) = w_{zc} + iw_{zs} = \overline{w}_z(z)[\cos(ax - \omega t) + i\sin(ax - \omega t)] \tag{17}$$

$$u_w(x,z,t) = u_{wc} + iu_{ws} = \overline{u}_w(z)[\cos(ax - \omega t) + i\sin(ax - \omega t)] \tag{18}$$

Substituting the above three harmonic functions of x, z displacements and pore pressure into the governing equilibrium and continuity equations (1), (2) & (3), produces three differential equations, written as a mixture of real & imaginary harmonic variables:

$$-a^2(\lambda + 2G)w_x + G\frac{\partial^2 w_x}{\partial z^2} + ia(\lambda + G)\frac{\partial w_z}{\partial z} - iaBu_w = 0 \tag{19}$$

$$+(\lambda + 2G)\frac{\partial^2 w_z}{\partial z^2} - a^2 G w_z + ia(\lambda + G)\frac{\partial w_x}{\partial z} - B\frac{\partial u_w}{\partial z} = 0 \tag{20}$$

$$-a^2\frac{k_{xx}}{\gamma_w}u_w + \frac{k_{zz}}{\gamma_w}\frac{\partial^2 u_w}{\partial z^2} + ia\frac{k_{xz}}{\gamma_w}\frac{\partial u_w}{\partial z} + ia\frac{k_{zx}}{\gamma_w}\frac{\partial u_w}{\partial z} = -i\omega C u_w + a\omega B w_x - i\omega B\frac{\partial w_z}{\partial z} \tag{21}$$

4 GALERKIN FINITE ELEMENT FORMULATION

Applying the Galerkin Finite Element formulation to the above equations in the vertical dimension, combined with Green's Theorem, results in:

$$\int \left[a^2(\lambda + 2G)N_I N_J\, w_{xJ} + G\frac{\partial N_I}{\partial z}\frac{\partial N_J}{\partial z}w_{xJ} + iaG\frac{\partial N_I}{\partial z}N_J w_{zJ} - ia\lambda\, N_I\frac{\partial N_J}{\partial z}w_{zJ} + iaB\, N_I N_J\, u_{wJ}\right]dz = S_{xI} \tag{22}$$

from equilibrium in the x-direction,

$$\int \left[(\lambda + 2G)\frac{\partial N_I}{\partial z}\frac{\partial N_J}{\partial z}\, w_{zJ} + a^2 G N_I N_J\, w_{zJ} + ia\lambda\frac{\partial N_I}{\partial z}N_J w_{xJ} - iaGN_I\frac{\partial N_J}{\partial z}w_{xJ} - B\frac{\partial N_I}{\partial z}N_J\, u_{wJ}\right]dz = S_{zI} \tag{23}$$

from equilibrium in the z-direction, and

$$\int \left[\frac{k_{zz}}{\gamma_w}\frac{\partial N_I}{\partial z}\frac{\partial N_J}{\partial z} - ia\frac{k_{xz}}{\gamma_w}N_I\frac{\partial N_J}{\partial z} + ia\frac{k_{zx}}{\gamma_w}\frac{\partial N_I}{\partial z}N_J + a^2\frac{k_{xx}}{\gamma_w}N_I N_J - i\omega C\, N_I N_J\right]u_{wJ}dz + \int\left[a\omega B N_I N_J w_{xJ} - i\omega B N_I\frac{\partial N_J}{\partial z}w_{zJ}\right]dz = Q_{wI} \tag{24}$$

from continuity principles incorporating Darcy's Law.

Substituting equations 16, 17, 18 into the above three mixed real & imaginary differential equations, then separating the real & imaginary terms, results in six differential equations, each with nodal harmonic dependent variables as follows:

$$(a^2(\lambda+2G)\bar{\Gamma}_{IJ}+G\bar{A}^{zz}_{IJ})\bar{w}_{xcJ} - (aG\bar{B}^{zN}_{IJ} - a\lambda\bar{B}^{Nx}_{IJ})\bar{w}_{zsJ} - aB\bar{\Gamma}_{IJ}\,\bar{u}_{wsJ} = \bar{S}_{xcI} \quad (25)$$

$$(a^2(\lambda+2G)\bar{\Gamma}_{IJ}+G\bar{A}^{zz}_{IJ})\bar{w}_{xsJ} + (aG\bar{B}^{zN}_{IJ} - a\lambda\bar{B}^{Nx}_{IJ})\bar{w}_{zcJ} + aB\bar{\Gamma}_{IJ}\,\bar{u}_{wcJ} = \bar{S}_{xsI} \quad (26)$$

$$((\lambda+2G)\bar{A}^{zz}_{IJ} + a^2G\bar{\Gamma}_{IJ})\bar{w}_{zcJ} - (a\lambda\bar{B}^{zN}_{IJ} - aG\bar{B}^{Nx}_{IJ})\bar{w}_{xsJ} - B\bar{B}^{zN}_{IJ}\,\bar{u}_{wcJ} = \bar{S}_{zcI} \quad (27)$$

$$((\lambda+2G)\bar{A}^{zz}_{IJ} + a^2G\bar{\Gamma}_{IJ})\bar{w}_{zsJ} + (a\lambda\bar{B}^{zN}_{IJ} - aG\bar{B}^{Nx}_{IJ})\bar{w}_{xcJ} + B\bar{B}^{zN}_{IJ}\,\bar{u}_{wsJ} = \bar{S}_{zsI} \quad (28)$$

$$\left(a^2\frac{k_{xx}}{\gamma_w}\bar{\Gamma}_{IJ}+\frac{k_{zz}}{\gamma_w}\bar{A}^{zz}_{IJ}\right)\bar{u}_{wcJ} - \left(a\frac{k_{zx}}{\gamma_w}\bar{B}^{zN}_{IJ} - a\frac{k_{xz}}{\gamma_w}\bar{B}^{Nz}_{IJ} - \omega C\bar{\Gamma}_{IJ}\right)\bar{u}_{wsJ} + a\omega B\bar{\Gamma}_{IJ}\,\bar{w}_{xcJ} + \omega B\bar{B}^{Nz}_{IJ}\,\bar{w}_{zsJ} = \bar{Q}_{wcI} \quad (29)$$

$$\left(a^2\frac{k_{xx}}{\gamma_w}\bar{\Gamma}_{IJ}+\frac{k_{zz}}{\gamma_w}\bar{A}^{zz}_{IJ}\right)\bar{u}_{wsJ} + \left(a\frac{k_{zx}}{\gamma_w}\bar{B}^{zN}_{IJ} - a\frac{k_{xz}}{\gamma_w}\bar{B}^{Nz}_{IJ} - \omega C\bar{\Gamma}_{IJ}\right)\bar{u}_{wcJ} + a\omega B\bar{\Gamma}_{IJ}\,\bar{w}_{xsJ} - \omega B\bar{B}^{Nz}_{IJ}\,\bar{w}_{zcJ} = \bar{Q}_{wsI} \quad (30)$$

where:

$$\bar{A}^{zz}_{IJ} = \int \frac{\partial N_I}{\partial z}\frac{\partial N_J}{\partial z}\,dz \quad (31)$$

$$\bar{\Gamma}_{IJ} = \int N_I\,N_J\,dz \quad (32)$$

$$\bar{B}^{xN}_{IJ} = \int \frac{\partial N_I}{\partial x}N_J\,dz \quad (33)$$

$$\bar{B}^{Nx}_{IJ} = \int N_I\frac{\partial N_J}{\partial x}\,dz \quad (34)$$

5 INCORPORATION INTO A FINITE ELEMENT MODEL

A two-noded linear finite element shape function is sufficient to approximate the above matrix equations (Thomas, 1989, 1995). This simulates accurately the displacement, stress and pore water pressure, both in-phase and out-of-phase of the harmonic loading wave.

The above Galerkin Finite Element formulation has been programmed into the software WISPP (Wave Induced Stresses & Pore Pressures, Thomas, 1988).

For poro-elastic soil properties, applied boundary conditions loading, wavelength and angular velocity, WISPP produces a graphical output of the in-phase and out-of-phase x & z-displacements and pore-pressure at each of the nodes over the seabed depth, and the x-x, z-z, x-z operative stresses at each element centroid.

6 EXAMPLE OF WAVE LOADING ON A TWO-LAYERED SOIL

Figure 2 depicts finite element modelling with linear elements, of a multi-layered saturated soil with a 5m upper layer of drained bulk modulus K_1 = 1 MPa, shear modulus G_1 = 750 kPa, overlying a second 10m layer with higher stiffness of K_2 = 4 MPa & G_2 = 3 MPa.

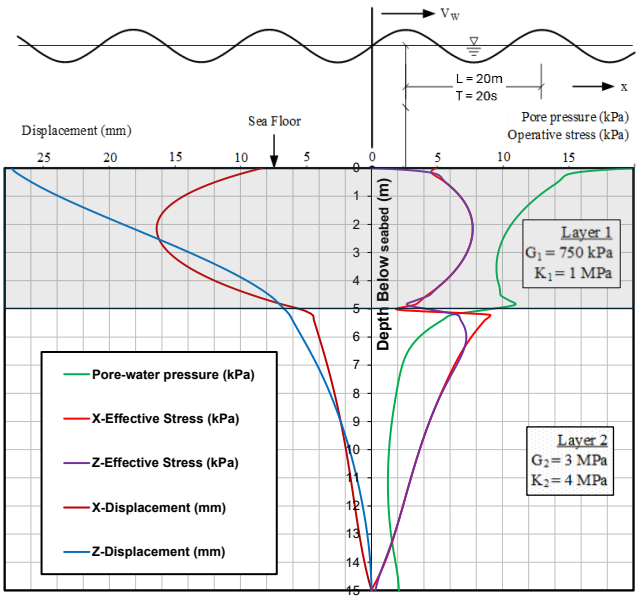

Figure. 2. Wave-induced x & z displacements, x & z operative stresses and pore-water pressures in a two-layer soil, simulated using the one-dimensional harmonic finite element WISSP model (Thomas, 1988).

A harmonic wave load of amplitude 20 kPa is applied to the soil surface with wavelength 20 m and wave period 20 s. The vertical domain has been discretised into 300 finite elements, with 100 elements in the upper layer and 200 elements in the lower layer. The permeability coefficient is 1 x 10^{-5} m/s for the upper layer, and 1 x 10^{-4} m/s for the lower layer. The output demonstrates that heterogeneity resulting from two layers with differing elastic moduli and permeability results in harmonic changes in effective stress, pore-pressure and soil displacement that are quite unexpected unless a harmonic model is applied.

7 CONCLUSIONS

Wave loading on a multi-layered poro-elastic seabed can result in unexpected displacements, stresses and pore-pressure behaviour. This is especially the case for a gassy soil seabed where undrained soil compression occurs. A Finite Element Model has been developed to simulate such behaviour under harmonic wave loading conditions using complex number theory.

ABSTRACT: The COVID-19 pandemic has led to widespread use of single-use face masks, primarily made of plastic materials, causing significant environmental concerns, notably the potential of microplastic pollution in terrestrial and aquatic environments. This study offers a geotechnical engineering-focused examination of the environmental effects of single-use face masks on soil properties in simulated natural conditions. Soil samples compacted with different concentrations of shredded face mask fibers underwent UV radiation exposure for 6 weeks. This period was considered to be sufficient for detecting potential differences in degradation. The hydraulical properties (water retention curve and saturated permability) and the physical properties of the soil samples were measured considering the presence of shredded face mask fibers. The findings indicate a substantial decrease in soil permeability and an increase in water retention capacity upon introducing face mask fibers into the soil, suggesting potential shifts in soil structure. Additionally, prolonged UV exposure led to a reduction in the soil's void ratio, possibly due to the degradation of soil and face mask particles into smaller fragments. These outcomes underscore the need for responsible disposal of single-use face masks and inform waste management policies, as well as highlight the need for further research into the broader environmental impacts of plastic waste on soil and water systems from a geotechnical engineering perspective.

RÉSUMÉ: La pandémie de COVID-19 a entraîné une utilisation généralisée de masques jetables, principalement fabriqués en matériaux plastiques, suscitant des préoccupations environnementales importantes, notamment en ce qui concerne la pollution potentielle par les microplastiques dans les environnements terrestres et aquatiques. Cette étude propose un examen axé sur le génie géotechnique des effets environnementaux des masques jetables sur les propriétés du sol dans des conditions naturelles simulées. Les échantillons de sol ont été compactées avec différentes concentrations de fibres de masque déchiqueté, et soumis à 6 semaines d'exposition aux rayonnements UV. Cette durée a été suffisante pour détecter des différences en dégradation. Les propriétés hydrauliques (capacité de rétention et perméabilité) et physiques du sol ont été mesurées en face de la présence de fibres de masque. Les résultats indiquent une diminution substantielle de la perméabilité du sol et une augmentation de la capacité de rétention d'eau lors de l'introduction de fibres de masque dans le sol, suggérant des modifications potentielles de la structure du sol. De plus, une exposition prolongée aux UV a entraîné une réduction du rapport de vidange du sol, probablement en raison de la dégradation des particules de sol et de masque en fragments plus petits. Ces résultats soulignent la nécessité d'une élimination responsable des masques jetables et éclaire les politiques de gestion des déchets, tout en mettant en évidence la nécessité de poursuivre la recherche sur les impacts environnementaux plus larges des déchets plastiques sur les systèmes sol et eau du point de vue du génie géotechnique.

Keywords: Soil contamination; single-use face masks; COVID-19; plastic pollution.

1 INTRODUCTION

The extended use of plastic products in daily life has contributed significantly to pollution in terrestrial and aquatic ecosystems. Plastic waste is known to have slow degradation, originating microplastics (MPs), which are characterized as small plastic particles ranging from 1 micron to 5 millimeters in size (Benson et al., 2021). Annually, an astonishing 8 million metric tons of plastic waste find their way into the oceans,

primarily originating from land-based sources, thus posing a sustained threat to the environment.

The emergence of the COVID-19 pandemic prompted a surge in the use of single-use face masks as a vital tool in preventing virus transmission. By the start of the pandemic, face masks have contributed to the global plastic production by almost 370 million tons. While these masks are vital for public health, environmental concerns have arisen due to their improper disposal practices, such as littering and landfill dumping. Despite guidelines for proper disposal of the masks, numerous reports have demonstrated the commonness of improper disposal practices, notably in regions with inadequate waste management systems, leading to significant environmental accumulation of such pollutants in terrestrial ecosystems (United Nations Environment Programme), thus supporting the relevance of this study's scenario in simulating potential soil contamination outcomes. These face masks, composed of polymer-based materials, are categorized as single-use plastics. Their presence in the environment, subjected to environmental conditions like biological degradation, UV radiation, temperature fluctuations, and contact with water, can lead to fragmentation, potentially generating MPs (Kumar et al., 2020).

To address these environmental concerns, this study delves into the impact of single-use face mask fibers on soil during the COVID-19 pandemic. It includes an original laboratory experiment designed to simulate the degradation process of face masks in soil submerged in water under natural conditions. The experiment spans approximately 0 and 6 weeks, being analysed the initial and final time periods. This period was considered to be sufficient for detecting potential differences in degradation. The investigation specifically focuses on understanding how the presence of face mask fibers affects the soil, as soil represents a substantial source of plastic contamination.

2 MATERIALS AND METHODS

2.1 Materials

The soil was collected from a construction site in Lisbon, Portugal. The grading size distribution analysis revealed that approximately 82% of the particles are sand size, 15% are gravel size, and only 3% consist of fines. The soil classifies as a well-graded sand (SW) with minimal fines, accordingly with the Unified Soil Classification System.

Despite the low presence of fines, the consistency limits were determined due to the presence of clayey minerals. The liquid limit (LL) was found to be 46%, while the plastic limit (PL) was approximately 28%, resulting in a plastic index (PI) of 18%. Based on these values, the fine fraction of the soil can be classified as a low plastic clay. Mineral analysis confirmed the presence of some expanding clay minerals, including montmorillonite and illite, which suggest that the soil has swelling potential when full saturated.

The masks used in the study were commercially available, single-use face masks type IIR, made from polypropylene (PP). The middle layer of the mask was made of melt blown PP while the two other layers were made of spunbonded PP. The material was then shredded using a heavy-duty cutting mill RETCH SM 2000 with a bottom sieve of size 2 mm. The shredding process produced small fibers with sizes varying between 2 and 0.02 mm (Figure 1a) and a significant amount of dust and finer fragments.

Finally, the specific gravity (Gs) of the solid particles was 2.5 due to the presence of some organic matter. This value was used for all prepared samples in the experiment, although the real Gs of soil samples containing face mask fibers may decrease with increasing fiber content.

2.2 Sample preparation and UV treatment

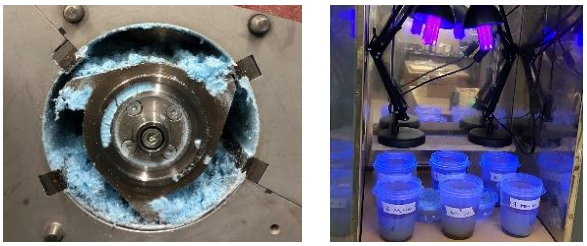
To investigate the impact of shredded face masks on soil, 12 samples were prepared, 6 with the addition of face mask fibers (MH), and 6 without fibers (NM). The concentration of shredded face masks added corresponded to 5% of the solid weight. Each sample was compacted into cylindrical plastic containers (diameter 7 cm and 6 cm height). Compaction was proceeded to fit the *in situ* soil water content and dry volumetric weight. The compaction process involved three layers, each receiving 20 hammer-blows. Water content control was performed to attain the appropriate initial water content for all prepared samples The average water content, γ_d and e values, can be found in Table 1. The saturated permeability was measured in two samples compacted with and without the fibers specially prepared for that purpose. Additionally, three samples were compacted in smaller cylindrical containers, with identical water contents and void ratios (Thomassen (2023).

Table 1. Average initial water content (w), dry density (γ_d), and void ratio (e) for all samples.

Fiber concentration (%)	w (%)	γ_d (kN/m^3)	e (-)
0	18	13	1.0
5	20	12	1.1

All compacted samples were submerged in distilled water. One sample of each type was stored in a

chamber with UV exposure for 6 weeks (Figure 1b), and the other was kept in laboratorial environment for the same period. The UV exposition was an ageing test, to intending to accelerate fiber degradation.



a) b)

Figure 1. a) Shredded mask fibers and b) Experimental setup of samples subjected to UV-exposure.

2.3 Measurement of hydraulic properties

The hydraulic properties of the soil samples compacted with and without the fibers were determined only for the cases after sample preparation. A variable water head test was performed to measure the saturated permeability as described by Thomassen (2023).

The water retention curve (WRC) was measured using vapor equilibrium technique, both for the wetting and drying branches. Suction was applied by vapor equilibrium. The known equation 1 was used to fit experimental data,

$$Sr = \left(1 + \left(\frac{s}{\rho}\right)^{\frac{1}{1-\gamma}}\right)^{-\gamma} \quad (1)$$

where Sr (%) is the degree of saturation computed as usual, s (MPa) is the suction and ρ and γ (MPa, -) are empirical shape-defining parameters, adjusted through curve fitting to experimental data (Thomassen, 2023).

2.4 Other tests

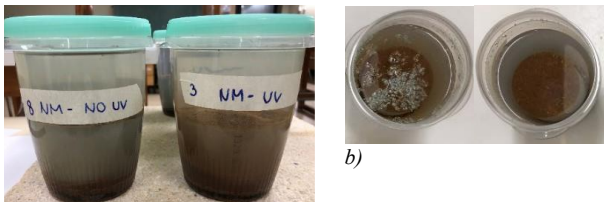
Mercury intrusion porosimetry (MIP) tests were performed to evaluate pore size distribution after preparation and at the end of 6 weeks submerged. An optical microscope was used to visualize the texture of the soil with and without mask fibers. Additionally, scanning electron microscopy (SEM) was used to provide information about the size, shape and morphology of the soil particles and mask fibers.

3 RESULTS AND DISCUSSION

3.1 Visual Observations

All samples experienced volume changes when submerged in water, likely due to the presence of the clay minerals previously identified. Independently from having the fibers or not, the UV-exposed samples were more disrupted because there was a larger amount of soil gathered at the bottom of their containers (Figure 2a). This was more evident in samples without mask fibers. Without UV exposition, the samples with shredded face masks exhibited more stability (Figure 2b). Both results indicate that the fibers were acting as a soil stabilizer.

These findings were corroborated by the analysis of the submersion water. Samples containing mask fibers exhibited clearer water. For samples with mask fibers exposed to UV, minimal fibers were released to the surface, suggesting that UV exposure has degraded some mask fibers (Figure 2b), even in such small period of exposure.



a) b)

Figure 2. a) NM samples and b) MH samples without UV exposure on the left and with UV exposure on the right.

3.2 Hydraulic properties

The saturated permeability of the samples with and without the mask fibers were, respectively, 5×10^{-7}m/s and 9×10^{-7}m/s. This small difference is probably explained by some disturbance introduced by the fibers. The WRC are presented in Figure 3, being the experimental points adjusted using Eq. 1, with ρ= 0.13 MPa and γ= 0.4 for the sample NM, and ρ= 1.0 MPa and γ= 0.4 for the sample MH.

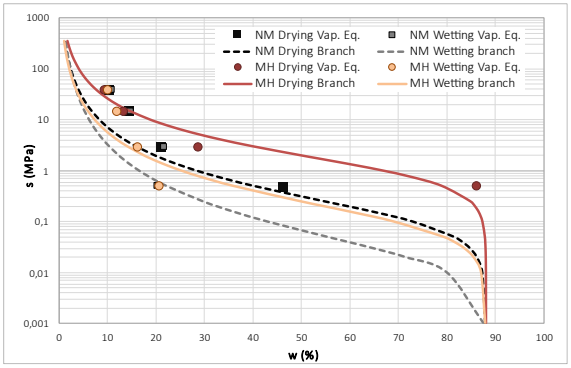


Figure 3. WRC for the samples with and without mask fibers (MH and NM, respectively).

The presence of the fibers increased the air-entry value, a result also found by Guo et al. (2022) for clays with high concentrations of MPs. It can be assumed that the presence of the impervious mask fibers increases the water retention capacity of the soil.

3.3 Other tests

The variation in pore size distribution measured in the MIP tests is presented in Figure 4.

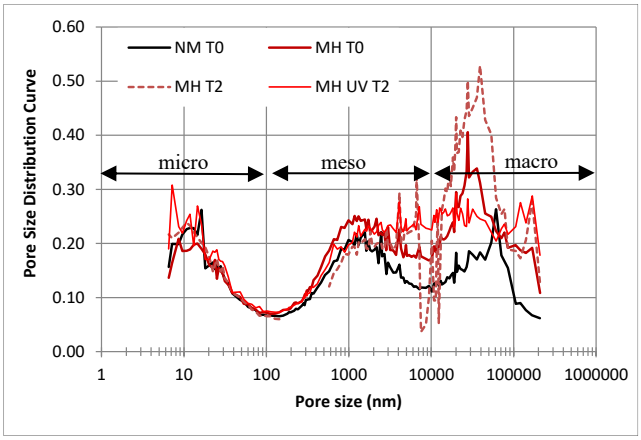

Figure 4. Distribution of pore sizes through soil samples with (MH) and without (NM) mask fibers.

The results for the samples without mask fibers (not saturated, NM_T0) served as reference. Its comparison with sample MH_T0 allows concluding that the presence of the fibers has increased macroporosity and slightly decreased microporosity. This may be explained by the formation of fiber-aggregate complexes, as shown in Figure 5a).

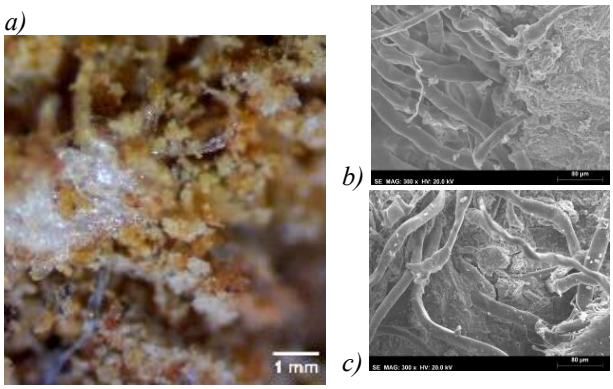

Figure 5. (a) Optical microscopy showing particles aggregation around a mask fiber; (b) SEM image of the sample without degradation and (c) with degradation after UV exposition.

Macroporosity has increased further after 6 weeks of submersion and no UV exposition (MH_T2), as well as mesoporosity. Considering the soil's low fine content, the mechanism driving these changes are not fully understood.It is hypothesized that swelling of the swelling of clay minerals present within the soil could be a factor, despite its low plasticity. However, this requires further investigation. Significant changes are observed after UV exposition (MH_UV_T2) because the amount of macropores reduce and the mesopores appear to dominate, as well as the appearance of micropores. This may be explained by some fiber degradation, producing MP that clog soil pores. Some bare degradation caused by UV exposition was observed in the fibers in SEM images presented in Figure 5a) and b), however it is not significant, probably due to the short duration of this ageing test.

Joining both results it can be concluded that the degradation of the face mask fibers with time and UV, and the formation of fiber-aggregate complexes further contributed to variations in pore size distribution and overall pore volume. Additionally, saturation also impacted the soil, being the analysis of the influence of the fibers on its volumetric behavior upon saturation not done in this paper.

4 CONCLUSIONS

This study has uncovered significant insights into the impact of shredded face mask fibers on soil properties and their response to simulated environmental conditions. The findings indicate that water and aging caused by UV exposition influenced the soil's pore structure. The presence of shredded face mask fibers in the soil led to an increase in water retention capacity, primarily due to the presence of impervious fibers, the formation of fiber-aggregate complexes, and changes in pore-size distribution due to pore clogging likely caused by fibers degradation. These findings emphasize the importance of proper disposal of face masks and the need for research on the long-term environmental consequences of face mask pollution.

Influence of culverts on frost depth in embankments: A field study

Influence des ponceaux sur la profondeur de gel dans les remblais: Une étude de terrain

K. Tommik*, S. Knutsson, J. Laue
Luleå University of Technology, Luleå, Sweden

**karina.tommik@ltu.se*

ABSTRACT: Frost-related damages around culverts are a common problem for roads and railways built on seasonally frozen ground. Culverts create altered thermal conditions in the embankment section where they are installed, leading to deeper frost penetration around the culverts compared to the rest of the road. However, estimating the depth of frost penetration and consequential heave is difficult due to the complex thermal conditions inside culverts, which depend on various factors. To monitor the influence of culverts on the surrounding soil and assess the effect of temperature distribution inside the culvert on frost penetration in the embankment, temperatures were measured inside a 0.6 m diameter culvert and in the soil 0.30 m from the culvert in northern Sweden during the winter of 2023. Control measurements were also performed in a road section without a culvert. Temperatures were recorded in seven locations in the embankment at depths ranging from 0.1 m to 2.55 m. Effect of the temperature distribution inside the culvert on frost penetration in the embankment is assessed. The results of this study could help in the design and management of culverts in cold climates and improve our understanding of the thermal conditions around culverts. This field study is part of a larger project where collected data will be used to verify numerical models, enabling assessment of the effect of culverts of any size on temperature distribution.

RÉSUMÉ: Les dommages causés par le gel autour des ponceaux constituent un problème courant pour les routes et les voies ferrées construites sur un sol gelé de façon saisonnière. Les ponceaux créent des conditions thermiques modifiées dans la section de remblai où ils sont installés, entraînant une pénétration du gel plus profonde autour des ponceaux par rapport au reste de la route. Cependant, il est difficile d'estimer la profondeur de pénétration du gel et le soulèvement qui en résulte en raison des conditions thermiques complexes à l'intérieur des ponceaux, qui dépendent de divers facteurs. Pour surveiller l'influence des ponceaux sur le sol environnant et évaluer l'effet de la répartition de la température à l'intérieur du ponceau sur la pénétration du gel dans le remblai, les températures ont été mesurées à l'intérieur d'un ponceau de 0,6 m de diamètre et dans le sol à 0,30 m du ponceau dans le nord de la Suède au cours de la période d'essai, l'hiver 2023. Des mesures de contrôle ont également été effectuées dans un tronçon de route sans ponceau. Les températures ont été enregistrées à sept endroits du remblai à des profondeurs allant de 0,1 m à 2,55 m. L'effet de la répartition de la température à l'intérieur du ponceau sur la pénétration du gel dans le remblai est évalué. Les résultats de cette étude pourraient aider à la conception et à la gestion des ponceaux dans les climats froids et améliorer notre compréhension des conditions thermiques autour des ponceaux. Cette étude sur le terrain fait partie d'un projet plus vaste où les données collectées seront utilisées pour vérifier les modèles numériques, permettant d'évaluer l'effet des ponceaux de toute taille sur la distribution de la température.

Keywords: Culvert; frost heave; cold climate.

1 INTRODUCTION

Culverts are essential components of the road and railway embankments, facilitating drainage and the flow of water from one side of the road to the other. However, in seasonally frozen ground, the presence of culverts allows cold air to pass through the road structure. This results in frost penetration not only perpendicular to the surface of the road but also perpendicular to the surface of the culvert. Leading to increased frost depth around the culvert, which results in frost related damages if frost susceptible soil is present. Manifesting as bumps and depressions over the culvert on the surface of the road. This poses significant challenges, reducing the lifetime of road structures, increasing maintenance costs, and compromising traffic safety.

Temperature distribution inside and around culverts is influenced but not limited to the following factors: diameter, length, and material of the culvert, placement of the culvert in the embankment, outside temperature, air or water velocity inside the culvert, snow cover and solar radiation (Hua et al. 2014). Increased frost depth underneath the culvert will be

directly caused by the thermal boundary conditions established inside of the culvert due to the interaction of the previously mentioned factors.

2 METHOD

To estimate the thermal effect a culvert has on the surrounding road structure a field experiment was designed in Northern Sweden, near town of Luleå. The study area was located near the airport, allowing access to weather data from the airport weather station.

The test section comprised of an 8 m wide, two-lane road with an embankment height from the shoulder of the road to the bottom of the ditch measuring 1.5 m. The slope of the embankment is 1:4. The project specification documents of the road were unavailable. However, based on the boreholes drilled for the installation purposes it could be estimated that the road structure had around 10 cm thick asphalt layer, 20 cm of crushed rock base and the embankment as well as natural soil below terrace level were sand. The measured embankment section included a culvert with a diameter of 0.6 m and a length of 22 m, covered with an overburden of 0.84 m of soil.

One lane of the road was instrumented with seven temperature measurement probes in the vicinity of the culvert, as seen in Figure 1, each with a length of 2.5 meters and nine thermocouples at varying heights. The top of the probe is placed 5 cm under the ground surface, as the first thermocouple is at 5 cm depth, the shallowest recording takes place at 10 cm depth.

The probes form two cross-sections parallel to the culvert. One is placed close to the culvert. The second is 3 m away from the first cross-section where the thermal regime of the culvert will not influence the developing frost depth (both cross-sections marked in Figure 1). Each of the two cross-sections has a probe close to the middle of the road, in the shoulder of the road at the edge of the asphalt cover and in the ditch. The cross-section further away from the culvert has an additional 4th probe in between the wheel path of the measured lane (exact locations marked in Figure 1).

Type T thermocouples produced by Pentronic are used for the temperature measurements alongside the CR1000X datalogger and 4 Granite temp 120 thermocouple modules, produced by Campbell scientific. Resulting in relative measurement accuracy of ± 0.2 C° (based on calibration performed) and absolute accuracy of ± 0.8 C°. Recording of the temperatures started on January 14th of 2023 and will continue until probes remain operational. The data is recorded every 12 hours.

Additional thermocouples were installed inside the culvert to measure the thermal boundary conditions. However, data from the instrumentation inside the culvert was considered unreliable due to grounding errors.

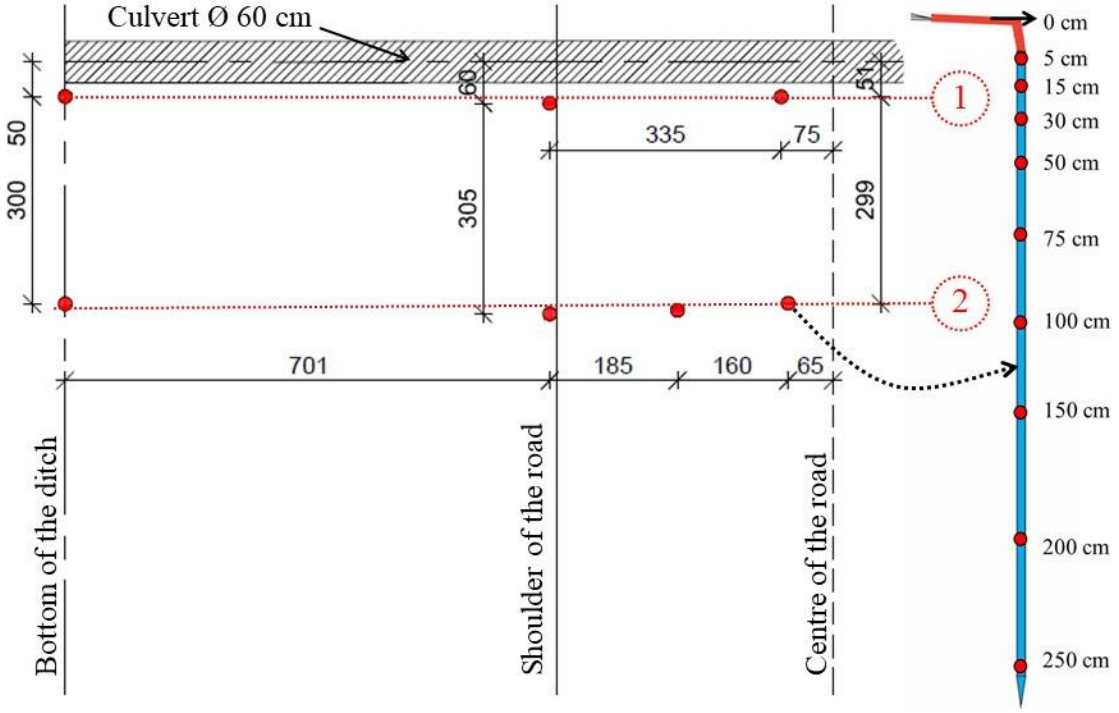

Figure 1. Top view of the installation probe locations in red, cross-section of the probe (to the right), thermocouples in red.

3 RESULTS

The results presented cover the period from Jan. 14th, when data recording commenced, to March 19th, when the maximum frost depth was reached. Frost depth was calculated by interpolating existing data using MATLAB (The MathWorks Inc., 2020). Frost depth progression at each of the probe locations through the freezing period is presented in Figure 2.

Throughout the recording period, the ground did not freeze in the ditch in either of the cross-sections due to the thick snow cover and the insulation it provided (Motamedi et al., 2024).

Frost depth in cross-section 1 (near the culvert) under the shoulder of the road was 170 cm in January, increasing to 184 cm by March, indicating a 14 cm increase over three months. In the same cross-section close to the centre of the road, frost depth increased from 184 cm in January to 193 cm in March, marking a 9 cm increase. The differences in frost depth between the shoulder and the centre of the road near the culvert were 14 cm in January and 9 cm in March. Frost depth at the shoulder is shallower due to the insulating properties of snow cover.

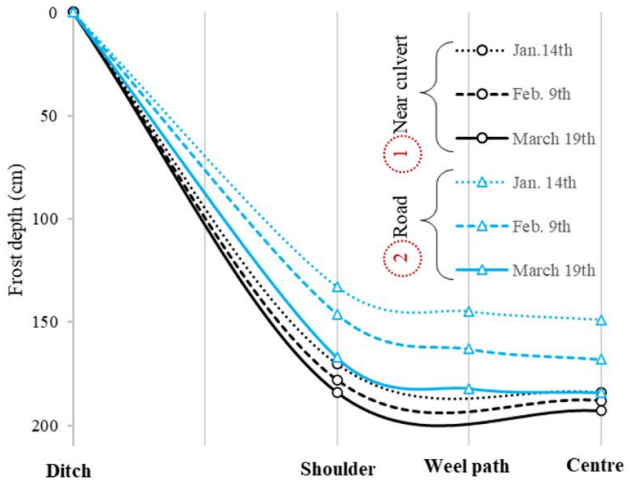

Figure 2. Frost depth progression during winter for each probe location.

Frost depth in cross-section 2 was 133 cm at the shoulder in January and increased to 167 cm in March, resulting in a 34 cm difference. For the same cross-section close to centre of the road, frost depth increased from 149 cm in January to 184 cm in March, resulting in 35 cm difference. The difference between the frost depth at the shoulder and centre of the road was 16 cm in January and 17 cm in March, with frost depth increasing towards the centre.

In cross-section 1 (near the culvert), frost penetration at the shoulder was 37 cm deeper in January and 17 cm deeper in March compared to the rest of the embankment (cross-section 2). Similarly, the difference in frost depth at the centre was 35 cm in January and 9 cm in March. Indicating that frost penetration at near the culvert is increased compared to the rest of the road. The maximum frost depth of 193 cm was recorded near the centre of the road near the culvert on March 19th. The temperature distribution in both cross-sections is seen in Figure 3, where frost depth is marked by the turquoise line. The temperature distribution and previously discussed frost depth values are obtained by interpolation between the existing measurement points.

No temperature measurements were performed in the slope of the road. Therefore, the shape of the frost

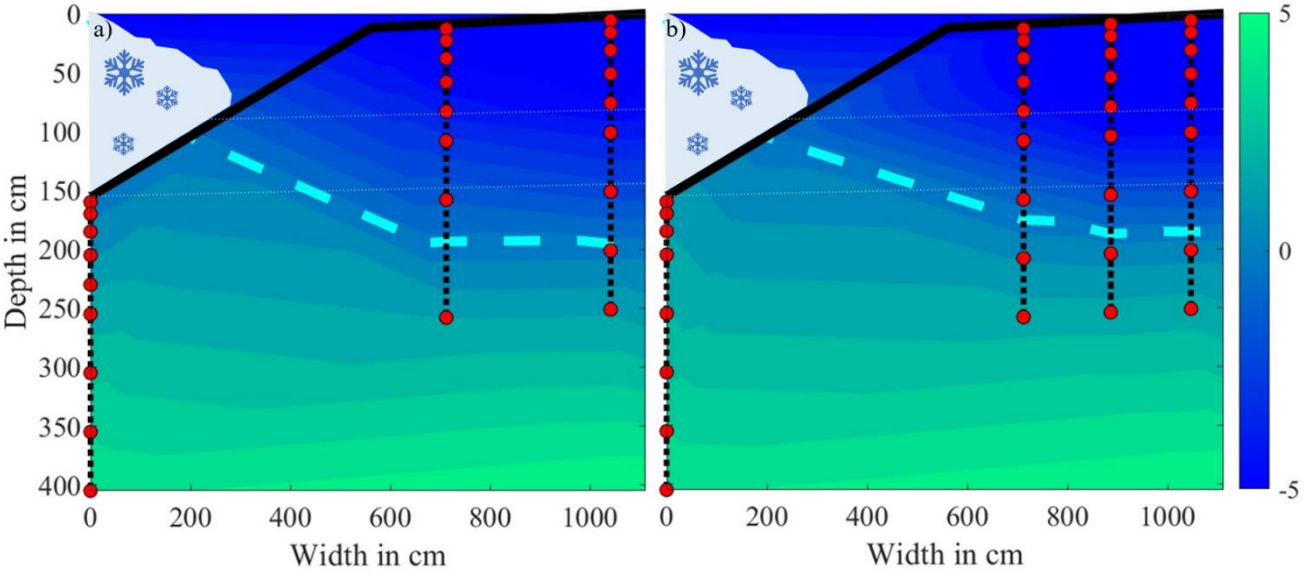

Figure 3. Temperature distribution in the embankment in a) cross-section 1 and b) cross-section 2 (temperature measurement locations in red, forst depth in turquise).

front in the slope was manually altered, to display the insulating effects of snow. As the ground never freezes in the ditch of the road and the frost depth in the shoulder is significant it is reasonable to assume that the frost front will end somewhere in the shoulder of the road, considering the volume of snow in the ditch. The increased amount of snow would increase the inclination of the line moving its end closer to the shoulder. While decrease in snow depth would lead to a flatter shape moving the end closer to the bottom of the ditch. The shape of the frost front will influence consequent frost heave as the frost heave propagation is perpendicular to the frost front line.

4 CONCLUSION AND DISCUSSION

At the start of the recording in January, frost depth near the culvert was significantly deeper (by 35 cm at the centre) compared to the rest of the road. However, this difference decreased as the winter progressed. The soil near the culvert froze faster, but the frost depth did not significantly increase during the subsequent months, while the soil in the rest of the road froze more gradually. This suggests that the increased frost depth and the speed of freezing are due to the proximity to the culvert, allowing cold air to enter the road structure before the culvert ends become covered by snow and are insulated, slowing down the frost penetration (Tommik et al., 2023).

The shoulder of the road displayed a shallower frost depth compared to the centre of the road due to the insulating properties of the snowpack in the ditch. Additionally, the ground at the bottom of the ditch did not freeze in either of the cross-sections. Frost depth differences between the shoulder and centre of the road near the culvert were smaller during the winter compared to the rest of the road, indicating that the culvert has an equalizing effect on the soil temperatures surrounding it. As a result, shape of the frost front near the culvert is flatter compared to the more bowl-shaped frost front in the rest of the road, as indicated by temperature difference between shoulder and centre of the road. This would lead to uniform heaving along the culvert rather than more severe heaving at the centre.

Presence of a culvert significantly changes the thermal balance of the road structure during the freezing period, resulting in increased frost depth around the culvert compared to the rest of the road. However, the measurements were conducted on the side of the culvert, and the deepest frost penetration in the area would be beneath the culvert itself, as frost penetration will expand radially outward from the surface of the culvert.

There is a great variation in both culvert and road dimensions as well as soil materials and weather conditions. Resulting in difficulty in knowledge regarding thermal boundaries to several locations based on one test site. Therefore, numerical models must be employed for the task. Data from such studies as presented is essential for calibrating and validating such models. Expanding the knowledge of thermal surrounding the culverts will result an improved road design in regions with seasonal frost.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to Swedish Transport Administration (Trafikverket) for the financial support of the research project within the research programme BVFF.

ABSTRACT: Soils in the vicinity of the foundations of offshore energy systems are subjected to cyclic stresses arising from repeated environmental loads. Long-term application of such loading alters the surrounding soil's strength and deformation characteristics and subsequently may put the performance of such systems at risk. The deformation of soil i.e., strain accumulation depends on both the soil parameters and the loading conditions. This paper presents the findings from an experimental study that focuses on strain accumulation in calcareous sands subjected to long-term cyclic loading. A series of drained cyclic triaxial tests were performed on saturated calcareous sand specimens up to 10,000 loading cycles. The influence of cyclic stress amplitude and sand density on the strain accumulation is investigated. The experimental results show an increase in strain accumulation with increasing cyclic stress amplitude and void ratio. The formulations of the High Cycle Accumulation Model are calibrated based on the experimental results. The test results provide valuable information on the deformation characteristics of the calcareous sands, which can be used to predict the performance of offshore structures under cyclic loads. The triaxial test results also provide a very useful database for calibrating advanced soil models to accurately assess the performance and behavior of the foundations of offshore energy systems.

RÉSUMÉ: Les sols à proximité des fondations des systèmes d'énergie offshore sont soumis à des contraintes cycliques résultant des charges environnementales répétées. L'application à long terme de ces charges altère la résistance et les caractéristiques de déformation du sol environnant, mettant potentiellement en danger la performance de ces systèmes. La déformation du sol, c'est-à-dire l'accumulation de contrainte, dépend à la fois des paramètres du sol et des conditions de chargement. Cet article présente les résultats d'une étude expérimentale axée sur l'accumulation de contrainte dans des sables calcaires soumis à un chargement cyclique à long terme. Une série d'essais triaxiaux cycliques drainés a été réalisée sur des échantillons de sable calcaire saturé jusqu'à 10 000 cycles de chargement. L'influence de l'amplitude de contrainte cyclique et de la densité du sable sur l'accumulation de contrainte est étudiée. Les résultats expérimentaux montrent une augmentation de l'accumulation de contrainte avec l'augmentation de l'amplitude de contrainte cyclique et du rapport de vides. Les formulations du modèle d'accumulation en haute fréquence sont calibrées en fonction des résultats expérimentaux. Les résultats des essais fournissent des informations précieuses sur les caractéristiques de déformation des sables calcaires, pouvant être utilisées pour prédire la performance des structures offshore sous des charges cycliques. Les résultats des essais triaxiaux fournissent également une base de données très utile pour calibrer des modèles avancés de sol afin d'évaluer avec précision la performance et le comportement des fondations des systèmes d'énergie offshore.

Keywords: Calcareous sand; cyclic stress ratio; strain accumulation; long-term drained response.

1 INTRODUCTION

Offshore wind turbine (OWT) foundations are subjected to environmental loadings during their life span of approximately 25 to 30 years. The response of OWT foundations is influenced by the loading characteristics and the soil conditions around the foundation. During extreme events such as storms or earthquakes, the high-amplitude cyclic loads (strain amplitudes $\varepsilon^{ampl} > 10^{-3}$) can induce undrained soil behaviour. This can lead to the rapid development of excess pore pressure, posing a potential risk of liquefaction.

Under regular operational loads of small amplitude ($\varepsilon^{ampl} < 10^{-3}$), as indicated by Wichtmann et al. (2005), the excess pore water pressure dissipates, and the soil behaves in a drained fashion. However, the soil behaviour may exhibit variability across different loading frequencies and soil permeability. The cyclic loading results in hysteresis loops that are not perfectly closed leading to strain accumulation in the soil, commonly referred to as "ratcheting" (Houlsby et al., 2017). The ratcheting is a primary concern for long-term serviceability. It is responsible for settlements that can compromise the operation of the OWTs. Therefore, it is crucial to account for both the short-term undrained behaviour under extreme loads, as well as the long-term cyclic response, in the design of such foundations.

Standards and codes i.e. API (2000), and DNV (2004) provide design guidelines for typical silica sands. In the presence of calcareous sands, there is limited available knowledge due to their susceptibility to crushing (Salem et al., 2021). This becomes of increasing importance considering that calcareous sands are commonly found in the marine environment in Europe and around the globe (e.g., Southern Mediterranean Sea, the Persian Gulf, Brazil, and Australia) (Spagnoli & Doherty, 2016). The physical properties of calcareous sands are different to silica sands (Cao et al., 2020; Shi et al., 2021). The calcareous sand is formed of marine biological debris mainly composed of calcium carbonate. The particles are irregular in shape, and flaky and porous which make it prone to breaking under loading (Ding et al., 2021).

Strain accumulation in calcareous sand under long-term cyclic loading is far more limited. Jafarian & Javdanian, (2020) examined the cyclic behaviour of calcareous vs silica sands, finding that for calcareous sand, increasing effective stress led to higher shear modulus and lower damping ratio compared to silica sand. The differences were attributed to the contrasting grain shape, mineralogy, and texture of calcareous sand. Similar behaviour was also reported by Yu, (2017). Jafarian et al., (2018) compared small-strain dynamic characteristics of calcareous and silica sands. It was found that the small-strain shear modulus of calcareous sand is more affected by mean effective confining pressure than the silica sands.

This paper investigates the cyclic behaviour of calcareous sand subjected to 10,000 loading cycles. To explore the influence of stress amplitude and density state, triaxial tests have been performed at selected densities and stress amplitudes. In addition, the results are used to calibrate the High Cycle Accumulation (HCA) model parameters.

2 HIGH CYCLE ACCUMULATION MODEL

To predict the strain accumulation at a high number of loading cycles ($N \geq 1000$), Niemunis et al., (2005) proposed the High Cycle Accumulation (HCA) model. The HCA model calculates the strain accumulation by combining two different numerical strategies. They are referred to as the *implicit* (low cycle) model and the *explicit* (high cycle) model of calculation. In the *implicit* model each cycle is calculated with hundreds of small increments and the accumulation appears as a by-product due to the not perfectly closed stress or strain loops. In the explicit model, the first two cycles are calculated conventionally with strain increments. The strain accumulation due to the following cycles is calculated using a direct (explicit) formula (Figure 1).

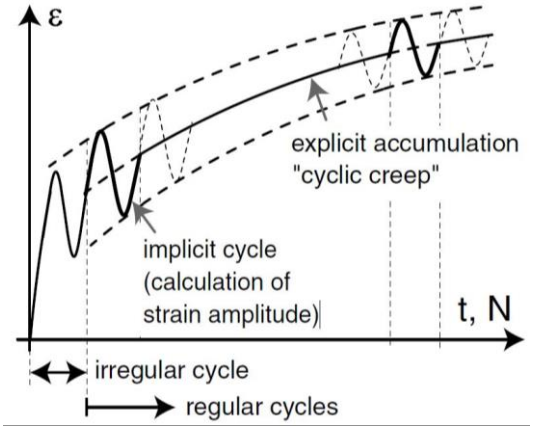

Figure 1. Calculation procedure of explicit models (Wichtmann et al., 2005).

According to the HCA model, the rate of strain accumulation can be calculated as the product of six functions (Table 1):

$$\varepsilon^{acc} = f_{ampl}\, f_N\, f_e\, f_p\, f_Y\, f_\pi \qquad (1)$$

Table 1 Summary of the functions, and material constants of the high-cycle model (Wichtmann et al., 2015)

Function	Const.
$f_{\text{ampl}} = \left(\varepsilon^{\text{ampl}}/10^{-4}\right)^{C_{\text{ampl}}}$	C_{ampl}
$\dot{f}_N = \frac{C_{N1}C_{N2}}{1+C_{N2}N} + C_{N1}C_{N3}$	C_{N1}, C_{N2}, C_{N3}
$f_p = \exp\left[-C_p\ (p^{\text{av}}/(100\ \text{kPa}) - 1)\right]$	C_p
$f_Y = \exp\left(C_Y\ \bar{Y}^{\text{av}}\right)$	C_Y
$f_e = \frac{(C_e - e)^2}{1+e}\ \frac{1+e_{\max}}{(C_e - e_{\max})^2}$	C_e

Each function considers distinctly the influence of different parameters that is strain amplitude (f_{ampl}), cyclic preloading history (f_{N}), void ratio (f_{e}), average stress (f_{p}), average stress ratio (f_{Y}), and polarization changes (f_{π}). The material constants of the functions can be obtained from drained cyclic triaxial test series. A minimum of three sets of tests are required to obtain such constants: C_e requires tests with different void ratios, keeping the same average stress and stress amplitude. C_p requires tests with different average mean pressure, under constant void ratios and average stress ratios. C_Y requires tests with different average stress ratios, under constant void ratios, average mean pressure, and stress amplitude.

Wichtmann et al. (2010) calibrated the HCA model parameters using results obtained from triaxial test results on eight different quartz sand. Further, Benoot et al. (2014) calibrated the model from cyclic tests on silica sand. However, the predictive capabilities of the HCA model had not been assessed for calcareous sands. Calcareous sands have some distinctive features, such as high void ratio, carbonate content, and crushability.

3 METHODOLOGY

3.1 Test material

The calcareous sand tested in this study was taken from a reclaimed site in the Persian Gulf. The particle size gradation of the calcareous sand is illustrated in Figure 2. The index properties are summarized in Table 2 (Shi et al., 2021), while the mean particle size (d_{50}) of the sand used in this study is much higher than for typical silica sands encountered in offshore wind projects. Figure 3 shows the grain morphology: the particles are thin, irregular, and extremely flaky, which makes them prone to breakage, and gives them an irregular shape, with some having round structures. The rough texture of the particles and the presence of more void spaces make it a highly compressible material when subjected to shearing.

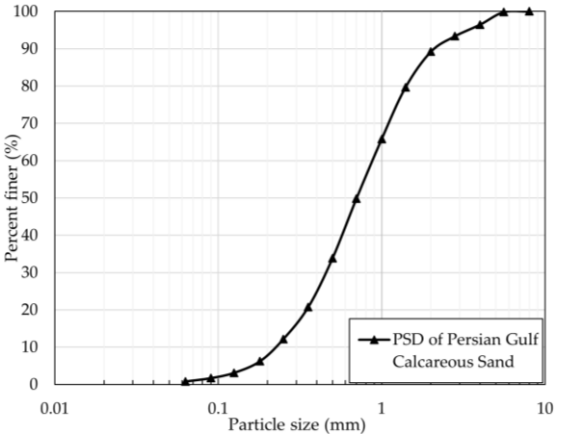

Figure 2. Particle size gradation of calcareous sand.

Figure 3. Grain morphology of calcareous sand (Shi et al., 2021).

Table 2 Basic physical and mechanical properties of calcareous sand

Property	Calcareous sand
Specific Gravity (G_s)	2.81
Maximum void ratio (e_{max})	1.21
Minimum void ratio (e_{min})	0.75
Coefficient of uniformity (C_u)	3.89
Mean particle size (d_{50}) (mm)	0.68

3.2 Triaxial apparatus

An electromechanical dynamic triaxial apparatus was used. This apparatus is comprised of pressure/volume controllers that provide cell pressure and back pressure. It includes a submersible load cell to measure the axial stress, as well as sensors for measuring displacements, and pore pressures. All components were calibrated before conducting tests.

3.3 Testing procedure

Cylindrical specimens of 50 mm in diameter and approximately 100 mm in height were tested. Soil specimens were prepared using the water pluviation technique. A pluviator equipped with five steel wire strainers, which was specifically designed to ensure

the even distribution of soil particles (Figure 4) was used. To achieve the targeted relative density and avoid sand particle breakage during the specimen preparation, the tapping of the mould from outside was employed by gently tapping the sides of the mould with a rubber hammer. Latex membranes with a thickness of 0.35 ± 0.01 mm were used.

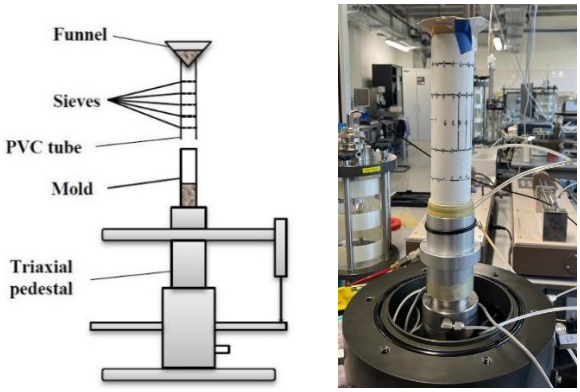

Figure 4. Water pluviation technique: (a) Schematic of pluviator, (b) pluviator with strainers used.

The specimens were saturated by flushing with de-aired water for 30 minutes and applying a back pressure of 700 kPa from 16 h to 24 h, to achieve the B-value higher than 0.95. In pre-experiment trials, it was required to apply such a high back pressure of 700 kPa to saturate the calcareous sand specimens, which was also adopted by Shi et al., (2021) using the same sand. After the saturation, the specimens were anisotropically consolidated ($K_o = 0.5$) to 100kPa initial mean effective stress levels. K_o consolidation was performed by using the Back Volume Change Measurement module in the GDS lab software. This back volume measurement is used to calculate the theoretical new height the specimen should attain to compensate for changes in volume while keeping the diameter constant.

Table 3 summarizes the stress-controlled drained triaxial tests with 10,000 load cycles conducted at a frequency of 0.5 Hz. The loading frequency of 0.5 Hz was selected based on the expectation that it would produce drained conditions based on previous studies (Ding et al., 2021; Witchmann et al., 2010). However, small fluctuations in pore water pressure of up to ±7 kPa were observed in selected tests in this study but were considered negligible relative to mean effective stress. It is also worth noting that loading frequency has minimal impact on sand deformation up to 1 Hz (Witchmann et al., 2010).

Table 3 Summary of the drained triaxial testing program.

Test ID	Void ratio	CSR= $q/2p'$	q_{ampl} (kPa)
1- CKDC	0.86	0.2	58
2- CKDC	0.89	0.2	58
3- CKDC	0.87	0.3	80
4- CKDC	0.89	0.2	58
5- CKDC	0.79	0.2	58
6- CKDC	0.79	0.3	80

4 RESULTS AND DISCUSSION

4.1 Accumulation of strain with number of cycles

Accumulation of strain with the number of cycles in sand samples subjected to cyclic loading is illustrated in Figure 5. Under cyclic loading the total strain develops in the soil sample, consisting of both recoverable (elastic) and non-recoverable (plastic/residual) components. Initial hysteresis loops showed primarily elastic behaviour with minimal plastic strain component. However, with further load cycles hysteresis loops deviated from the initial path, indicating a rise in plastic strains. The results also showed that the residual axial strain develops gradually with each additional loading cycle.

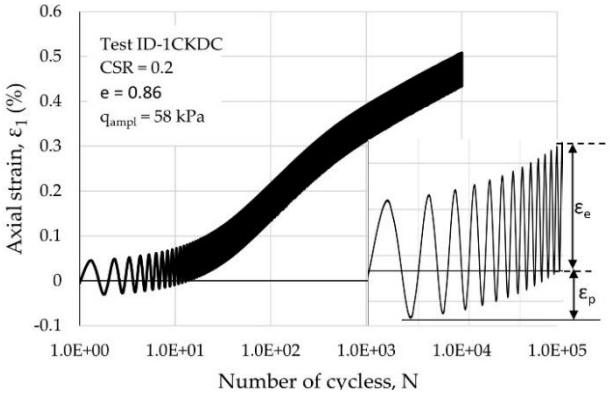

Figure 5. Axial strain progression with number of cycles, N.

4.2 Effect of cyclic stress ratio

Figure 6 presents the development of axial strain (ε_1^{acc}) versus the number of cycles (N). Four tests were conducted under selected void ratios (medium dense 0.89 and dense 0.79) and selected CSR (0.2 and 0.3). At the starting phase, a similar strain development was observed in all the curves and then, the rising rate of strain accumulation varied depending on the test conditions. For the denser specimen (tests 5 and 6), increasing the CSR from 0.2 to 0.3 resulted in higher strain accumulation. This occurred as the larger cyclic

stresses induced greater deformations with each cycle. A similar trend has been observed in the medium-dense soil specimens (tests 1 and 3). Overall, as anticipated, denser specimens exhibited lower accumulated strains than looser samples under similar CSR.

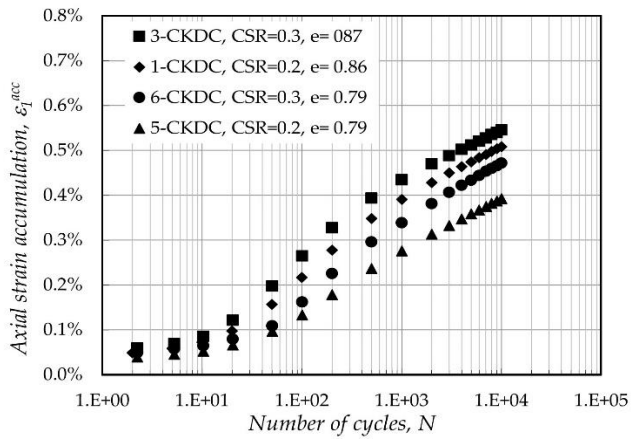

Figure 6. Axial strain accumulation with the number of cycles N in tests with different CSRs.

4.3 Effect of void ratio

Figure 7 plots the axial strain accumulation (ε_1^{acc}) as a function of the number of cycles (N). To investigate the influence of the relative density on the strain accumulation, four drained tests were performed. Tests 2 and 4 were performed under identical conditions to verify the repeatability of the test data.

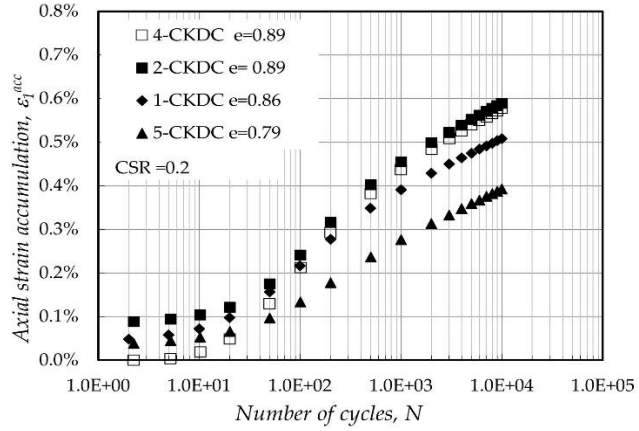

Figure 7. Axial strain accumulation with the number of cycles N in tests with varying void ratios.

A similar trend is observed for all samples in terms of strain accumulation. However, samples with higher void ratios exhibited greater accumulation of residual axial strain. Higher strain accumulation in samples with higher void ratios can be attributed to their ability to accommodate more grain arrangements under cyclic loading.

4.4 Calibration of HCA model functions

To eliminate the influence of strain accumulation on void ratio and strain amplitude, two out of six HCA model functions are used to normalize the measured strain accumulation. Function f_{ampl} accounts for the dependence of strain amplitude on the strain accumulation rate. Functions f_e accounts for the influence of the initial void ratio on the strain accumulation. In f_{ampl} and f_e functions the material constants C_{ampl} = 2 and C_e = 0.58 are determined employing non-linear regression analysis, using reference strain $\varepsilon_{ref}=10^{-4}$ and reference void ratio $e_{ref}= e_{max}=1.21$. Figure 8 and 9 show the normalized measured residual axial strain curves by f_{ampl} and f_e functions.

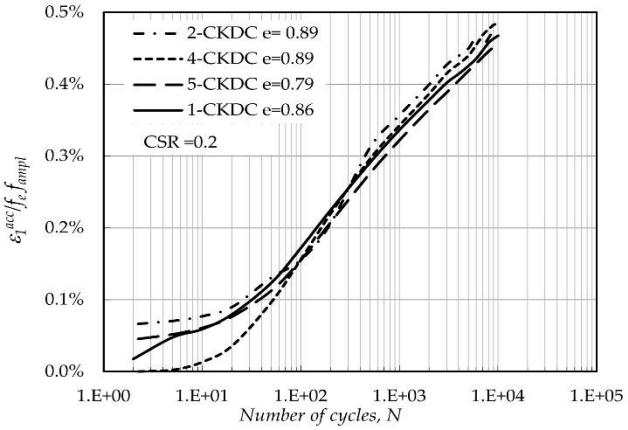

Figure 8. Normalized accumulated axial strain as a function N with different void ratios.

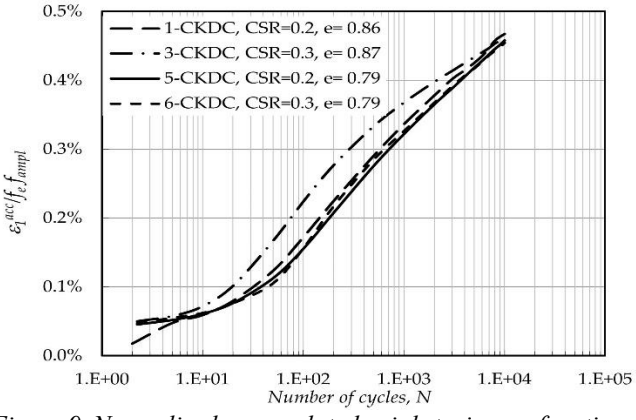

Figure 9. Normalized accumulated axial strain as a function of N with different CSRs and void ratios.

The close alignment of normalized curves suggests a close correspondence in strain accumulation behaviour. The normalization process effectively eradicated the influence of different test parameters on the strain accumulation behaviour. This suggests the HCA model functions i.e. f_{ampl} and f_e could be applied for calcareous sand, despite the Wichtmann framework being developed for silica sand.

5 CONCLUSIONS

The accumulation of strain in calcareous sand under cyclic loading was explored through a series of drained cyclic triaxial tests. The accumulated strains were normalized using the HCA model functions to facilitate comparisons across varying test conditions. The following main findings are reported:

(1) With increasing the CSR higher strain accumulation was observed. This occurred as the larger cyclic stresses induced greater deformations with each loading cycle.

(2) The strain accumulation depends strongly on the soil density. Medium dense samples ($e = 0.86, 0.87, and\ 0.89$) exhibit higher axial strains than the denser sample ($e = 0.79$).

(3) The HCA model's functions f_e and f_{ampl} are calibrated for the calcareous sand, yielded material constants $C_{ampl} = 2$ and $C_e = 0.58$. These functions were used to normalize the accumulated strain. This allowed a meaningful comparison of strain accumulation trends between tests with varying conditions. The normalization process effectively suppressed the influence of different parameters on the strain accumulation.

ACKNOWLEDGEMENTS

This research was supported by the *Cyclic soil-structure interaction framework for the foundations of offshore renewable energy structures* project, funded by the "KU Leuven Global PhD Partnerships with The University of Melbourne" scheme (GPUM/21/023) and "The University of Melbourne Chancellery Strategic International Research Collaboration funds". ABSTRACT: The hydraulic properties of compacted soils play a key role in evaluating the performance of earthworks during both design and operation. Soil hydraulic properties are influenced by compaction processes and can vary over time due to changing hydrometric and climatic conditions, significantly affecting the stability of earth structures. This study focuses on laboratory experiments aimed at determining the water retention characteristics and saturated permeability of mixtures obtained by blending different weight percentages of Ticino sand and Pontida clayey sandy silt, two Italian soils commonly used in geotechnical engineering. The interplay between soil composition and compaction conditions is systematically explored to study how these factors influence on hydraulic behaviour of river embankments.

RÉSUMÉ: Les propriétés hydrauliques des sols compactés jouent un rôle clé dans l'évaluation des performances des travaux de terrassement tant pendant la conception que pendant l'exploitation. Les propriétés hydrauliques des sols sont influencées par les processus de compactage et peuvent varier au fil du temps en raison des conditions hydrométriques et climatiques changeantes, affectant significativement la stabilité des structures terrestres. Cette étude se concentre sur des expériences en laboratoire visant à déterminer les caractéristiques de rétention d'eau et la perméabilité saturée de mélanges obtenus en mélangeant différents pourcentages pondéraux de sable du Ticino et de limon sableux argileux de Pontida, deux sols italiens couramment utilisés en ingénierie géotechnique. L'interaction entre la composition du sol et les conditions de compactage est explorée de manière systématique afin d'étudier comment ces facteurs influent sur le comportement hydraulique des digues fluviales.

Keywords: Soil mixtures; soil water retention curve; saturated permeability; earth embankments.

1 INTRODUCTION

Given the escalating frequency of catastrophic floods, there is currently a great interest in river embankments and the crucial role they play in mitigating the impact of floods. In this context, understanding and accurately assessing the hydraulic properties of compacted soils used for the construction of embankments, including water retention curve and hydraulic conductivity function, is essential for designing resilient and sustainable river infrastructure (Ventini et al., 2023a).

Compacted soils exhibit complex hydraulic behaviour due to their inherent heterogeneity and anisotropy. Various factors, such as compaction methods, soil composition, initial water content and stress history, contribute to the intricate hydraulic response of these materials (Mitchell et al., 1965, Vanapalli et al., 1999). Changes in hydrometric and climatic conditions over time further contribute to the variability of soil hydraulic properties, posing challenges in predicting and managing the performance of river embankments.

In this framework, the present study deals with laboratory investigations aimed at characterizing the hydraulic properties of different mixtures of compacted soils under controlled conditions. Specifically, the effects of the soil composition and the compaction on the hydraulic behavior of compacted soils used for river embankments construction are explored.

2 SOIL MIXTURE

The compacted heterogeneous mixtures of sand, silt and sometimes clay are typically employed in the construction of the body of the river embankments along the tributaries of the Po River (Italy). To

experimentally characterize this soil type, two well-known Italian soils were selected: Ticino sand (TS) and Pontida sandy clayey silt (PON). These soils were suitably mixed by weight in the laboratory, and three different mixtures were tested: TS50%-PON50%, TS70%-PON30% (Ventini et al, 2021, Ventini et al., 2023b), and TS85%-PON15%. The numbers in percentage represent the amount of soil by weight.

The grain size distributions and the physical properties of the tested mixtures, as well as those of TS and PON individually, are reported in Figure 1 and Table 1, respectively.

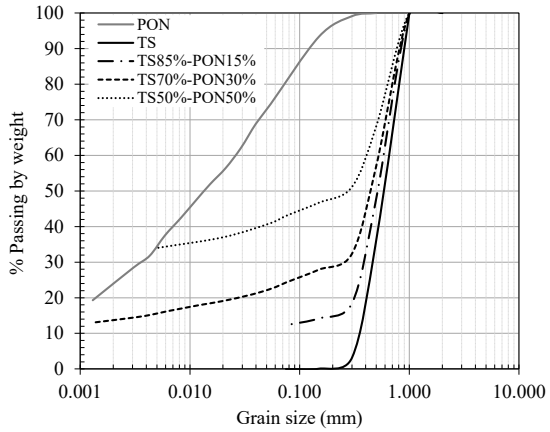

Figure 1. Grain size distributions of the tested soils.

Table 1. Average on index properties of the tested materials (G_s specific soil density, D_{50} mean particle size, U_c uniformity coefficient, LL_{cup} limit liquid from the percussion cup, PL plastic limit, PI plasticity index).

Soil	G_s	D_{50}	U_c	LL_{cup}	PL	PI
	-	mm	-	%	%	%
TS	2.671	0.574	1.83	-	-	-
PON	2.744	0.015	-	23.62	13.13	10.49
TS50%-PON50%	2.650	-	-	24.00	18.00	6.00
TS70%-PON30%	2.684	0.458	246.06	17.66	10.23	7.42
TS85%-PON15%	2.676	0.520	-	-	-	-

2.1 Compaction tests

The Proctor tests are distinguished into "standard" and "modified" and represent a compaction procedure typically used as a reference for earthworks. The Standard Proctor (SP) test results in a substantially lower degree of compaction than the Modified Proctor (MP) due to the lower compaction energy applied. Higher energy results in higher shear strength, lower void volume and lower permeability. For the mixtures considered here, the compaction curves are shown in Figure 2. The data in Figure 2 include two compaction curves for the TS70%-PON30% mixture, one for SP and another one for MP test. As mentioned before, for the same soil, the optimum dry density from MP test is higher than that from SP test and it is shown a shift of the compaction curve to the right in the γ_d - w plane when the soil is subjected to the SP effort.

Then, when the TS85%-PON15% mixture is compared to the TS70%-PON30%, determined both under the MP test, the first mixture results in both a lower variability of dry density and a significantly lower $\gamma_{d,opt}$. In contrast, the w_{opt} is almost the same for the two mixtures.

A comparison is also possible in Figure 2 between TS70%-PON30% and TS50%-PON50% mixtures, compacted under SP test (Manassero et al., 2005). These two compaction curves have a similar shape but the mixture with the same weight percentage of TS and PON records higher values at the optimum of both dry density and water content. Then, particle size analyses performed after Proctor compaction showed no significant grain breakage or particle collapsing.

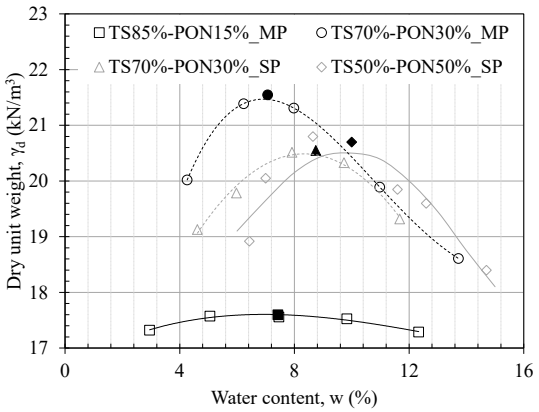

Figure 2. Proctor compaction curves of the tested soils.

2.2 Hydraulic behaviour

The hydraulic conductivity and water retention characteristics, strongly influenced by the soil texture resulting from compaction, were determined by following the procedure described in Ventini et al., (2023b). The saturated hydraulic conductivity (k_{sat}) was measured in a permeameter test at a constant load, while the hydraulic conductivity and water retention characteristics along the main drying branch were obtained using a *ku-pF* (Umwelt-Geräte-Technik GmbH) commercial apparatus and a Richards plate in series. The experimental data were then modelled by the Van Genuchten (1980) equation.

As reported in Table 2, the TS85%-PON15% mixture, characterized by a higher percentage of sand, displays significantly greater saturated permeability

than the other mixtures (about two orders of magnitude higher). This observation holds true despite the heightened compaction energy applied. When using the same compaction technique, the mixture with a higher coarse-grained component demonstrates trivially greater saturated permeability while, considering the same grain size distribution, the k_{sat} is higher for a lower initial dry unit weight.

Table 2. Optimum dry unit weight $\gamma_{d,opt}$ and water content w_{opt}, Van Genuchten model parameters for the tested specimens (saturation volumetric water content θ_{sat}, residual volumetric water content θ_r, n and α dimensionless parameters) and saturated permeability k_{sat}.

Soil	$\gamma_{d,opt}$ kN/m³	w_{opt} %	θ_{sat} -	θ_r -	n -	α 1/kPa	k_{sat} m/s
TS50%-PON50%_SP	20.70	10.00	0.16	0.13	1.50	0.06	1.10 E-08
TS70%-PON30%_SP	20.55	8.75	0.20	0.09	1.33	0.20	5.51 E-07
TS70%-PON30%_MP	21.55	7.07	0.17	0.07	1.40	0.09	6.11 E-08
TS85%-PON15%_MP	17.60	7.43	0.30	0.06	2.00	1.00	1.93 E-06

The soil water retention curves (SWRCs – θ) for the tested mixtures are depicted in Figure 3, where the TS85%-PON15% mixture, compacted with higher energy and characterized by a prevalent coarse-grained component, exhibits a low water retention capacity. This finding is consistent with the behaviour of soils dominated by sand particles.

When comparing two mixtures with the same grain size distribution (TS70%-PON30%), the role of compaction in altering soil density and subsequently affecting water retention characteristics emerges. The MP compaction technique, which results in a higher $\gamma_{d,opt}$, provide a retention curve characterized by: lower values of saturation water content (θ_{sat} -Table 2), higher air entry value (1/0.09=11 kPa), higher value of the *n* parameter, indicative of a steeper curve; lower θ_r parameter, indicating a lower ability to retain water at high suctions respect to the same mixture compacted under SP test. It results that the MP technique amplifies the hydraulic features of the finer soil component close to saturation, by providing a reduction in k_{sat} and an increase in the air entry value.

The water retention capacity demonstrated by the TS50%-PON50% mixture, characterized by a higher fine content, aligns with expectations. This mixture exhibited a hydraulic response characterized by a higher suction entry value and higher θ_r parameter respect to the TS70%-PON30% mixture obtained using the same SP technique. These two retention curves mainly differ in the high suction range.

The distinct characteristics exhibited by each mixture underscore the importance of considering both soil composition and compaction conditions in understanding water retention capacity.

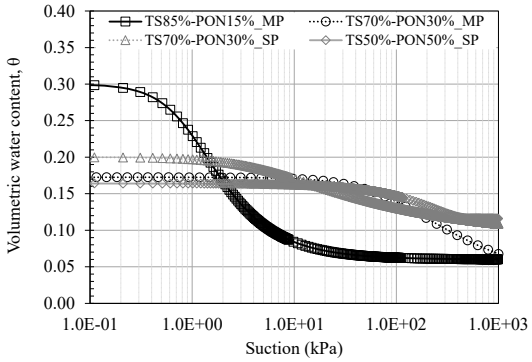

Figure 3. Soil water retention curves of the tested mixtures.

The soil hydraulic conductivity functions (*k*) obtained for the tested mixtures are shown in Figure 4.

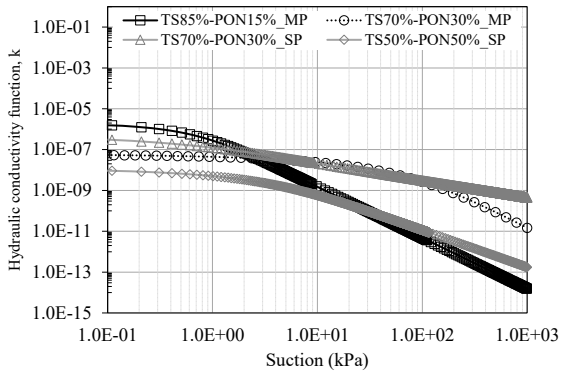

Figure 4. Soil hydraulic conductivity functions of the tested mixtures.

Generally, the hydraulic conductivity functions reflect the soil water retention curve by supporting the considerations stated above.

Comparing the mixtures TS70%-PON30%_SP and TS70%-PON30%_MP allows to observe the effects of different compaction on hydraulic conductivity. The shapes of the obtained hydraulic conductivity functions are similar, with intermediate segments running overlapping each other. However, some differences are evident close at both saturation and residual condition due to a different energy of compaction.

Then, the hydraulic conductivity of the TS85%-PON15% mixture, dominated by sand, is much higher for suction lower than 5 kPa and much lower for the

rest of the suction range than that of the TS70%-PON30%_MP.

2.3 Mechanical implications

The hydraulic response of the partially saturated material has evident implications also for the mechanical behavior. Figure 5 reports the apparent cohesion (c_a - eq.1) determined by adopting the Bishop stress approach, with χ equal to degree of saturation S_r, for soil shear strenght against suction for the TS70%-PON30% mixtures:

$$c_a = tan\varphi' \cdot S_r \cdot s \qquad (1)$$

In eq.1, φ' is the peak friction angle: 45° for the MP mixture and 41° for the SP mixture. The values of S_r (degree of saturation) and s (matric suction) have been determined by soil water retention curves (Figure 3) and by the initial soil porosity neglecting the volume variation of soil during the evaporation test. The TS70%-PON30%_MP mixture exhibits a significantly higher apparent cohesion, with a deviation that tends to approach zero at high suctions. This confirms the better performance of the MP technique, even from a mechanical point of view, making it more suitable for the construction of river embankments.

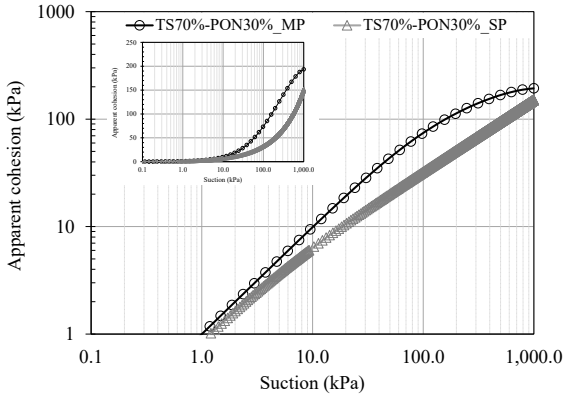

Figure 5. Apparent cohesion versus suction for the two TS70%-PON30% mixtures

3 CONCLUSIONS

The observed variations in soil hydraulic conductivity and water retention characteristics, influenced by both soil composition and compaction conditions, highlight the nuanced interplay between these factors. The greater saturated permeability exhibited by the TS85%-PON15% mixture, despite heightened compaction energy, underscores the significance of initial porosity in coarse-grained compositions. Then, the MP technique amplifies the hydraulic feature of the finer soil component close to saturation, by providing a reduction in k_{sat} and an increase in air entry value. Additionally, the notable differences in hydraulic conductivity among mixtures emphasize the need for tailored engineering solutions, recognizing that a one-size-fits-all approach may not be suitable for embankments with different soil compositions.

Viscoplasticity and large strain consolidation modelling with converging isotaches

Viscoplasticité et grande déformation avec des isotaches convergentes

T.A. Vergote*, Y. Devrieze
DEME Group, Zwijndrecht, Belgium

**vergote.thomas@deme-group.com*

ABSTRACT: Large strain consolidation models are widely used for prediction of soft soil behavior in hydraulic filled reclamations. Large strain models typically consider an elastoplastic response with time independent constitutive relations for both permeability k(e) and compressibility e(σ'). This approach may be insufficient for soft soils subject to long consolidation times for which time dependent effects of soil are more prominent. Based on long-term column settling tests on kaolinite clay it is observed that incorporating time dependent effects (viscoplasticity) with the isotache theory improves the large strain model predictions significantly. The tests suggest changes on the amount of viscoplastic strain at high void ratio, leading to non-parallel (converging) isotaches. Therefore, a large strain converging isotache model is developed for better predictions of both settlements and pore pressures of soft soils.

RÉSUMÉ: Les modèles de consolidation par déformation importante sont largement utilisés pour prédire le comportement des sols mous dans les réhabilitations hydrauliques. Les modèles de grandes déformations considèrent une réponse élastoplastique avec des relations indépendantes du temps pour la perméabilité k(e) et la compressibilité e(σ'). Cette approche peut s'avérer insuffisante pour les longues périodes de consolidation où les effets dépendant du temps sont plus importants. Avec d'essais de tassement en colonne à long terme sur de l'argile kaolinite, il a été observé que l'incorporation de la théorie des isotaches améliore considérablement les prédictions du modèle de grandes déformation. Les tests suggèrent des isotaches non parallèles (convergentes). Par conséquent, un modèle d'isotache convergent de grande déformation est développé pour de meilleures prévisions des tassements et des pressions interstitielles de sols mous.

Keywords: Land reclamation; creep; visco-plasticity; large strain; consolidation.

1 INTRODUCTION

Recent reclamation projects are subjected to a challenge since scarcity of good quality fill material is increasing worldwide. Offshore dumping of dredged material and importing external quality fill material becomes unacceptable for both environmental and economic reasons. The reuse of soft dredged material as reclamation fill is increasing to solve these issues. From an economic and practical point of view it is interesting to hydraulically fill reclamation areas with soft dredged material, but it also leads to additional challenges in estimating the settlement behaviour of the reused dredged material with high moisture contents (100% - 300%) directly after filling.

One-dimensional consolidation of soils is conventionally analysed with the theory of Terzaghi, which is restricted to infinitesimal strains. In soils with a high moisture content this theory will be highly inaccurate. One of the most well-known large strain models (LSM) are the model of Gibson et al. (1967) and the CS2 model presented by Fox and Berles (1997). This model uses a finite difference method to calculate elastoplastic soil behaviour from the constitutive relations of the soil: permeability k(e) and compressibility e(σ'). Empirical parameters of the constitutive relations are commonly calibrated with laboratory tests. Although the model of Fox and Berles (1997) is widely used for large strain analyses, it may be insufficient for reused dredged material subject to long consolidation times for which time dependent effects of soil (creep) may be more prominent.

In recent research by Li et al. (2023), Xia et al. (2023) and Gheisari et al. (2023), time dependent effects are incorporated in a large strain model, which leads to a more accurate prediction of self-weight consolidation of soft soils when comparing the model with laboratory or large-scale tests.

In large CRS tests done by Vergote (2020) it is observed that variations in strain rate influence the loading-unloading response of soft soils. This effect is much stronger at high void ratio and low stress compared to higher stresses. This suggests that the isotaches at high void ratio do not run parallel.

The scope of this paper is to incorporate time dependent effects in the large strain model as presented in Vergote et al. (2021) by means of non-parallel isotaches (converging isotaches) and to compare the model behavior with laboratory tests.

2 LARGE STRAIN CONSOLIDATION TESTS ON SOFT SOIL

2.1 Long-term column settling tests with piezometers

Long-term column settling tests are used to evaluate the large strain model response. Large sized columns (2m high & diameter 0.2m), equipped with 4 piezometers equally distributed over their height, are filled with a slurry with predefined uniform bulk density, typically ranging between 11 and 14kN/m³. The interface between clean water and slurry and the pore pressures are measured over time.

Three column tests were performed on pure Kaolinite clay, with initial bulk densities between 11 and 12.5kN/m³. In Figure 1 the soilwater interface (m), the bulk density (kN/m³) and the excess pore pressure (%) measured at 4 heights are shown over time (hours).

2.2 Rate-dependence in CRS tests on soft soil

To understand the loading and unloading response of soft soil at higher stress, tests in large CRS tests were by Vergote (2020). Figure 2 shows such a CRS test with variations in strain rate during compression. From the test the strain rate effect is much stronger at high void ratio and low stress compared to higher stresses. This suggests that the isotaches at high void ratio do not run parallel, in line with Xia et al. (2023) and observations in column settling tests. As part of the current work, additional CRS tests will be conducted to corroborate this hypothesis.

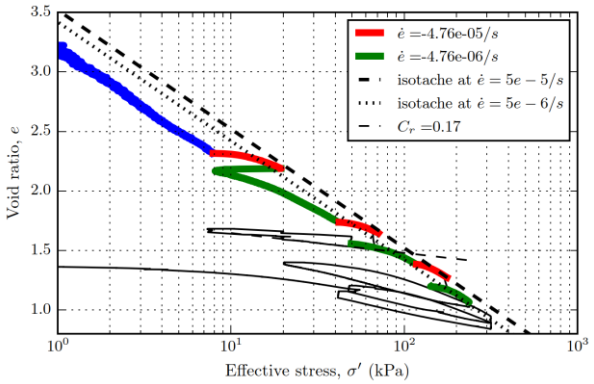

Figure 2. CRS test on soft soil with strain rate changes, from Vergote (2020).

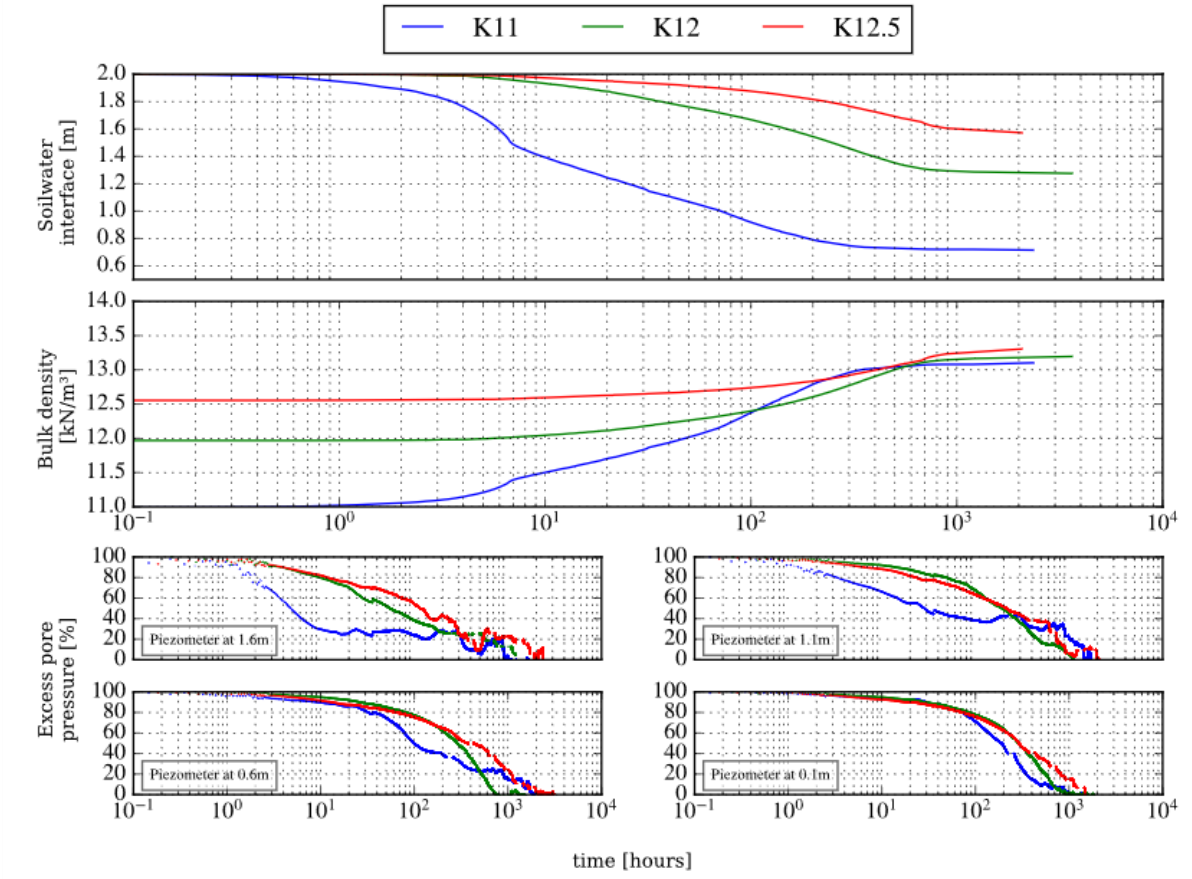

Figure 1. Column test results on Kaolinite samples with initial bulk densities: 11, 12 and 12.5kN/m³.

3 LARGE STRAIN CONVERGING ISOTACHE MODEL

3.1 Model features

The large strain isotache model as presented in Vergote et al. (2021) is extended to handle converging isotaches. The basis of the model is a set of isotaches constructed from a flexible reference isotache. This is the compression line corresponding to a fixed void ratio rate $\dot{e}_{ref}$. The reference isotache can be expressed in multiple ways:

$$e = e_{ref} - C_c \cdot log_{10}\,\sigma' \tag{1}$$

$$ln\left(\frac{e}{e_{ref}}\right) = -\rho_c \cdot ln(\sigma') \tag{2}$$

where e_{ref} is the reference void ratio at $\sigma' = 1kPa$, C_c the compression index, in case reference isotache of the shape (1) is used and ρ_c the compressibility parameter for a log-log response as eq. (2).

The isotaches are constructed relative to this reference isotache with the reference over-consolidation ratio $OCR_{ref} = \sigma'_{p,ref}/\sigma'$ with $\sigma'_{p,ref}$ the preconsolidation pressure calculated relativelly to the reference isotache.

A non-linear isotache system is adopted, where the spacing $\hat{C}_\alpha$ depends is expressed as proposed by Yuan (2016):

$$\frac{\hat{C}_\alpha}{C_{\alpha,ref}} = \frac{2}{\left(\dot{e}_{vp,c}/\dot{e}_{vp,c,ref}\right)^{-\beta_2/\beta_3}+1} \tag{3}$$

where the parameters β_2 controls the non-linearity of the isotache spacing, $\beta_3 = (C_c - C_r)/C_{\alpha,ref}$ and $C_{\alpha,ref}$ is the secondary compression index at the reference isotache. This implies that the spacing $\hat{C}_\alpha$ of the isotaches gets smaller at higher OCR_{ref} if $\beta_2 > 0$.

This flexible expression of isotaches enable further extensions to the model, if the constructed set of isotaches does not fully describe the observed behaviour. For example, distortion of isotaches is observed during unloading as an effect of swelling, which is expressed and validated in Vergote et al. (2021). For very soft soil, converging isotaches can be expressed similarly by adjusting the expression of $\hat{C}_\alpha$ as:

$$\frac{\hat{C}_\alpha}{C_{\alpha,ref}} = \frac{2 \cdot max\,(e^\eta, 1)}{\left(\dot{e}_{vp,c}/\dot{e}_{vp,c,ref}\right)^{-\beta_2/\beta_3}+1} \tag{4}$$

where a new convergence parameter η is introduced to express the non-parallel nature of isotaches at high void ratio. The effect is illustrated by comparing linear (Figure 3) with converging isotaches (Figure 4).

The model assumes that the isotaches get a larger spacing in function of the void ratio based on the empirical results to date. Additional lab test data is needed to confirm this relation. In this paper a validation is done based on column tests with kaolinite clay.

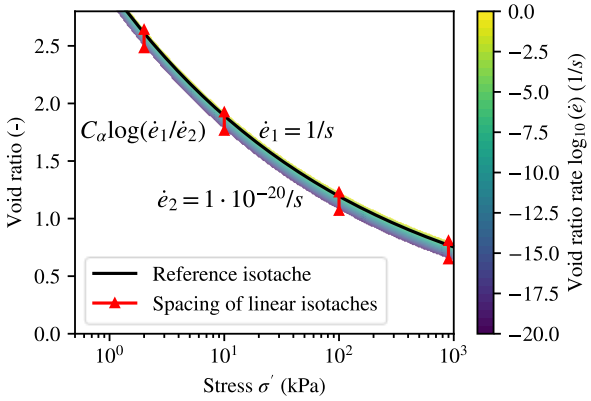

Figure 3. Isotaches for a linear system, $\beta_2 = 0$ and reference isotache expressed with eq. (2).

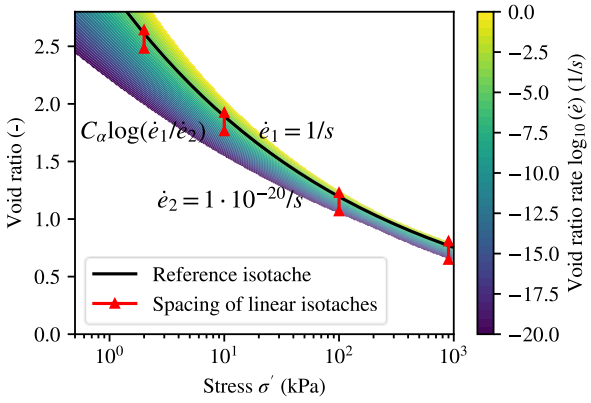

Figure 4. Converging isotaches, $\beta_2 = 0$ and $\eta = 2$.

3.2 Numerical implementation of large strain hydro-mechanical coupling with flexible isotaches

To validate the converging isotache model, simulate lab tests and create field predictions, a numerical model is implemented using the finite difference method. The process works in two steps: first the isotache relations are calculated in a fine grid $(e, \sigma, \dot{e}_{vp,c})$ for a set of parameters. Then the consolidation simulation is done with an implicit finite difference solution of the partial differential equation:

$$\frac{\dot{e}}{1+e} = -\left(\frac{k}{\gamma_w}\frac{\partial^2 u}{\partial z^2} + \frac{1}{\gamma_w}\frac{\partial k}{\partial z}\frac{\partial u}{\partial z}\right) \tag{5}$$

with a variable permeability $k(e)$, the weight of water γ_w and pore pressure u. The void ratio rate is the sum of the elastic and viscoplastic rate: $\dot{e} = \dot{e}_e + \dot{e}_{vp,c}$. The viscoplastic void ratio rate is defined by the isotache system, for every position e, σ', the viscoplastic rate is known. The elastic rate is defined by:

$$\dot{e}_e = \frac{C_r}{ln(10)} \cdot \frac{\dot{\sigma}}{\sigma} \qquad (6)$$

with the recompression index C_r. The solution is capable of handling large strains thanks to a piecewise updating of the grid at every depth Δz. Validation of the solver was done in Vergote (2020). Figure 5 shows the response of the current model with ($C_\alpha > 0$) and without viscosity ($C_\alpha \approx 0$).

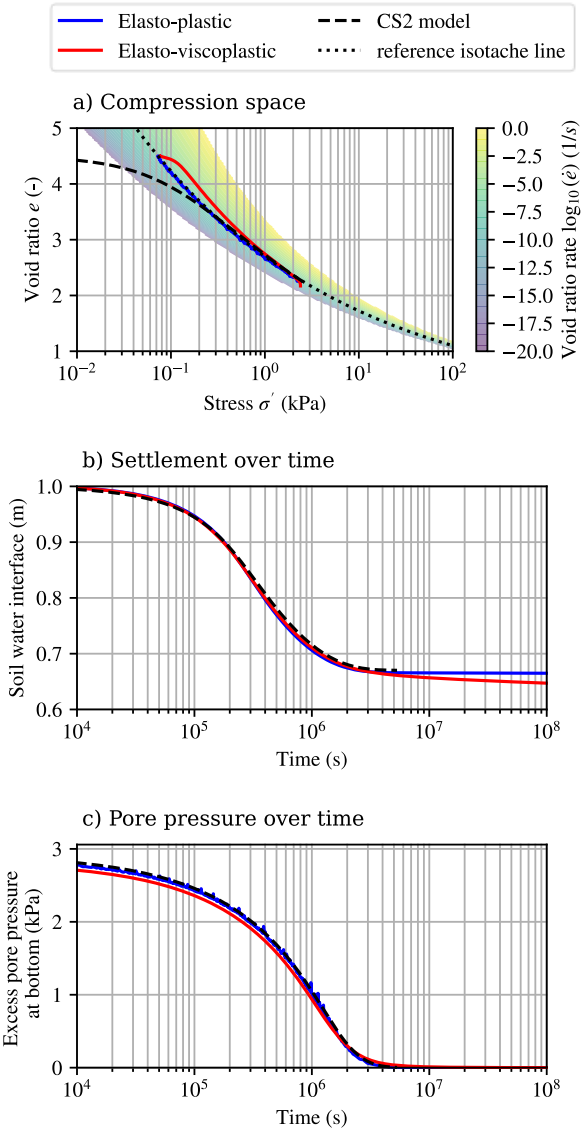

Figure 5. Model response for an elasto-plastic and elasto-viscoplastic model variant.

4 MODEL PERFORMANCE TO LAB TESTS

4.1 Large strain elastoplastic model

The elastoplastic large strain model as presented in Vergote and Mengé (2015) and based on the theory by Fox & Berles (1997), is not able to accurately predict both settlement and pore pressures as observed in the three column tests using any combination of material parameters in constitutive relations; permeability k(e) and compressibility e(σ'). Moreover, calibration of three homogeneous Kaolinite samples, with different initial bulk densities, leads to three different material parameter sets.

These findings are illustrated with a calibration and validation example, shown in Figure 6. First, the column test results of sample K12, with initial bulk density 12kN/m³, were used for model calibration. Afterwards, the calibrated model was validated with results of column tests K11 and K12.5 with bulk densities 11kN/m³ and 12.5kN/m³.

In Figure the soilwater interface and excess pore pressure of the lowest piezometer (0.08m height) are shown for the three column tests. After calibration, the elastoplastic large strain model (CS2), does not predict both settlements and pore pressures of sample K12 with high accuracy. When modelling the behavior of samples K11 and K12.5 with the calibrated model, shown in red in Figure 6, predictions are (slightly) inaccurate. For sample K11 the modelled settlements occur too slow and pore pressure dissipation is slightly overestimated. For sample K12.5 the modelled settlements occur too fast. Prediction of column tests with other boundary conditions (f.e. initial bulk density) lead with the elastoplastic large strain model (CS2) to less accurate results. One of the main reasons is the model assuming unique constitutive relations (k(e) and e(σ')) for the material. However, in soft soils these relations can change significantly over time and particularly at lower void ratios or higher effective stresses. In the column tests very large deformations are observed at low stresses. Depending on the initial bulk density of the sample the observed deformation at low stresses changes significantly between the tests, leading to 3 different material parameter sets for the same homogenous material. This effect (visco-plasticity) is not incorporated in the elastoplastic large strain model (CS2) due to time and strain independent constitutive relations. The elasto-viscoplastic effects should therefore be considered for more accurate predictions of large strain behavior of soft soils.

4.2 Large strain converging isotache model

After extending the large strain model with converging isotaches, the calibration, using a linear reference isotache (eq. (1)), leads to a better prediction of both settlement and pore pressure of individual column tests compared to the large strain elastoplastic model (CS2). However, inconsistencies between pore pressure and settlement predictions remain when modelling the behaviour of samples with different bulk densities.

Using the large strain converging isotache model with calibration based on column test K12 using a log-log reference isotache (eq. (2)), leads to an even better prediction of both settlement and pore pressure of individual column tests, as shown in blue (LSI (1)) in Figure 6. When using the log-log reference isotache (LSI(1)) both settlements and pore pressures are predicted with reasonable accuracy for all three column tests with one unique set of material parameters. After model calibration on sample K12 the settlements of sample K11 are predicted accurately but the pore pressure dissipation is slightly overestimated. For sample K12.5 both settlements and pore pressures are predicted with reasonable accuracy.

In the previous calibration and validation example calibration was performed solely on the results of column test K12. When using all three column tests for calibration a slightly better fit is obtained for both soil water interface and pore pressures, as shown in green (LSI (2)) in Figure 6.

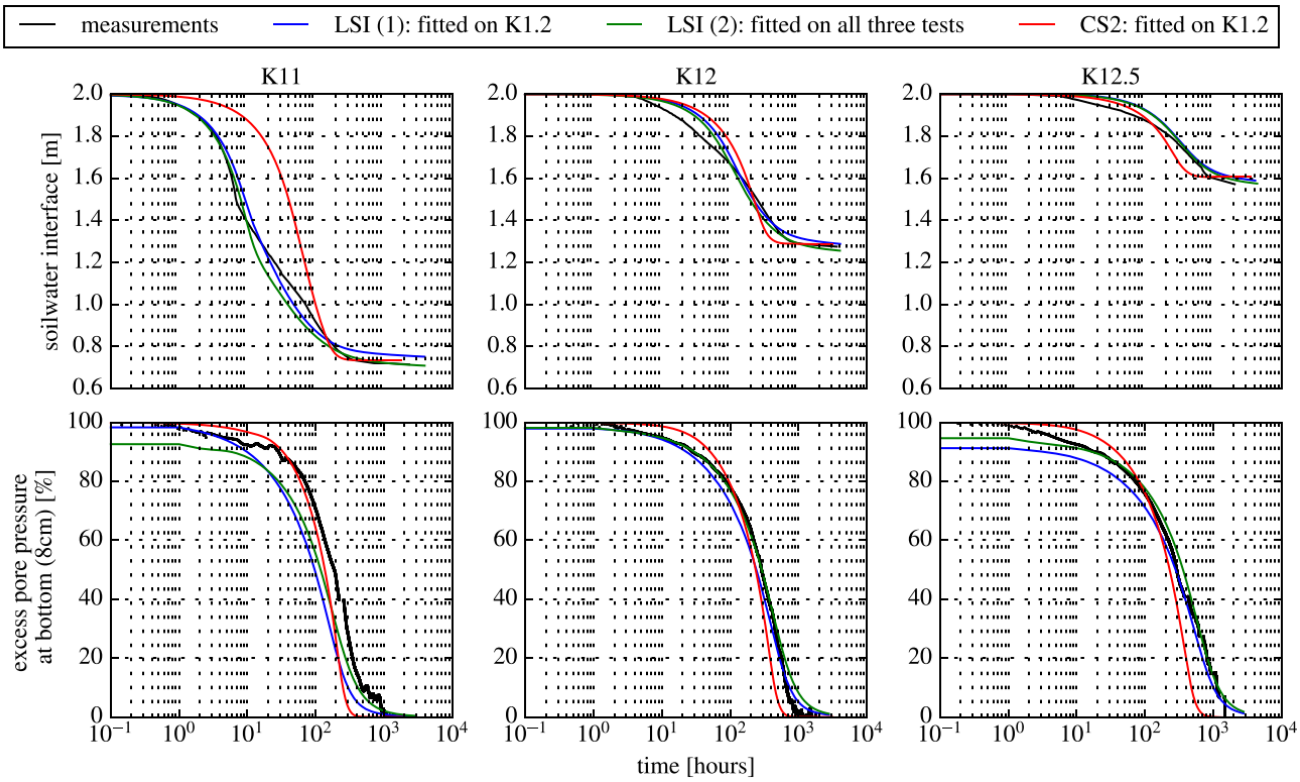

Figure 6. Column test results in black, elastoplastic large strain model (CS2) calibrated on K12 in red, large strain converging isotache model calibrated on K12 in blue (LSI (1)) and large strain converging isotache model calibrated on all three column tests in green (LSI (2)).

5 FUTURE WORK

The large strain converging isotache model improves the prediction of settlements and pore pressures in soft soils. More research would be required to explain the converging isotaches from a microstructural point of view. Additional experimental work on the strain rate effect during loading and unloading of soft soils will lead to a better understanding of the observations and can be used to further improve the converging isotache model. The experimental work can be extended with future long-term column tests on low plasticity clay, low plasticity silt and clay-silt mixtures. Additional CRS tests can be performed to obtain a better understanding of the strain rate effect.

The existing numerical model can be further improved to improve speed and numerical stability and can be further extended to increase the applicability of the model with additional features such as: the transition of sedimentation to consolidation, unloading, reloading, simulation of hydraulic filling, implementation of an axisymmetric model, prefabricated vertical drains and multi-layer soils.

6 CONCLUSIONS

Integrating the isotache theory in large strain consolidation models allow for more accurate consolidation predictions. Thanks to consideration of viscoplasticity, a more unified method for settlement predictions can be done, across time scales and strain levels.

Especially for very soft soils, experimental results suggest that the isotaches do not run parallel, but instead converge towards larger stress levels. In this paper, an extension to the large strain isotache model is proposed to align the isotaches closer to the experimental data with the introduction of a convergence factor η. The model is validated with three columns at varying density, indicating the convergence factor is needed to fit the data accurately.

ACKNOWLEDGEMENTS

The tests were carried out in the laboratory of the DEME Group. The authors are grateful for the help provided by Xavier Lepère and Iso Audenaert in designing and building the instrumented column set-up.

Effects of sustained loads on geogrid pullout behaviour embedded in a recycled construction and demolition waste

Effets de charges soutenues sur le comportement d'arrachement des géogrille intégrée dans des déchets de construction et de démolition recyclés

C.S. Vieira*, P.M. Pereira
CONSTRUCT, Faculty of Engineering, University of Porto, Porto, Portugal
**cvieira@fe.up.pt*

ABSTRACT: A suitable behaviour of backfill/geosynthetic interfaces is one of the key points to achieve a good performance of any geosynthetic reinforced structure. Previous researches have been showing that the interfaces between recycled construction and demolition (C&D) wastes and some geosynthetics have coefficients of interaction in the range of usual values for soil/geosynthetic interfaces. However, most of these studies only evaluated the geosynthetics pullout resistance under monotonic loading conditions (constant displacement or load rates during pullout) and do not consider their long-term behaviour. This paper presents a preliminary laboratory study conducted to investigate the effects of multistage loading on a geogrid pullout behaviour. After reaching a predefined value (40% or 70% of the geogrid pullout resistance) under load-controlled conditions, the pullout force was kept constant for 30 or 120 minutes and then increased until the geogrid pullout failure. The results obtained to date show that sustained loads periods did not reduced the geogrid pullout resistance and thus the usual pullout tests are on the safety side. The duration of the sustained load stage affected mainly the cumulative deformations on the geogrid, which are more significant when the constant load level is closer to the geogrid's pullout resistance.

RÉSUMÉ: Un comportement approprié des interfaces remblai/géosynthétique est un des points essentiels pour assurer une bonne performance de toute les structures renforcée par géosynthétique. Des recherches antérieures ont montré que les interfaces entre les déchets de construction et de démolition recyclés (C&D) et divers géosynthétiques ont des coefficients d'interaction qui se situent dans la gamme des valeurs habituelles pour les interfaces sol/géosynthétique. Cependant, la plupart de ces études n'ont évalué la résistance à l'arrachement des géosynthétiques que dans des conditions de charge monotone (déplacement constant ou taux de charge constant pendant l'arrachement) et n'ont pas considéré leur comportement à long terme. Cet article présente une étude préliminaire conduite en laboratoire pour étudier les effets d'un chargement en plusieurs étapes sur le comportement à l'arrachement d'une géogrille. Après avoir atteint une valeur prédéfinie (40 % ou 70 % de la résistance à l'arrachement de la géogrille) dans des conditions de charge contrôlée, la force d'arrachement a été maintenue constante pendant 30 ou 120 minutes, puis augmentée jusqu'à la rupture de la géogrille. Les résultats obtenus à cette date montrent que les périodes de charges soutenues n'ont pas réduit la résistance à l'arrachement de la géogrille et que les tests d'arrachement habituels sont donc du côté de la sécurité. La duration de la phase de charge soutenue affecte principalement les déformations cumulées sur la géogrille, qui sont plus importantes lorsque le niveau de charge constante est plus proche de la résistance à l'arrachement de la géogrille.

Keywords: Geosynthetics; recycled C&D wastes; pullout behaviour; sustained loads; long-term behaviour.

1 INTRODUCTION

In recent years several studies and applications of recycled Construction and Demolition (C&D) wastes have been carried mainly focused on their use in base and sub-base layers of transportation infrastructures or in concrete production. The valorisation of C&D waste in geosynthetic reinforced structures, such as steep slopes or retaining walls, is also a topic of recent interest (Vieira and Pereira 2018; Santos et al. 2013).

A suitable behaviour of backfill/geosynthetic interfaces is one of the key points to achieve a good performance of any geosynthetic reinforced structure (steep slopes and retaining walls). Previous researches have been showing that C&D waste/geosynthetic interfaces have coefficients of interaction in the range of usual values for soil/geosynthetic interfaces (Santos and Vilar 2008, Arulrajah et al. 2013, Vieira and Pereira 2016, Vieira and Pereira 2022). However, these studies, as most of those found in the literature for soil/geosynthetic interfaces, do not account for the long-term behaviour.

In typical pullout tests, an increasing force is applied to one end of the geosynthetic at a constant

displacement rate (displacement-controlled tests) until the geosynthetic failure (pullout). As will be mentioned below, pullout tests can also be carried out with a constant load rate (load-controlled tests). In this paper the effect of applying a constant pullout force (sustained load) at a pre-defined load level and time period before leading the geosynthetic to failure is studied. The influence of this different approach on a geogrid's pullout resistance and on the displacement for which it is mobilised is presented and discussed.

2 MATERIALS AND METHODS

2.1 Materials

The study was carried out with a fine-grained recycled construction and demolition (C&D) material, coming from the recycling process of non-selected C&D wastes (Figure 1a). Thus, it has a very heterogeneous composition (soil, stones, concrete and mortars, ceramics, …).

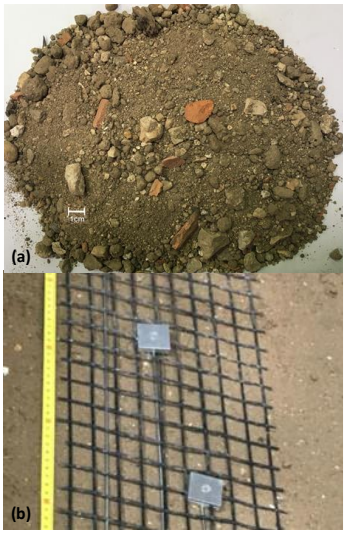

Figure 1. Materials: (a) recycled C&D waste; (b) geogrid.

Their constituents were evaluated following the European Standard EN 933-11:2009 for coarse aggregates. As the particles are sorted by hand, it is not humanly possible to classify particles smaller than 4 mm, so the test specimen according to the standard only includes particles with a higher dimension. Figure 2 shows the relative proportion of the constituents of recycled C&D material, where R_c refers to concrete, concrete products, mortar, concrete masonry units; R_u corresponds to unbound aggregate, natural stone, hydraulically bound aggregate; R_b refers to clay masonry units, calcium silicate masonry units, aerated non-floating concrete; R_a and R_g correspond to bituminous materials and glass, respectively and X is for other materials.

Table 1 summarises some grain size and compaction properties of the recycled C&D waste. Further details can be found in Carneiro et al. 2023).

A polyester geogrid (Figure 1b) with nominal tensile strength of 35 kN/m and corresponding elongation of 10.5% (values provided by the manufacturer) was used in this study.

2.2 Laboratory study

The laboratory study comprises benchmark monotonic pullout tests and multistage pullout tests (Figure 3).

Geosynthetics pullout tests (monotonic tests) are usually carried out under displacement-controlled conditions, i.e. imposing a constant frontal displacement rate equal to 2 mm/min (± 10%) - EN 13738: 2004. According to this standard, constant stress loading methods, where the pullout force is applied to the geosynthetic under a uniform loading rate not exceeding 2 kN/m/min can also be used. In this study, benchmark monotonic load-controlled tests under a constant load increment rate of 0.55 kN/m/min were also carried out, since multistage pullout tests must be performed under load-controlled conditions in order to ensure that the pullout force remains constant during a predefined period of time (Figure 3).

Multistage pullout tests consist of an initial monotonic loading (load increment rate equal to 0.55 kN/m/min) to a predefined value of the pullout force (40% or 70% of the pullout resistance, P_{max}), followed by a sustained load stage (during 30 or 120 minutes), and after that, a constant load rate of 0.55 kN/m/min is applied again untile the geogrid pullout failure (Figure 3).

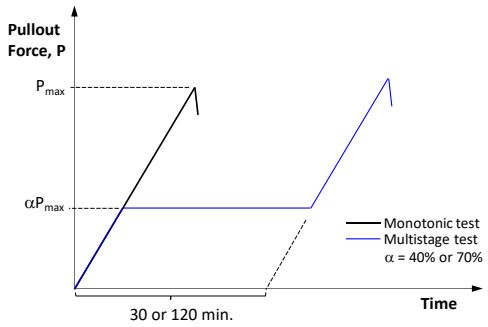

Figure 3. Schematic representation of the different setups of pullout tests carried out.

In all these tests the recycled C&D material was compacted to 90% of its maximum dry density and at the optimum moisture content (standard Proctor test) and the normal stress at the interface level was around 10 kPa. The material was compacted to 90% of its maximum dry density (although higher values are usually used on construction sites), because laboratory compaction above this value, using manual means, revealed to be very difficult.

The geogrid specimens were tested with initial dimensions of 250 mm wide × 750 mm long (inside the pullout box).

3 RESULTS AND DISCUSSION

3.1 Monotonic pullout tests

The displacements throughout the geosynthetic length are usually monitored, during pullout tests, using inextensible wires connected to the geosynthetic specimen (Figure 1b) and to linear potentiometers placed outside the pullout box (Vieira and Pereira 2022). However, the presence of the fixing elements affects the interface conditions and may even have influence on the pull-out resistance, depending on the geosynthetic type and strength (Lopes and Ladeira 1996; Ferreira et al. 2016). Figure 4 illustrates the effects of the displacement recording system (fixing elements, inextensible wires and linear potentiometers) on the geogrid's pulllout behaviour.

Figure 4 shows that the presence of this system leads to an overestimation of around 13% of the geogrid pullout resistance, meaning that the presence of the inextensible wires and corresponding fixing system (Figure 1b) somehow restricts the geogrid from being pulled out. In view of this evidence, the remaining pullout tests were carried out without monitoring of the displacements along the geogrid's length.

As mentioned in 2.2, monotonic pullout tests were carried out under displacement-controlled and load-controlled conditions. Figure 5 compares the geogrid´s pullout behaviour under both scenarios.

The geogrid's pullout resistance was 10 % higher when it was pulled out under a constant load increment rate when compared to its resistance under at a constant displacement increment. Although the load increment rate was selected such that the duration of both tests was similar, it was found that the geogrid was pulled out slightly more slowly under displacement-controlled conditions.

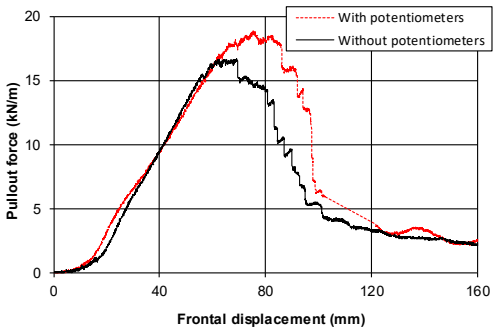

Figure 4. Influence of the presence of displacement recording system.

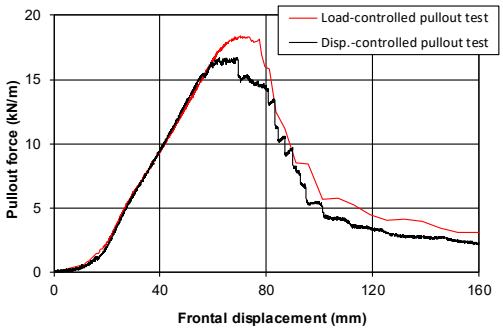

Figure 5. Geogrid pullout behaviour under displacement-controlled and load-controlled conditions.

Previous researches (Lopes and Ladeira 1996; Vieira et al. 2020) have shown that, due to intrinsic viscous response of polymeric geosynthetics, the geosynthetics pullout resistance is affected by the rate of loading and generally increases with an increase of the displacement rate. Thus, the conclusion drawn by the analysis of Figure 5 is consistent with what was expected.

3.2 Multistage pullout tests

3.2.1 Effect of sustained load level

Figure 6 presents the influence of the sustained load on the geogrid's pullout behaviour. It can be inferred from the analysis of Figure 6 that multistage loading led to a slight increase (lower than 10%) in the pullout resistance.

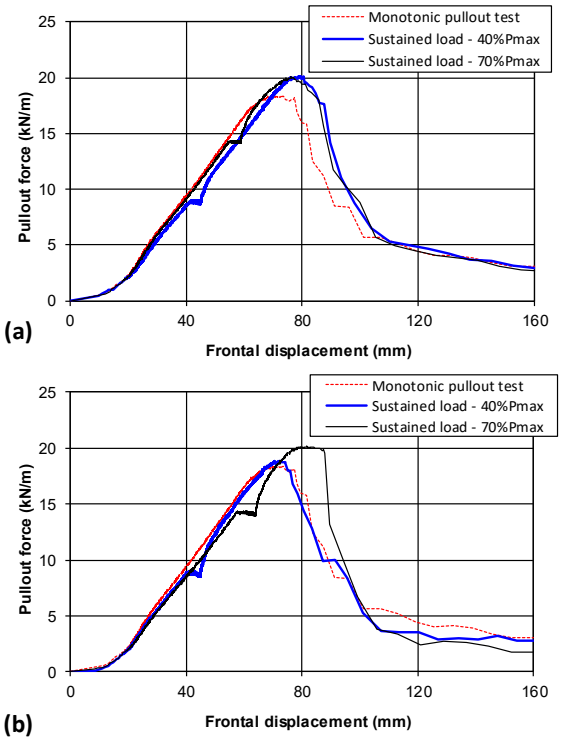

Figure 6. Influence of the sustained load (at 40%Pmax and 70% Pmax) on the geogrid's pullout behaviour: (a) for t = 30 minutes; (a) for t = 120 minutes.

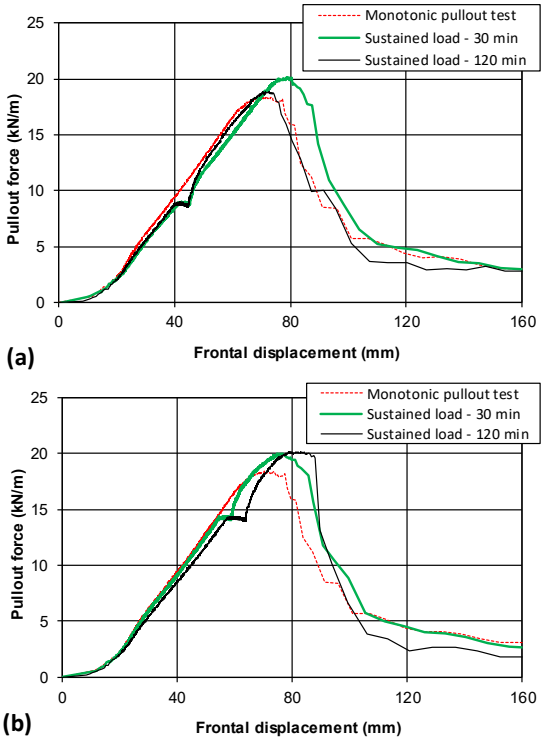

Figure 7. Influence of the time period of the sustained load: (a) at 40%Pmax; (b) at 70%Pmax.

For a sustained load stage of 30 minutes, the behaviour of the geogrid tested with sustained loading at 40%P_{max} and 70%P_{max} was very similar, both in terms of pullout resistance and of the displacement at which the peak resistance was reached. For the higher sustained load period (120 minutes), the behaviour of the geogrid at 40%P_{max} was very similar to that of the monotonic test (an increase in the pullout resistance of only 2.7%), while at 70%P_{max} there was an increase in the peak pullout resistance of around 10% (Figure 6b). The influence of the duration of the sustained load stage will be presented in the next section.

3.2.2 Influence of the duration of sustained load

The effects of the duration of the sustained load stage is shown in Figure 7. For the pullout tests with sustained load at 70%P_{max}, as expected, the longer period of constant load (120 minutes) led to the cumulative deformation on the geogrid and therefore the peak resistance tended to be mobilised for greater deformations. This evidence was not observed in the sustained load tests at 40%P_{max} (Figure 7a). This may be explained by the fact that geogrid´s deformation under constant load is more significant for higher loads, but this point needs to be further explored in future research.

Figure 8 presents the development of geogrid´s frontal displacements during the constant load period. The dashed vertical line marks the beginning of the constant load stage. While the cumulative displacements for 40%P_{max} were 3.8 mm and 4.6 mm, for t = 30 minutes and t = 120 minutes, respectively, the increase is more significant when the sustained load stage occurs at 70%P_{max} (from 4.2 mm to 6.6 mm, for t = 30 minutes and t = 120 minutes, respectively). It is also visible that for 40%P_{max} the displacements tend to stabilise, i.e. small variations after some time (Figure 8a), this is not the case for 70%P_{max} (Figure 8b).

4 CONCLUSIONS

This paper presented a laboratory study to characterize the pullout behaviour of a polyester geogrid embedded in a recycled C&D waste, with emphasis on the effects of sustained loads applied to the geogrid before its pullout failure.

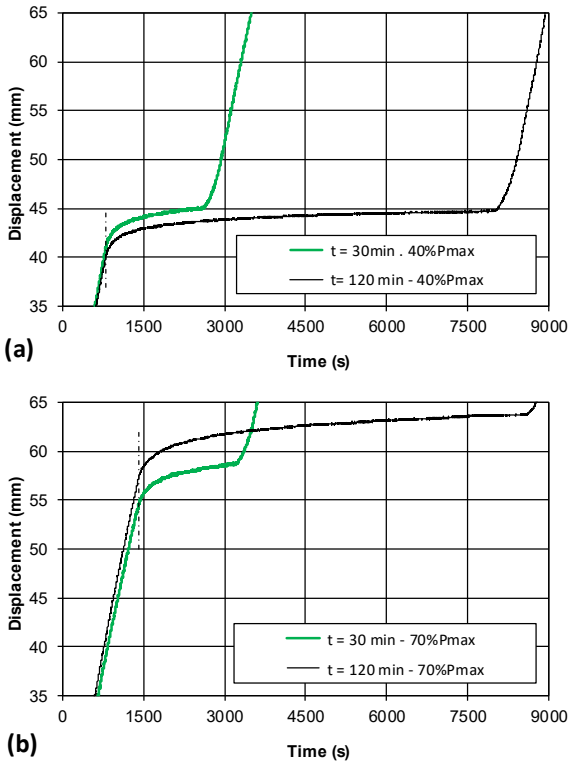

Figure 8. Development of geogrid pullout displacement during the sustained load periods: (a) for 40%Pmax; (b) for 70%Pmax.

The main conclusions of this study are summarized as follows:

- The geogrid's pullout resistance tended to be slightly higher when it was pulled out under a constant load increment rate when compared to its resistance under a constant displacement rate.
- Multistage pullout tests with a constant load stage did not significantly affect the geogrid´s pullout resistance. A slight increase in the pullout resistance was observed.
- The effect of the duration of the sustained load on the geogrid pullout behaviour is mostly seen in the cumulative deformations, which are more significant when the constant load is higher, i.e., is closer to the geogrid's pullout resistance.

It should be highlighted that this is a preliminary study that requires a more comprehensive research programme with other materials, other sustained load levels and longer durations.

Effect of cyclic loading stress level and amplitude on the behaviour of a soft soil chemically stabilized unreinforced and fibre-reinforced

Effet du niveau et de l'amplitude des contraintes de chargement cycliques sur le comportement d'un sol meuble chimiquement stabilisé, non renforcé et renforcé de fibres

ABSTRACT: This works aims to characterise the effect ofin cyclic loading stress level and amplitude, on the behaviour of a soft soil chemically stabilized and reinforced with polypropylene fibres by comparing the results of unconfined compressive strength (UCS) and split tensile strength (STS) tests (STS) carried out before and after a cyclic loading stage. The laboratory work is based on the following tests: i) monotonic UCS and STS test (reference values); (ii) cyclic UCS and STS tests and (iii) monotonic UCS and STS tests performed after the cyclic loading stage (UCSpc and STSpc). From the results it is observed that the permanent deformations show a sharp increase at the beginning of the cyclic stage followed by a decrease in the strain rate for unreinforced and fibre-reinforced samples. In terms of cyclic loading stress level and amplitude, Ffor levels of stress and amplitudes of up to 50% of the maximum strength/load, the samples exhibit lower permanent strains but become stronger and stiffer than the reference values (monotonic tests). These observations are valid for both stabilised materials (unreinforced and fibre-reinforced).

RÉSUMÉ: Ce travail vise à caractériser l'effet du niveau de contrainte et de l'amplitude de la charge cyclique sur le comportement d'un sol meuble chimiquement stabilisé et renforcé avec des fibres de polypropylène en comparant les résultats des essais de résistance à la compression non confinée (UCS) et de résistance à la traction par flexion (STS) réalisés avant et après une étape de chargement cyclique. Le travail en laboratoire est basé sur les tests suivants: i) essai monotone de l'UCS et de la STS (valeurs de référence); ii) essais cycliques de l'UCS et de la STS; et iii) essais monotones de l'UCS et de la STS réalisés après l'étape de chargement cyclique (UCSpc et STSpc). Les résultats montrent que les déformations permanentes augmentent brusquement au début de la phase cyclique, suivies d'une diminution du taux de déformation pour les échantillons non renforcés et renforcés de fibres. En ce qui concerne le niveau de contrainte et l'amplitude de la charge cyclique, pour des niveaux de contrainte et d'amplitudes allant jusqu'à 50% de la résistance/charge maximale, les échantillons présentent des déformations permanentes plus faibles mais deviennent plus résistants et plus rigides que les valeurs de référence (essais monotones). Ces observations sont valables pour les matériaux stabilisés, qu'ils soient renforcés de fibres ou non.

Keywords: Ground improvement; unconfined compressive strength; split tensile strength; monotonic and cyclic loading; stabilisation of soft soils.

1 INTRODUCTION

When infrastructures such as bridge foundations or embankments are built on soft soil deposits, these soils tend to exhibit deformation over long periods due to consolidation and creep phenomena. Such behaviour of soft soils is a consequence of their weak geotechnical characteristics (low strength and

excessive deformability) fundamentally due to the high-water content, high specific surface of the particles (clays, silts) and high organic matter (OM) content. Therefore, it is essential to ensure stability and to control/minimise the deformations during the construction stage and structure life (Kitazume and Terashi, 2013). It is important to mention that in the past construction on soft soil deposits was avoided (Venda Oliveira et al., 2018) due to the above-mentioned stability and deformation problems. However, due to the population growth, development of societies and expansion of urban and industrial areas, the pressure to build on these soft soils has increased, which poses challenges in terms of geotechnical engineering. There are two main geotechnical solutions to solve these types of problems: add reinforcement elements to the ground, or improve the soil's properties by mechanical, physical or chemical methods (Kitazume & Terashi, 2013). The presence of the fibres attenuates the brittle behaviour of the composite material, and improves its tensile strength (Sukontasukkul and Jamsawang, 2012; Correia et al., 2015). The field of application of this technique is vast, for example: embankments on soft soils, stabilisation of slopes, stabilisation of contaminated soils, mitigation of vibrations induced by high-speed trains, retaining walls, etc. (Correia, 2011; Kitazume and Terashi, 2013). Some geotechnical structures are often subjected to cyclical loadings induced by different types of actions, such as wind, earthquakes, traffic loads, heavy machinery, sea waves on offshore structures and even vibrations due to explosives. It is very important to assess the repercussions of cyclical loadings on the mechanical behaviour of chemically stabilised, fibre-reinforced soft soils (Venda Oliveira et al., 2018). Despite the research to date, the impact of the cyclic loading stress level and the amplitude on the compressive strength and tensile behaviour of a stabilized soft soil reinforced with fibres has not been properly studied.

The main goal of this research is to analyze the effect of the cyclic loading in stress level and amplitude on the compressive and tensile and post-cyclic behaviour of a stabilized soft soil, unreinforced and reinforced with polypropylene fibres. The permanents strains or displacement developed during the cyclic stage and the stress-strain, and the load-displacement curves will be used to assess the effect of the parameters studies on the cyclic loading in both materials. To achieve such goals, the following experimental testing program was designed: (i) monotonic unconfined compressive strength (UCS) splitting tensile strength (STS) tests performed with samples not subjected to cyclic loading; (ii) cyclic (Cyc) UCS - STS tests; (iii) and post-cyclic UCS and STS tests (UCSpc - STSpc). Table 1 summarizes the experimental testing plan.

2 MATERIALS

This study was carried out using a Portuguese soft soil, from the "Baixo Mondego" area, located in the centre of Portugal near the Mondego river, which has been characterised by many researchers (Coelho, 2000; Correia, 2011; Teles et al., 2014). The soil deposit was formed more than 20.000 years ago in a fluviomarine depositional environment and shows a thickness higher than 20 metres. On this work it was used a sample that was collected at a depth of 2.5 meters. Table 2 summarizes the main physical and chemical properties. It may be seen that the soil has a largely silty grain size distribution (71%) a low unit weight (14.6 kN/m^3), a high void ratio (> 2.0), a high natural water content (80.6%) and a higher organic matter (OM) content (9.3%). Also, those results have a high influence in the mechanical behaviour, inducing a low undrained shear strength ($c_u \approx 25$ kPa) and a high compressibility (Coelho, 2000). This clayey-silt organic soil with high plasticity was classified as OH (ASTM D2487). The chemical composition of the soil shows a high silica content (SiO_2=62%) and an alumina (Al_2O_3) content of 16%, which conferred pozzolanic properties to the soil.

The soft soil was stabilised with a Portuguese Portland cement binder (Portland cement Type I 42.5 R, produced by CIMPOR), which main chemical characteristics are presented in Table 3. Portland cement reacts immediately with water producing a high quantity of reaction products in the short terms; with time, the physico-chemical reactions (pozzolanic reactions) develop at a lower rate, helping the production of more cementitious products responsible for the enhancement of the mechanical properties of the stabilised soil.

The polypropylene fibres used in this study are 12 mm in length, 32 mm in diameter and exhibit a great flexibility, a high specific surface (134 m^2/kg), a density of 905 kg/m^3, a tensile strength of 250 N/mm^2 and a Young's modulus of 3500 - 3900 N/mm^2 (in accordance with the product datasheet supplied by the manufacturer BEKAERT).

3 SAMPLE PREPARATION AND TESTING

The procedures and methodologies described below are based on the recommendations from EuroSoilStab (2001) and Correia (2011), though with slight differences. First, the soil was manually mixed to obtain a uniform paste. Then, a specified amount of cement (250 kg/m^3) was mixed with the required volume of water to increase the natural soil's water content from 80.67% to 115%. This paste was then mixed with the natural soil using a mechanical mixer at 142 rpm for 4 minutes. The soil-cement-water mixture was layered into cylindrical PVC molds (37 mm in diameter and 78 mm in height). After introducing each layer, the mold was lightly tapped by hand (20 times), and then it was lightly scarified before the next layer was added (each sample was divided into three equal layers). The samples were cured for 28 days in a controlled environment with a temperature of 20 ± 2 °C and humidity of 95 ± 5%. Subsequently, the samples were carefully removed from the PVC molds. Both surfaces were accurately ground to maintain parallelism, resulting in specimens measuring 37 mm in diameter and 76 mm in height. The remaining material was used to determine the moisture content of each sample. The specimens were then placed in the compression machine, and electronic devices (load cell and displacement transducer) were configured and adjusted. Unconfined compression strength (UCS) tests were conducted at a constant strain rate of 1% per minute (BS 1377-7, 1990). Cyclic loading tests were performed at 5.000 cycles, varying deviatoric stress level from 10%, 25%, and 70% ($0.50\times q_{u\text{-}max}$), with sinusoidal excitation at 0.5 Hz and an varying amplitude of ±5, ±10, ±20 ($\pm\ 0.10\times q_{u\text{-}max}$). After the cyclic stage, a monotonic UCS test (UCSpc) was carried out. To ensure the reliability of the procedure used, the tests were repeated at least twice.

4 ANALYSIS OF THE RESULTS

4.1 Effect of cyclic loading stress level

In Table 4, will be show the results of permanent strain resulted from the cyclic loading stress and the postcyclic test, strength parameters ($q_{u\ max}$, and strain). Is observed that concerning a higher stress level the strength starting to lose and the sample became fragile. On the case of the reinforced with fibres samples, the results show an improve of the behaviour on 50% of $q_{u\ max}$ of the level of stress. On the other side, is affected to higher stress level, taking the samples more brittle and losing strength.

In contrast, the split tensile test, STS and post cyclic stage and (STSpc), the higher forces applied, the sample became fragile however with less strength. In the case of reinforced occurs similarity effects (Table 5).

Table 4. STS test – effect of level of cyclic loading stress level.

In Figure 1 and 2 shown a pronounced increase in permanent axial strain on samples but is more showed in samples reinforced with PP fibres. This shown that the structural matrix of the soft soil became more affected by the cyclic loading when they have more force/strength applied due the mobilization of fibres inside of the solid skeleton of the sample.

The results suggest that applying different levels of stress leads to an increase in the strength and load-bearing capacity of the fiber-reinforced material when compared to the standard monotonic tests. However, it's worth noting that for higher stress levels, there is a decrease in strength and load-bearing capacity.

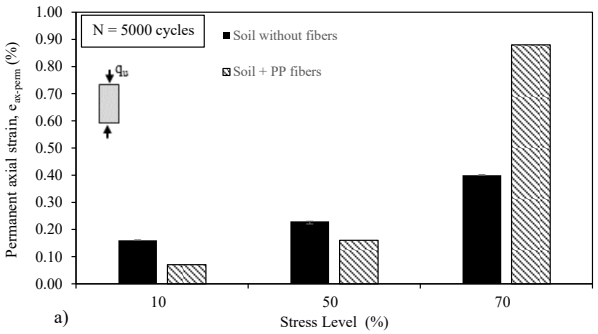

Figure 1. Effect of cyclic loading stress level on UCS_{pc} tests.

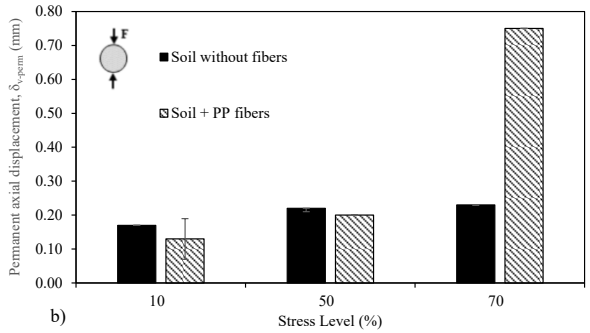

Figure 2. Evolution of permanent axial strain during the cyclic stage with cyclic loading stress level for STS_{pc} test.

These results seem to imply that, during the cyclic stage, the tensile strength of the fibres couldn't fully compensate for the deterioration of the cementitious matrix caused by the cyclic stage. Additionally, the presence of fibres impedes the development of certain cementitious bonds, leading to a loss in unconfined compressive strength and stiffness. Comparing unreinforced and reinforced samples, it becomes evident that permanent deformation is similar in both cases for stress amplitudes ranging from 5% to 10%. However, for a 20% stress amplitude, the reinforced samples subjected to UCS tests exhibit lower permanent deformation. This suggests that as material deformation increases, the fibres progressively engage, helping to reduce permanent axial strain (UCScyc tests) compared to their unreinforced counterparts.

4.2 Effect of cyclic loading amplitude

In case of the effect of cyclic loading amplitude, the results shown similar behaviour in contrast with stress level. Comparing unreinforced and reinforced samples, it becomes evident that permanent deformation is similar in both cases for stress amplitudes ranging from 5% to 10%. However, for a 20% stress amplitude, the reinforced samples subjected to UCS tests exhibit lower permanent

deformation. This suggests that as material deformation increases, the fibres progressively engage, helping to reduce permanent axial strain (UCScyc tests) compared to their unreinforced counterparts. Tables 6 and 7, as well as Figures 3 and 4, provide a summary of the results obtained during post-cyclic UCS and STS tests immediately after altering the cyclic stage's stress amplitude for the stabilized samples reinforced with polypropylene fibres. These results demonstrate an increase in the strength and load-bearing capacity of the stabilized fiber-reinforced material in comparison to the reference monotonic tests, albeit with a reduction as stress amplitude increases, which is linked to greater degradation of the cementitious matrix during the cyclic stage.

Table 6. UCS test – effect of cyclic loading amplitude.

5 CONCLUSIONS

From the monotonic UCS and STS tests performed before cyclic loading (references values) and after cyclic loading stage (UCSpc and STSpc) for the stabilized soil reinforced with fibres and not reinforced are drawn:

a. As other works shown that could be observed that the permanent strains show a sharp increase at the beginning of the cyclic stage followed by a decrease in the strain rate for unreinforced and fibre-reinforced samples. In this work results are not shown, mainly for the highly effect on the detriment of the cementitios matrix due the load/stress applied above 50% of the $q_{u\text{-}max}$.

b. Addition of fibres promotes a reduction in the permanent axial strains for the UCS cyclic tests, the opposite effect could be observed for the STS cyclic tests, explained by the different failure mechanisms associated with each test.

c. Up to stress levels and amplitudes of 50% of the maximum strength/load, the samples display reduced permanent deformations and also demonstrate increased strength and stiffness when compared to the reference values from the monotonic tests. These findings hold true for both stabilized materials, whether they are unreinforced or fiber reinforced.

ACKNOWLEDGEMENTS

Parametric study of stability in landfills due to changes in waste composition

Etude paramétriqueet de la stabilité dans les décharges dues aux changements dans la composition des déchets

ABSTRACT: The modern trend in waste management in most developed countries in Europe and the world is based on waste reduction, reuse and recycling, while landfilling is considered the least desirable method in the waste management process. Despite this trend, landfilling is still the leading method of waste disposal in most countries. Considering the increasing amount of waste, even if all methods to reduce the amount of waste are used, there will still be a need to build a landfill. Waste is a heterogeneous material whose physical, mechanical and chemical properties are highly dependent on the composition of the waste, so even minor changes in composition can affect the change in these properties. In Croatia, in the process of approaching European Union standards, the composition of disposed waste has changed significantly, primarily due to the fact that biowaste, plastic waste and paper are increasingly separated from total municipal waste. The separation of these constituents significantly affects the density, moisture and granulometric composition of the deposited waste, which in turn affects the stability and deformations of the landfill body itself, as well as the stability of the protective layer system. In this work, the effects of changes in the physical and mechanical parameters of the landfilled municipal waste on the stability of the landfill body were analyzed.

RÉSUMÉ: La tendance moderne en matière de gestion des déchets dans la plupart des pays développés d'Europe et du monde est basée sur la réduction, la réutilisation et le recyclage des déchets, tandis que la mise en décharge est considérée comme la méthode la moins souhaitable dans le processus de gestion des déchets. Malgré cette tendance, la mise en décharge reste la principale méthode d'élimination des déchets dans la plupart des pays. Compte tenu de la quantité croissante de déchets, même si toutes les méthodes visant à réduire la quantité de déchets sont utilisées, il sera toujours nécessaire de construire une décharge. Les déchets sont des matériaux hétérogènes dont les propriétés physiques, mécaniques et chimiques dépendent fortement de leur composition, de sorte que même des changements mineurs dans leur composition peuvent affecter l'évolution de ces propriétés. En Croatie, en voie de se rapprocher des normes de l'Union européenne, la composition des déchets éliminés a considérablement changé, principalement en raison du fait que les biodéchets, les déchets plastiques et le papier sont de plus en plus séparés des déchets municipaux totaux. La séparation de ces constituants affecte de manière significative la densité, l'humidité et la composition granulométrique des déchets déposés, ce qui à son tour affecte la stabilité et les déformations du corps de décharge lui-même, ainsi que la stabilité du système de couches protectrices. Dans ce travail, les effets des changements dans les paramètres physiques et mécaniques des déchets municipaux mis en décharge sur la stabilité du corps de la décharge ont été analysés.

Keywords: Landfill; MSW; kitchen waste; stability.

1 INTRODUCTION

Municipal solid waste (MSW) landfills are still a necessary part of the MSW management system although the current, modern waste management, requires minimization of the amount of mixed waste which is to be disposed at landfills (Puntarić et al., 2023). The 3R principle (*reduce, reuse, recycle*), and especially the intensive separate collection of waste, will certainly reduce the quantities of waste ending up at the landfill thus affecting the characteristics and properties of the disposed waste which will in turn affect the stability of landfill (Gomes et al., 2013; Singh & Uchimura, 2023). There is an open question: if the large, old landfill which is being filled for a couple of decades with the mixed MSW, starts receiving different waste material, with less glass, plastics, metals, and biodegradables, what will change considering geomechanical properties of the disposed material and the stability of the landfill? To answer that question, it is necessary to quantify the reduction of certain waste components and either measure or assess changes in the properties of waste.

Construction of Prudinec, the MSW landfill for the city of Zagreb, Croatia, begun in 1995 with the preparation of the new disposal surface and the construction of the bottom protective layer system (BPLS), on which a part of the old waste was transferred from an insanitary dumpsite in the immediate vicinity, as well as the newly collected waste (Budiša et al., 2014). A mixture of old and fresh waste was disposed of on the new prepared location, until 2003 when the disposal of only fresh MSW begun (Budiša et al., 2014). Separate waste collection in the city of Zagreb begun in 2002 (Fundurulja, 2009) and in the period 2002-2018 there was gradual increase of the separate waste collection of plastics, metals, glass, paper, and textile. According to the Companies Act (City of Zagreb, 2018) from the January 30th 2018, separate collection of the mixed plastic and metal waste. On September 23rd 2022 a decision was made by the Zagreb Holding, company which was incorporated in 2007 in line with the Companies Act and is 100% owned by the City of Zagreb, according to which mixed MSW must be collected in "blue bags" whose purchase price is 1,06€/40 l (Zagreb Holding, 2022). Therefore, since the September of 2022 collected and landfilled mixed MSW has a reduced amount of paper, metal, plastics, and compostable waste.

Changes in the composition of waste by removing compostable materials (unused cooked food is still being collected as a part if the mixed waste), plastic and metal, paper and cardboard, are reflected by changes in cohesion, angle of the internal friction, density, water content and other parameters (Gomes et al., 2013; Singh & Uchimura, 2023). Taking into consideration these changes it can be concluded that the stability of the Prudinec landfill might be changed, and the possible changes and effects are addressed in this paper.

2 THE MSW LANDFILL SITE PRUDINEC

Modern landfills are designed to protect human health and the integrity of the environment by controlling water and air emissions. The engineered protective systems incorporate advanced design features, including multi-layered liner construction, gas extraction and leachate removal systems.

The landfill site Prudinec is located on the southern bank of the Sava River, today, in the City of Zagreb. The decision to open dumpsite was made back in 1964.

The current Prudinec landfill is divided into cells 1 to 6, the area of each cell varies between 6 and 9 ha. The landfill has an almost rectangular shape with a length of approx. 1400 m and a width of approx. 450 m.

2.1 Landfill protective layers

An approx. 8 m high berm construction were erected at the foot of the deposited waste. The BPLS consists of 1 m thick clay layer and a 2.5 mm thick geomembrane as a barrier layers, above which a protective geotextile, a 0.5 m thick drainage layer for leachate collection and a filter geotextile are placed. The clay protective layer consists of highly plastic clay (Vukelic et al. 2004).

The final protective layer system of the landfill consists of gas drain composite, GCL and geomembrane, water drainage composite for the drainage of precipitation water, 0.85 m thick protective soil layer and 0.15 m thick humus layer. The membrane is only used in the upper part of the landfill, on the slopes only GCL is used as a barrier layer.

2.2 Historical instabilities of landfill site Prudinec

Slope stability analyses of municipal solid waste landfills are important to determine a safe landfill height and slopes inclination.

In August 2002, a localised landslide of the mentioned landfill was observed on the south side of landfill at the contact between the cover protection layer and the berm. The estimated affected area of the landslide was approximately 50 m long and 140 m wide. It had spread an estimated 100,000 m^3 of waste.

The field investigations carried out showed that the waste deposited in the area of the landslide did not differ in content and characteristics from the waste deposited elsewhere in the landfill. These were large quantities of old inert waste consisting of deposited municipal waste, soil and construction waste. As part of a field investigation, the leachate height was measured at the top of the bottom barrier layer in wells. The height of the leachate varied from 0.7 m to 11.5 m (Vukelic et al. 2004). In determining the cause of the landslide, other factors were also taken into account, such as the composition and properties of the protective layers and waste, the contacts of the layers and the performance and construction control of the landfill design.

The planning of a MSW landfill requires an appropriate characterization of the mechanical properties of the waste it contains. This is often very difficult due to the heterogeneity and highly variable composition of the waste. However, this is necessary to accurately assess the slope stability of the landfill and the interaction of the waste with other landfill

structures such as liners and gas and leachate collection systems (Gomes et al. 2013).

2.3 The impact of waste composition on landfill stability

In addition to the geometry, parameters such as compaction effort, pore pressure, protective layers, etc., the stability of the landfill is significantly influenced by the composition of the waste. Therefore, knowledge of the waste composition is generally one of the most valuable factors for estimating the properties of municipal waste (Cho et al. 2011; Jahanfar et al. 2017).

The changes that have occurred in recent years because of the introduction of a new waste separation and disposal policy can be seen, among other indicators, primarily in changes in waste parameters, unit weight, cohesion, and the friction angle. These changes certainly have an impact on the stability of the landfill slope. Based on these assumptions, an analysis of the effects of the change in strength parameters on the stability of the landfill slope and the safety factor was carried out.

The quantity of individual components such as paper, glass, plastic and biowaste previously made up a large proportion of municipal waste. Between 2002 and 2018, this composition gradually changed and is now significantly different. According to this trend, it is assumed that since the end of 2022 the proportion of plastic, paper, glass and metal has largely decreased and therefore the largest proportion of the total composition of municipal waste is kitchen waste. For this reason, it is assumed that the geotechnical parameters of the waste have also changed as a result of this change, which has an impact on the stability of the landfill.

For the numerical analysis of stability, it was necessary to collect data for the protective soil layers and the waste at the landfill. Certain materials in MSW are continuously degraded over time by various chemical and biological processes, while the properties of some materials do not change (Štefanák and Chalmovský 2022; Machado et al., 2002). For this reason, it was necessary to use parameters corresponding to a specific composition of the waste.

3 NUMERICAL MODEL

For the slope stability analysis of the landfill, a model with dimensions of 306 m width and 77 m height was created. The geometry of the landfill is simplified and consists of a subsoil, protective layer, drainage layer, dyke on the edge of the waste layer and the waste layer. The slope stability analysis of the model was carried out using Plaxis and soil and waste material were modelled using the Mohr-Coulomb model. The analysis was carried out for three proportions of kitchen waste in municipal waste, in percentages of 10%, 30% and 60%. The input parameters for waste were obtained from previous experimental studies (Cho et al. 2011; Ivšić et al. 2004). The material properties of the soil layers were taken from studies describing the Prudinec landfill (Kovačević Zelic et al. 2002, Vukelic et al. 2004). Geotechnical parameters are presented in Table 1.

Table 1. Geotechnical parameters.

Parameter	Unit weight (kN/m^3)	Friction angle (°)	Cohesion (kN/m^2)
Subsoil	18	32	10
Drainage layer	18	30	0,3
Sealing layer	19	21	24
Dyke	19	24	15
Kitchen waste 10%	8	33	5
Kitchen waste 30%	9	26	6
Kitchen waste 60%	10	17	7

3.1 Results of numerical analysis

The numerical analysis was performed for different percentages of kitchen waste in the waste composition. Three cases were modelled with 10%, 30% and 60% of kitchen waste in the composition of municipal waste (Figure 1).

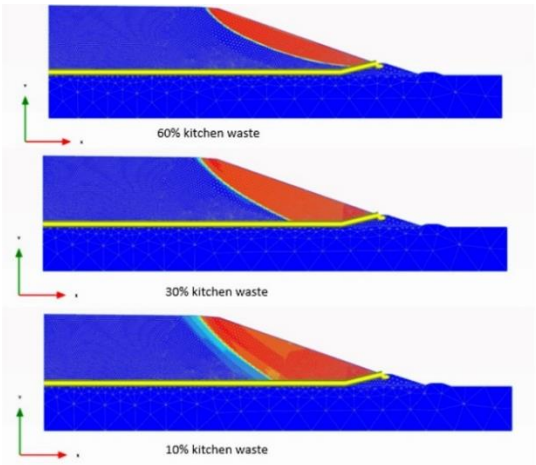

Figure 1. Failure planes for different amount of kitchen waste – 10%, 30% and 60%.

The results of the numerical analysis show that as the proportion of kitchen waste increases, the safety factor decreases and the slip surface is shallower (Figure 2).

For waste with a low proportion of kitchen waste, the contact layers in the lower sealing layer have the greater influence and the sliding surface runs largely

through the contact of these layers. For waste with a low proportion of kitchen waste, the contact layers in the lower sealing layer have the greater influence and the sliding surface runs largely through the contact of these layers. For waste with a higher proportion of kitchen waste, the probability of a sliding surface forming in the landfill body itself is higher.

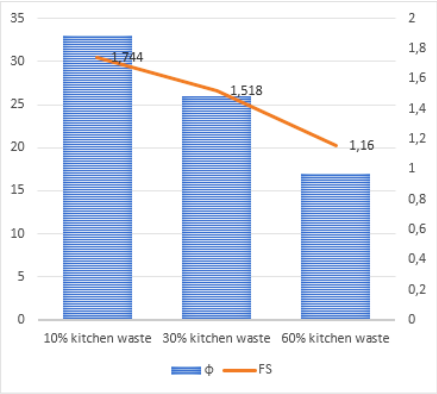

Figure 2. Change of the factor of safety with the change in the proportion of kitchen waste and friction angle of waste.

4 CONCLUSIONS

The stability of the landfill depends largely on the mechanical properties of the waste and the protective layer system. In contrast to the material parameters of the protective layers, the waste parameters change considerably over the years, not only due to the aging of the waste, but also due to changes in the composition of the deposited waste. Due to frequent changes in the waste management policy, the composition of the waste has changed significantly during the operational life of the Prudinec landfill. The composition of waste with the largest proportion of paper and plastics has now been replaced by waste with the largest proportion of kitchen waste. These changes mainly affected the reduction of the friction angle and, to a lesser extent, the reduction of cohesion. The results of the numerical analysis show that such a change has a significant effect on the reduction of the safety factor and the stability of the landfill. It can be concluded that the selection of relevant waste parameters and protective layer system is very important when assessing the overall safety of a landfill.

During the writing of this article, two landslides occurred at the Prudinec landfill. The first smaller one occurred in mid-November 2023 after a short but very intense period of rainfall. According to initial estimates, the area affected by this landslide was around 100 metres wide and 30 metres high. The second occurred in early December 2023 in the early morning when the air temperature was around -5 °C.

This landslide affected a significant part of the eastern side of landfill.

Critical state behaviour of anthropogenic clay in a direct simple shear test

Comportement à l'état critique d'argile anthropogénique dans un essai de cisaillement simple direct

ABSTRACT: In practical engineering the direct simple shear, DSS, tests are a valuable tool for parameter assessment, despite its known shortcomings. The shear stress mobilised at the end of the test is often used as a proxy for critical state strength. Several aspects complicate conducting reliable tests at large strain, in specific for clay samples. One of these effects is slippage between the sample and the platens. When slippage occurs, the measured resistance follows from the interface properties rather than soil behaviour. To better understand the critical state behaviour of clays during a DSS tests a test series is conducted on an anthropogenic stiff silty clay. The test series not only demonstrates that critical state conditions are reached before the end of the tests, but also that slippage tends to occur after reaching critical state conditions. Complimentary series of direct shear, DS, tests were conducted to further confirm critical state conditions are obtained. This confirms the applicability of DSS tests to obtain a soil specific proxy for critical state conditions without the influence of slippage. Hence, the presented method to derive critical state strengths from DSS tests, for anthropogenic clay, and thereby discarding the influence of slippage provides useful and reliable strength parameters for design.

RÉSUMÉ: En ingénierie pratique, les essais de cisaillement simple direct (DSS) sont un outil précieux pour l'évaluation des paramètres, malgré leurs limitations connues. La contrainte de cisaillement mobilisée à la fin de l'essai est souvent utilisée comme un indicateur de la résistance à l'état critique. Plusieurs aspects compliquent la réalisation de tests fiables à grande déformation. L'un de ces effets est le glissement entre l'échantillon et les plateaux. Lorsque le glissement se produit, la résistance mesurée dépend des propriétés de l'interface plutôt que du comportement du sol. Afin de mieux comprendre le comportement à grande déformation des argiles dans des conditions de DSS, une série de tests est réalisée sur une argile limoneuse anthropogénique rigide. Cette série de tests montre non seulement que les conditions d'état critique sont atteintes avant la fin des tests, mais aussi que le glissement a tendance à se produire après avoir atteint les conditions d'état critique. Une série complémentaire de tests de cisaillement direct (DS) est réalisée pour confirmer davantage l'obtention des conditions d'état critique. Cela confirme l'applicabilité des essais OC DSS sur les argiles anthropogéniques dans la conception des digues, à condition qu'un indicateur spécifique au sol pour les conditions d'état critique ait été déterminé à partir de tests en laboratoire, plutôt que la résistance à la fin de l'essai.

Keywords: Direct simple shear testing; anthropogenic clay; shear strength; slippage; laboratory testing.

1 INTRODUCTION

Parameter assessment using DSS testing is hampered by the unclear stress state of the sample (DeGroot et al., 1992). However, it is considered the best method to represent shearing conditions along a potential failure surface (Grimstad et al., 2012) especially in soft clays with anisotropic stress-strain-strength behaviour. DSS tests involve the rotation of principal stresses during the test making it suitable to study the rotation of principal stress directions beneath an embankment which leads to varying shear strength at different locations. This study explores the derivation of critical state behaviour during DSS testing, which is crucial for obtaining a reliable parameter assesment.

Critical state conditions are typically reached at large deformations, and the mobilized strength at the end of the test is often used as a proxy for critical state strength (Leroueil et al., 1990). However, large strains in DSS tests can induce anomalies like slip planes and slip between the sample and plates, making it challenging to determine model parameters for constitutive models in practical engineering applications.

In a typical DSS test the stack of rings is sheared uniformly. Figure 1 shows an example where slip between the sample and bottom plate has occurred. Three separate zones can be distinguished: i) at the top platen, ii) in the middle, and iii) at the bottom platen. The negative influence of the boundaries on the sample in DSS testing is well acknowledged. However, it is assumed that the centre of the sample is sheared in simple shear and governs the overall behaviour (i.e. DeGroot et al., 1992, Den Haan and Grognet, 2014). The deformation pattern depicted in Figure 1 indicates that, at least at the end of the test, the mobilized resistance is influenced by friction between the sample and the bottom plate, which raises questions regarding the validity and application of the test results.

The series of DSS tests that were perfomed to study the critical state behaviour focuses in particular on determining useful critical state strength parameters before slip occurrence, which we hypothesize to be in response to a significant amount of applied strain with critical state behaviour occur before slippage occures.

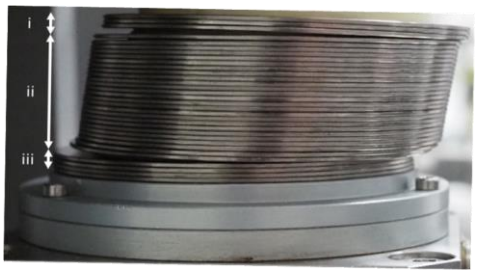

Figure 1. A result at the end of an OC DSS test with slippage.

2 SAMPLE CHARACTERISTICS

The research is performed on undisturbed anthropogenic samples from Ravenstein-Lith along the Meuse river in the Netherlands. The samples were retrieved above the phreatic line and tested at natural water content, γ_n, 22.2 to 42.4%. The dry density of the samples is 1.21-1.60 g/cm^3 with a void ratio of 0.65-1.15. The medium plasticity samples are characterized by a clay (< 2μm) content of 24.3%, a silt (2 < x < 63μm) content of 56.3%, a 17.5% sand (63 < x < 2000μm) content and 1.9% of organic content.

3 APPROACH AND METHODOLOGY

This study used a GDS instruments DSS apparatus with a 2 kPa loadcell with internal and external displacement sensors. Intact clay specimens were trimmed and fitted in between porous stones with distributed conical pins enclosed by a rubber membrane and a stack of low-friction rigid rings providing the lateral confinement but also allowing simple shear to occur. Bjerrum's (1973) recompression technique was used to reconsolidate the samples to the estimated in-situ vertical stress. During the stage of simple shearing a strain rate of 2%/hr was applied. Constant volume tests were conducted under undrained conditions per ASTM D6528-17 (2017) where the change in normal stress was assumed to be equivalent to the change in pore pressure (Dyvik et al., 1987). Corrections for membrane and slide table friction were applied to the horizontal load readings (Greeuw et al., 2016). In addition to DSS tests, DS tests were performed to verify at which strain level critical state conditions are reached using a Wille Geotechnik apparatus under water, following ISO 17892-10 (2018) guidelines, together with an area correction per Bareither et al. (2008).

4 RESULTS

During a DSS test, slippage was observed at the end of the test, occurring after applying some strain to the sample. This slippage along the upper and lower surfaces of the specimen leads to partial transfer of shear force from the platens to the sample, exceeding the mobilized friction at the soil-platen interface. Previous studies by e.g. Le Meil et al. (2016) have shown that using porous platens with protruding pins on cohesive soils can prevent slippage, allowing continued deformation of the specimen even after slippage has initiated. However, Le Meil et al. (2016) suggested that the embedment of protruding pins may create uneven stress concentrations in the boundary zone, as the shear strength undergoes changes when the pins cut through the soil. Consequently, the boundary zone surrounding the central region of the sample, where a simple shear stress state exists, exhibits interrelated slippage and shear. If the protruding pins cut through the soil in the boundary zone, localized softening occurs, and uniform simple shear conditions cannot be maintained due to strain localization.

The tests reveal that observed slip often corresponds to the formation of a distinct sliding plane (Figure 2). A schematic representation of this hypothesized stage is depicted in Figure 3b, where the initiation of a rupture plane occurs after a standard test

onset (Figure 3a). Additionally, Figure 3c illustrates the impact of excluding rings and a membrane during testing, while Figure 3d demonstrates the strain localization that occurs along the bottom and top platens in response to ongoing slippage along the shear plane.

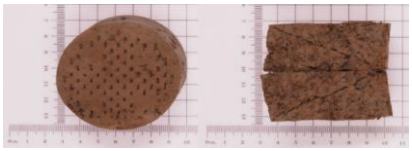

Figure 2. An OC DSS sample which experiences slip and shows a clear internal shear plane.

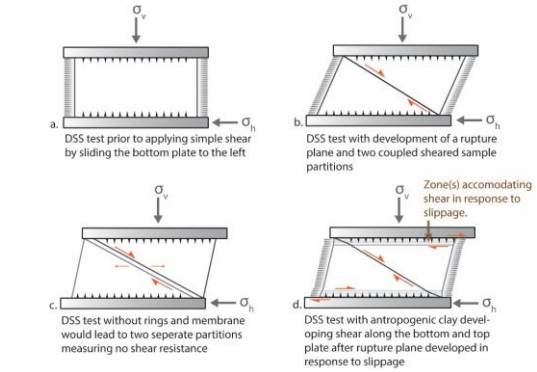

Figure 3. Schematic overview of the different stages of a DSS test result.

4.1 Tests under OC conditions

A total of seven DSS tests were conducted under overconsolidated (OC) conditions at natural water content. The corresponding stress – strain curves and normalised stress paths are shown in Figure 4 and 5 (i). The test results demonstrate unconventional behaviour with certain stress-strain curves exhibiting dips between 5 and 15% shear strain, and some normalised stress paths displaying odd behaviour in the form of a loop. Moreover, upon removing the sample from its set-up, a diagonal shear plane has formed within the sample, and it exhibits signs of slippage (see Figure 2).

In addition to tests at γ_n, five fully saturated tests were conducted (for test results see Figure 4 and 5 (ii)) and these showed, albeit less, still signs of slippage, but not a sign of the formation of shear bands or loop in the normalised stress paths.

4.2 Tests under NC conditions

Three additional normally consolidated (NC) DSS tests were conducted, and the test results align with those typically observed for NC clay (Figure 4 and 5 (iii)). In these tests, no slippage was observed, possibly due to the NC conditions where the vertical stress level surpasses the yield stress (> 100 kPa), resulting in adequate soil-platen interface grip. Moreover, no visual indications of diagonal shear zones were observed.

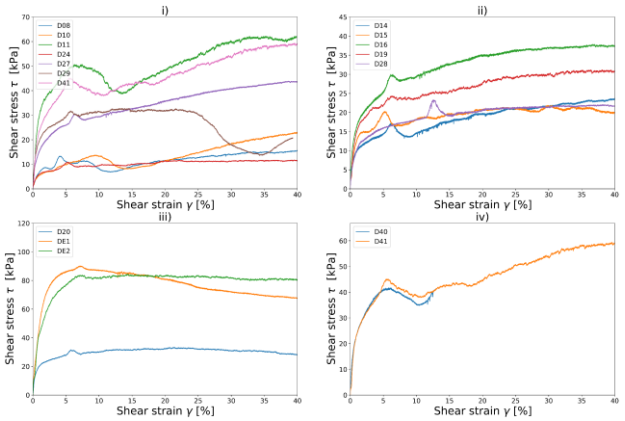

Figure 4. Shear stress - shear strain graphs of DSS tests under OC conditions at γ_n (i) OC conditions fully saturated (ii), NC conditions (iii) and fully developed and pre-maturely stopped DSS test (iv).

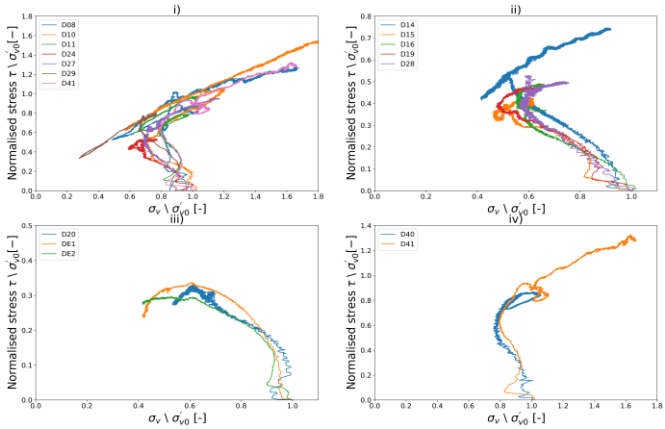

Figure 5. Stress paths of DSS tests under OC conditions at γ_n (i) OC conditions fully saturated (ii), NC conditions (iii) and fully developed and pre-maturely stopped DSS test (iv).

4.3 Direct shear tests

Although DS and DSS test are different, both in terms of failure mechanism and imposed boundary conditions, generally similar results are to be expected if these effects are accounted for (Hanzawa et al., 2007). Eight DS tests were performed which showed a constant mobilised shear stress when reaching 15% shear strain, indicating that critical state conditions have been reached and that critical state strength parameters in DSS tests can be determined earlier than the current proxy for shear strain, γ, of 40%.

4.4 Formation of the diagonal failure plane

During eight DSS tests a time-lapse video has been recorded. Test results showed both signs of slippage and development of a diagonal rupture surface. It is hypothesized that the sample has reached critical state

before slip occurs. To validate this hypothesis, two DSS tests were performed on samples from the same boring with sequential depth and in-situ water content (see Figure 4 and 5 (iv)). The first test (D40) was stopped at $\gamma = 13\%$ strain and the subsequent test (D41) was performed until reaching the prescribed $\gamma = 40\%$.

In sample D40, no signs of slip were observed at $\gamma = 13\%$, but an initiation of a diagonal rupture plane was evident. Sample D41 exhibited both slippage and a fully developed rupture plane, confirming the hypothesis. This suggests that a reliable practical indication of critical state strength can be obtained using DSS tests on an OC sample, provided a soil-specific proxy for critical state conditions is determined. The findings support the hypothesis depicted in Figure 4, showing the reliability of DSS tests until the development of the sliding plane and slightly beyond, offering an indication of critical state strength just prior to slip between the sample and plates. However, test results beyond these strain levels are considered unreliable as they do not reflect the true strength characteristics of the tested soil, but rather include other factors such as membrane strength.

5 CONCLUSIONS

A series of 17 DSS tests was conducted on both NC and OC samples of an anthropogenic clay. Under NC conditions, the tests exhibited textbook behaviour without slippage, as the clay behaved plastically without the formation of discrete failure surfaces. However, under OC field stress conditions, the tests displayed a noticeable dip in the stress-strain curve, corresponding to the development of a diagonal rupture plane. Continued testing revealed slippage between the sample and platens. It was observed that the stresses measured after the formation of the rupture plane no longer represented soil behaviour but were influenced by the membrane and ring stack that forced the parts to move according to the applied displacements from the device. Consequently, in DSS tests on anthropogenic clay, the strength at large strains cannot serve as a proxy for critical state strength, as is typically assumed for NC conditions. However, this research demonstrated that if a soil-specific proxy for critical state conditions is utilized, the results of OC DSS tests can be applied to determine strength parameters for geotechnical design.

ACKNOWLEDGEMENTS

This research was conducted as part of an MSc thesis at TU Delft in collaboration with Arcadis and SOCOTEC Geotechnics.

ABSTRACT: The successful deployment of Offshore Wind Turbines (OWTs) requires fast, low- cost, reliable and environmentally friendly foundation installation methods. Vibratory driving, which is an attractive alternative to impact driving, has recently showed great potential in real-world applications. However, the knowledge about its effects on soil properties, and thus on the response of OWTs during the installation of monopiles is still limited. This study focuses on investigating the soil liquefaction which occurs in the vicinity of the foundation during vibratory monopile driving, in a 1G scale test. The combined approach of a vibratory driven pile in the laboratory, by introducing pertinent scaling laws, and the use of a numerical model to simulate the scale model in the laboratory is adopted. The findings from the numerical model provide insight into liquefaction initiation and progression and highlight the potential and limitations of linear models.

RÉSUMÉ: Le déploiement réussi d'éoliennes offshore (OWT) nécessite des méthodes d'installation de fondations rapides, peu coûteuses, fiables et respectueuses de l'environnement. La conduite vibratoire, qui constitue une alternative intéressante à la conduite par impact, a récemment démontré un grand potentiel dans les applications réelles. Cependant, les connaissances sur ses effets sur les propriétés des sols, et donc sur la réponse des OWT lors de la pose des monopieux, restent limitées. Cette étude se concentre sur l'étude de la liquéfaction du sol qui se produit à proximité de la fondation lors du battage vibratoire d'un monopieu, dans le cadre d'un essai à l'échelle 1G. L'approche combinée d'un pieu battu vibratoire en laboratoire, en introduisant des lois d'échelle pertinentes, et l'utilisation d'un modèle numérique pour simuler le modèle réduit en laboratoire est adoptée. Les résultats du modèle numérique donnent un aperçu de l'initiation et de la progression de la liquéfaction et mettent en évidence le potentiel et les limites des modèles linéaires.

Keywords: Monopile foundation; soil liquefaction; vibratory driving.

1 INTRODUCTION

Offshore wind power is a key component in the transition towards a more sustainable energy future. Despite the effectiveness of the predominantly used impact hammering for monopile installation, it poses challenges like noise pollution and concerns over pile durability, which makes vibratory driving an interesting alternative. Vibratory driving uses a high-frequency vibrator that transmits vertical vibrations to the monopile. These vibrations can increase the pore pressures in the vicinity of the driven foundation, resulting in reduction in the inter-particle soil friction, and thus, a decrease in effective stresses, which can lead to liquefaction. While vibratory driving offers a fast, environmentally friendly alternative, there is insufficient knowledge regarding its effects on the evolution of the mechanical properties of the soil, which control the (long-term) response of the OWT systems. In this regard, there has been an increasing interest in studying the development of liquefaction

during the installation process (Chrisopoulos et al. 2019; Esfeh and Kaynia 2019). Most efforts use non-linear models, while the application of simpler linear model is limited (Zhang et al. 2012).

This study is structured to present first a scaled 1g test in the laboratory followed by the linear numerical model used to calculate the force imposed on the pile and hence the soil-pile response to the applied force. Then, the model's ability to simulate pore water pressure development corresponding to liquefaction is assessed. Finally, conclusions from the study are presented.

2 PHYSICAL MODELING

The laboratory setup employed is based on the system initially developed by Holeyman et al. (Holeyman 2017; Jafari 2020) and is modified to meet our research needs. The current set up consists of a drop weight (ram) which is attached to a rope and a pulley system, and an anvil. The pile is kept in position using a centring rod and lateral supports. The pile is a hollow steel cylinder of external diameter D = 6 cm, length L = 50 cm and wall thickness t = 6 mm. The pile is driven in a saturated homogeneous sand of unit weight γsat =1920 kg/m^3, and relative density Dr = 68% that is representative of the densities of the soils met in the North Sea. The sand is placed in a steel container of inner diameter D_{box} = 110 cm, inner height H_{box} = 125 cm and thickness t_{box} = 2 mm. The relative density of sand is controlled using a sand pluviation system which allowed relatively homogeneous sand samples to be generated. The acceleration and hence the force imposed on the pile is measured using a 10000g accelerometer. Scaling laws required for down-scaling the applied force by a vibrohammer are adopted as explained byMazutti et al (Hein Mazutti et al. 2022) which designed a mini-vibro hammer for centrifuge testing. However, since we are considering a 1g test,the forces are scaled by a factor of 1/N^2.

3 VIBRATORY DRIVING MODEL

Herein a sub-structure approach is adopted: (i) the pile-soil system (pile and sandbox) is modeled using an axisymmetric finite element (FE) model to provide the pile head stiffness; and (ii) the calculated pile head stiffness is implemented in the Hybervib analytical model (Holeyman and Whenham 2017) to obtain the dynamic force imposed by the vibratory hammer. The force is then applied on the pile head using the FE model to conduct the drivability analysis. Within the framework of the analytical model, the harmonic force exerted by a vibro-hammer F_r working at frequency ω is defined as the mass of the eccentric masses *me*, multiplied by their corresponding acceleration.

$$F_r = me\omega^2 \sin(\omega t) \quad (1)$$

However, this model is extended to account for the displacement of the vibratory block m_b that constantly moves during the driving process. This is achieved by defining the total displacement of the system u_m as the relative displacement of the rotating masses u_r and the displacement of the block u_b:

$$u = u_r + u_b = e \sin \omega t + u_b \quad (2)$$

The different elements of the model are shown in Figure 1 in which the rigid pile is represented by its dynamic stiffness k^*.

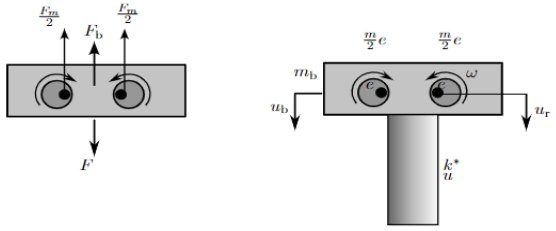

Figure 1. Schematic representation of the different elements of the vibratory driving model.

Hence, the total force exerted by a vibrohammer F is the summation of the force F_r and the force by the block F_b, which is defined as the product of the mass m_b and its acceleration $\ddot{u}_b$.

$$F = F_r + F_b \quad (3)$$

And in the frequency domain is,

$$k^*\hat{u} = me\omega^2 + m_b\omega^2 \quad (4)$$

where $\hat{u}$ is the pile head displacement at in the frequency domain, which is function of the dynamic stiffness of the rigid pile. Hence, this is computed initially and then followed by solving the system of equations of motion of the rigid system to compute the displacement.

The numerical implementation is done in MATLAB using the toolbox Stabil (François et al. 2021). The pile and the soil, which reflect on the setup, have been discretized using 2-noded line elements and 4-noded quadrilateral elements, respectively. The mesh size has been determined based on a 10-elements-per-wavelength rule.

Figure 2 shows the wave propagation in the sand box for a selected amplitude of the applied force at a

frequency equal to 1000 Hz which is representative of real scale driving at 25 Hz, using the proposed FE model. As shown in the figure, Rayleigh waves at the surface lose energy and attenuate with distance. Surface waves (C_s = 140 m/s) along the depth of the pile continue to propagate horizontally with a wavelength big enough to be fully captured in the system. P-waves, which travel at a faster speed (C_p = 280 m/s), are seen as a standing wave in the pile and propagate in radial direction below the pile. In order to mitigate reflections at the edge of the box, a 2 cm thick damping layer from rubber material is proposed whose effect is shown in figure 2.

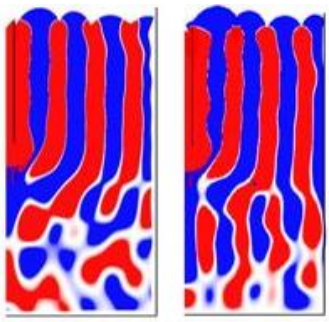

Figure 2. Animated representation of the wave propagation in the axisymmetric sand box model with a damping layer (left) and without a damping layer (right) at 1000 Hz.

4 LIQUEFACTION POTENTIAL

To evaluate the potential for liquefaction, the scheme described in (Seed 1971 and Towhata et al. 2008) is adopted. The strains within the soil are determined from the nodal displacements, leveraging the use of finely discretised transfinite mesh elements. The stress-strain relationship of the soil adheres to Hooke's law allowing us to employ a material stiffness matrix **D** that relates stresses **σ** to strains **ε** in the axisymmetric finite element model using the soil's modulus of elasticity E, and Poisson's ratio, ν:

$$\begin{Bmatrix} \hat{\sigma}_{rr} \\ \hat{\sigma}_{\theta\theta} \\ \hat{\sigma}_{zz} \\ \hat{\tau}_{rz} \end{Bmatrix} = \begin{bmatrix} 1-\nu & \nu & 0 & 0 \\ \nu & 1-\nu & 0 & 0 \\ 0 & 0 & 1-\nu & 0 \\ 0 & 0 & 0 & 0.5-\nu \end{bmatrix} \frac{E}{(1+\nu)(1-2\nu)} \begin{Bmatrix} \epsilon_{rr} \\ \hat{\epsilon}_{\theta\theta} \\ \hat{\epsilon}_{zz} \\ \hat{\epsilon}_{rz} \end{Bmatrix} \quad (5)$$

The stresses (all in kPa) obtained in the radial $\hat{\sigma}_{rr}$, circumferential $\hat{\sigma}_{\theta\theta}$ and the longitudinal directions $\hat{\sigma}_{zz}$ are used to calculate the maximum cyclic deviatoric stress exerted on the soil element, $\hat{q}$ where:

$$\hat{q} = \tau_{cyc} = \sqrt{3\hat{J}_2} \quad (6)$$

and

$$\hat{J}_2 = \frac{1}{6}[(\sigma_{rr} - \sigma_{\theta\theta})^2 + (\sigma_{\theta\theta} - \sigma_{zz})^2 + (\sigma_{zz} - \sigma_{rr})^2 + \sigma_{rz}^2] \quad (7)$$

This shear stress is then utilized to compute the Cyclic Stress Ratio (CSR), which is defined as the ratio between the shear stress and the effective vertical stress σ'$_v$:

$$CSR = \frac{\tau_{cyc}}{\sigma_v'} \quad (8)$$

Subsequently, the relative excess pore pressure r_u, which is equal to the ratio between excess pore pressure Δu and initial effective vertical stress σ_v' is employed as described by (Seed and Rahman 1978, Meijers 2007).

$$r_u = \frac{\Delta u}{\sigma_v'} = \frac{2}{\pi} \arcsin\left(\frac{N}{N_{liq}}\right)^{\frac{1}{2\theta}} \quad (9)$$

In which N is the applied number of cycles, equivalent to the frequency, N_{liq} is the required number of cycles to cause liquefaction and the empiral parameter θ = 0.7 is chosen (Seed and Rahman 1978, Meijers 2007). N_{liq} is calculated from the relationship proposed by (Rahman and Jaber 1986).

$$CSR = 0.44aN_{liq}^{-b} \quad (10)$$

in which b = 0.2 and a=0.44.

Figure 3 illustrates the results obtained employing an in terms of deviatoric stress q, critical stress ratio (CSR), and relative excess pore pressure, the latter being essential for computing the excess pore water pressure induced during the pile driving process. An eccentric moment of $1.2\text{x}10^{-3}$ kg.m is employed which demonstrates both the impact and the necessity for a minimal mass. These findings show stress concentration beneath the pile while driving in addition to stress generation due to surface waves. The results also underscore the potential for soil around the pile, rather than within it, to experience liquefaction.

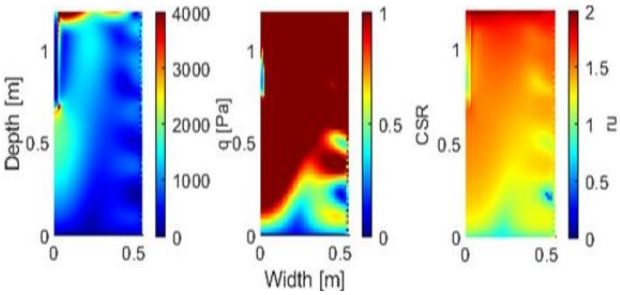

Figure 3. Variation of cyclic deviatoric stress q (left), the critical stress ratio CSR (middle) and the relative excess pore pressure r_u (right) along the sand box depth.

5 CONCLUSIONS

This paper presents an attempt to study induced liquefaction during vibratory pile driving with a focus on offshore applications. For this purpose, a a linear numerical model reflecting on an existing laboratory-scale experimental setup is employed. This is achieved by adopting scaling laws to obtain a vibratory hammer force. The results provide an overview of the wave propagation in the sand box, highlighting the need for adding a damping layer. Results in terms of cyclic shear stress development accounting for liquefaction phenomenon during driving, indicate the need to further investigate such mechanism using an equivalent linear approach.

ACKNOWLEDGEMENTS

Results presented in this paper were obtained within the frame of the project 3E220488 “Novel Installation and Extraction methods for Foundations. of Offshore Wind Turbines” funded by the Global PhD partnerships (between KU Leuven and UCLouvain). The financial support is gratefully acknowledged.

Seabed and sub-seabed boulders as an engineering hazard in the marine environment; methods of detection and quantification

Les risques techniques liés aux blocs rocheux de surface et enfouis dans l'environnement marin; une stratégie d'atténuation des risques pour les câbles sous-marins

M.J. Wetton*, D.P. Vaughan, N. Dyer
Cathie Associates, Newcastle upon Tyne, United Kingdom

**matthew.wetton@cathiegroup.com*

Abstract: Seabed and sub-seabed boulders are a significant design constraint, and financial risk to the design and installation of foundations for offshore Wind Turbine Generators, the trenching and installation of export and intra-array cables, and project design. Many windfarms under development in northern Europe and USA are built on geological formations which are either a direct product of, or subsequently influenced by, glaciation. These formations often contain high numbers of seabed and sub-seabed boulders; for example, the Marr Bank Formation of the North Sea. A primary objective for pre-construction geophysical surveys is to provide data to support a boulder mitigation strategy. This is required prior to installation to allow for an optimised construction methodology to be selected. The detection and quantification of boulders is the first step in a proposed five-step mitigation strategy. In this paper, we present an overview of the geophysical methods utilised for the detection of seabed and sub-seabed boulders, including the key considerations for the boulder detection requirements and subsequent survey specifications to meet these requirements. We present the technical and practical limitations to detection, as well as state-of-the-art solutions. The detection of boulders is followed by a detailed quantification of boulders, in order to understand the risks posed to engineering activities. The overall objective is to reduce engineering risk by better informing the location, design, and installation associated with emplacing infrastructure at and below the seabed.

Résumé: Les blocs rocheux présents sur le fond marin ou enfouis sous sa surface constituent une contrainte de conception importante et un risque financier non négligeable pour la conception et l'installation des fondations des générateurs d'éoliennes en mer, l'ensouillage et l'installation des câbles d'exportation et des câbles inter-éoliennes, ainsi que la conception du projet. De nombreux parcs éoliens en développement en Europe du Nord et aux États-Unis sont construits sur des formations géologiques qui sont soit le produit direct de la glaciation, soit qui ont été influencées ultérieurement par celle-ci. Ces formations contiennent souvent un grand nombre de blocs rocheux en surface et sous la surface; par exemple, la formation Marr Bank de la mer du Nord. L'un des principaux objectifs des études géophysiques préalables à la construction est de fournir des données permettant d'étayer une stratégie d'atténuation des risques liés aux blocs rocheux. Il est nécessaire de disposer de ces données avant l'installation, afin de permettre la sélection d'une méthodologie de construction optimale. La détection et la quantification des blocs rocheux constituent la première des cinq étapes d'une stratégie d'atténuation des risques. Dans cet article, nous présentons une vue d'ensemble des méthodes géophysiques utilisées pour la détection des blocs rocheux de surface et enfouis, incluant les considérations clés pour les exigences de détection des blocs rocheux et les spécifications des levés associés pour répondre à ces exigences. Nous présentons les limites techniques et pratiques de la détection, ainsi que les solutions les plus récentes. La détection des blocs rocheux est suivie d'une quantification détaillée de ceux-ci, afin de comprendre les risques posés aux activités d'ingénierie. L'objectif global consiste à réduire les risques techniques en informant mieux sur leur emplacement et fournir des données pour la conception et l'installation associés à la mise en place d'infrastructures sur et sous le fond marin.

Keywords: Geophysics; geophysical survey; boulders; hazard mitigation; risk analysis.

1 INTRODUCTION

Licenses for new offshore windfarm developments are being awarded with increasing frequency, with a trend towards larger lease areas as the size of turbines increases to meet power generation demand. Across some of the most active offshore wind regions (North Sea, Baltic Sea, and northeast USA), the geology at these sites is shaped or influenced by glaciation. Glacial sediments, typically till, consisting of a heterogenous mixture of clay, sand, gravel, and boulders varying widely in size and shape (McMillan & Powell, 1999) is often a source of seabed and sub-seabed boulders, in these environments.

The presence of boulders can have significant impact on the engineering works associated with development of a windfarm. They represent a significant constraint to a wide range of activities including: the installation of foundations; cable routing; trenching; design operations; installation operations for export and inter-array cables; and jack up operations. Failure to sufficiently identify and quantify the magnitude of the constraint can lead to considerable financial risk to a project. This may lead to problems where developers exceed project budgets, with increased installation timescales, encounter unexpected delays, and have to mitigate for wear or damage to installation equipment.

Where boulders are potentially present, a clear strategy is required to successfully manage the potential constraint using a risk-based approach. A five-step mitigation strategy is presented, the objective of which is to reduce the risk boulders may present to a practical and commercially viable level (Figure 1). This strategy can be employed at any stage of the project life cycle prior to construction, from desktop study to final engineering corridor planning. However, the greatest benefits result from implementation at the earliest stages of planning.

This paper focuses on the first stage of the strategy: the identification of the hazard and quantification of the risk, to allow for further mitigation to take place. The detection of boulders followed by a detailed quantification, allows for an improved understanding of the risks to engineering activities. Resulting in improved design, and installation of engineering infrastructure at and below the seabed.

2 DETECTION

The detection of boulders on and below the seabed is generally achieved through acoustic geophysical survey techniques. Geophysical surveys are often performed to inform a range of development activities concurrently, for example, cable thermal design, seabed mobility, UXO risk mitigation, and other constraints like anthropogenic material and infrastructure. Knowledge of the requirements for each constraint may allow for a single integrated survey to capture all the required data, with minimal risk of unanticipated re-survey requirements.

Geophysical techniques for this purpose are used throughout the world as a matter of routine. However, the regulations governing data acquisition, processing, and interpretation, vary significantly. In the USA and Germany, regulatory bodies publish exacting minimum standards of survey data accuracy and detectability (BOEM, 2017; BSH, 2014), whereas in other territories, less specific guidelines are available (BSI, 2015). Some of these guidelines are derived from oil and gas pipeline and rig site survey, standard industry practice, updated to meet the requirements of the renewables industry. Others originate from bodies such as the Carbon Trust (Carbon Trust, 2020) and offer a recommended practice when planning a marine geophysical survey.

Beyond aligning with regulatory requirements, successful detection, and quantification of boulder hazards at a given site first requires understanding the minimum object detection size and the sequence of site-characterisation operations (e.g., route selection and corridor alignment). Smaller objects are more challenging to detect so require a more highly specified survey to enable identification. The minimum object detection size would ideally be established at an early stage of planning the survey, as it defines a key objective of the data collection. Collaboration with engineers and designers to inform strategy and specification requirements is key to ensuring surveys are planned to meet the requirements for designing a mitigation strategy, (Burley et al., 2023; Carbon Trust, 2020).

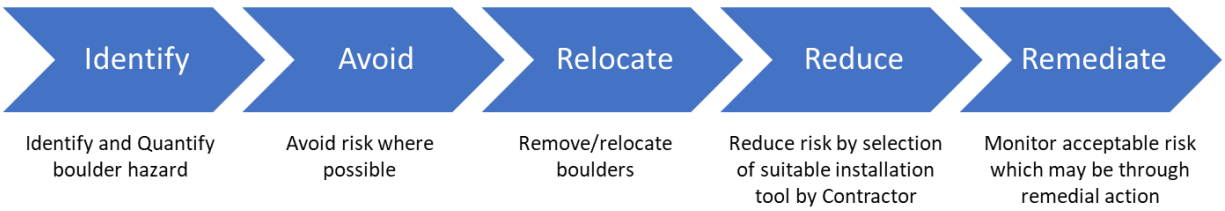

Figure 1. A five-step mitigation strategy, beginning with the identification of boulders followed by each mitigation option.

2.1 Seabed boulder detection techniques

For detection of seabed boulders, a combination of sidescan sonar (SSS), and multibeam echosounder (MBES) data, would typically be acquired, with new methods such as synthetic aperture sonar also becoming more common. A SSS system is a deep-towed sensor, flying a few meters above the seabed, scanning the seabed at a low angle of incidence. This setup allows a minimised distance between sensor and target, resulting in reduced travel time of the acoustic energy and typically giving a high resolution. The low angle of incidence produces the 'shadow', allowing for the measurement of object height. However, the accuracy is limited by underwater acoustic positioning which typically has an accuracy of +/- 2 m. The sensor operates a port and starboard channel (both sides of the sensor), but cannot look vertically down, resulting in a stripe of null coverage known as the "nadir" along the track of each survey line. Surveys specifications usually require a 200% coverage of SSS data. The overlapping adjacent swathes of data provides coverage of the nadir and can create multiple ensonifications of seabed objects from different directions, improving detection potential. The need to achieve this overlap contributes to the line spacing requirements of the survey and the swathe range of the SSS.

The MBES system is typically a hull mounted sensor, which then benefits from accurate Global Navigation Satellite System (GNSS) positioning and delivers a quantitative depth of objects, where SSS does not. MBES images a swath centred on the survey track. MBES systems can be mounted on subsea remotely operated vehicles (ROVs) and autonomous underwater vehicle (AUVs), that can overcome these shortcomings and provide solutions for challenging deep-water environments.

The key factor limiting object detectability for both systems, is the number of acoustic signal beams which might be expected to hit or illuminate a target of a given size. The higher the density of 'hits', the greater the potential to image smaller targets.

To reliably detect seabed boulders, a certain number of hits is required. For MBES a minimum of 9 hits is recommend for resolving an object from its surroundings (IHO, 2011) Objects can theoretically be interpreted from a one pixel footprint hit, however, to increase interpretation certainty, a 2-3 pixel footprint is preferred (IHO, 2011). If a survey is required to detect small objects, there will be an upper limit on the detection range (swathe) of each sensor. By definition wider swathes cover a larger footprint, but suffer from lower ping rates, and increased signal attenuation at higher frequencies, limiting resolution.

Once the engineering requirement is known, the survey specification to support detection of the minimum object size can be calculated. An indicative set of smallest resolvable sizes are provided for a range of typical equipment settings for SSS (Table 1), and MBES data (Table 2). These values are indicative and must be confirmed for survey planning, as specific equipment and survey conditions will cause variability in performance. Note that these values are specified to achieve a one-pixel footprint only.

Table 1. The maximum SSS range and suggested survey specification to detect various sizes of item.

Smallest resolvable item [m]	Maximum Range [m]	Line spacing (200% coverage) [m]	Suggested Frequency [kHz]
0.30	45	30	540
0.40	60	45	540
0.50	85	70	410
0.60	100	80	410

Table 2. The maximum MBES range and suggested survey specification to detect various sizes of item, for a 400 kHz sensor and water depth of 50 m.

Smallest resolvable item [m]	Required Ping density [/0.5 m^2]	Maximum Range [m]	Line spacing [m]
0.30	53	30	25
0.40	31	45	40
0.50	20	60	55
0.60	15.5	70	65

In this case, note that SSS data is higher resolution for any given range. This is fairly representative, although may not always be the case if a particularly high specification MBES system is deployed.

2.2 Sub-seabed boulder detection techniques

The detection of sub-seabed boulders is more challenging than seabed boulders. Industry standard practice is to utilise 2D sub bottom profiler (SBP) or 2D ultra-high resolution seismic reflection (2D UHRS) data. As with seabed methods, an appropriate survey plan and equipment specification is critical to ensure the detection of the required minimum size object.

SBP data is typified by high frequency content, which provides high vertical resolutions at the expense of a limited penetration of approximately 5 – 10 m below seabed depending on geological conditions. SBP systems often have a short firing interval (5Hz), providing high lateral resolution. SBP data is normally acquired for structural mapping of very shallow geological units but can be used to identify boulders in the sub-seabed through the interpretation of diffraction hyperbolae of the buried boulders.

2D UHRS data generates a more powerful signal at lower frequencies. Achieving deeper penetration of 50 – 100 m, depending on geological conditions, but with reduced vertical resolution. 2D UHRS data is useful for structural mapping of geological units, which can present a valuable input into boulder risk analysis, tracing the depth and extent of boulder-bearing units such as glacial till. A indicative set of parameters with the same limitations as Table 1 and Table 2 is provided in Table 3.

2D sub-seabed seismic techniques are limited by profiling in a narrow volume vertically below the sensor track, cannot reliably return precise locations of boulders below a survey-defined size limit, and boulder sizes are not precisely determined. However, 2D methods are useful to discover boulder-bearing strata, particularly in conjunction with geological interpretive ground models. As such, these techniques can only provide estimations for the spatial distribution of geological units and boulder density.

Table 3. Table outlining how expected vertical resolution and penetration of seismic data vary with frequency.

Data Type	Frequency (Hz)	Estimated Penetration* (m)	Approx. Vertical Resolution (m)*
SBP	5,000	10	0.10
	10,000	5	0.05
UHRS (Sparker)	500	100	0.40
	1000	50	0.20

* Based on typical glacial geology, with an assumed seismic velocity 1600 m/s

To reduce uncertainty, and increase the boulder detection potential, 3D seismic data may offer an alternative approach. The use of 3D data for offshore wind is currently limited but increasing. As demand to further understand the sub-seabed grows, new technologies and methods applicable to boulder detection are becoming available. 3D is available at all scales including: SBP-like, Sparker source UHRS, and airgun site survey and exploration data. In the very near seabed methods such as 3D high resolution imaging may provide an alternative to 2D profile data for the detection of boulders. Although costs for 3D seismic are higher than 2D, the increased information for sub-seabed boulder positioning, burial depth, and size estimates provides advantages not available with 2D methods.

3 QUANTIFICATION

Quantification begins, after the completion of acquisition and processing, with a full interpretation of all the available datasets. The interpretation should identify and measure the dimensions of each individual contact that poses a constraint to the engineering requirements. For seabed boulders this task is usually carried out on high frequency SSS data, utilising MBES data to verify positioning. The result is a contact list, with interpreted objects given a unique ID, X and Y coordinate, and dimensions (length, width, and height). For sub-seabed boulders, this typically requires interpretive mapping of the extent of boulder bearing units, ground modelling, and the identification of diffraction hyperbolae. Here emerging technologies such as automated or machine learning interpretation are becoming increasingly available.

Quantification of boulders does not always require interpretation of each ensonified object. Interpretation specifications should be proportional to the risk, engineering requirements, and mitigation strategy. For example, in areas of high-density boulders (boulder fields), knowledge of the exact dimensions and position of each boulder is not required, should an appropriate mitigation strategy be available (Burley et al., 2023).

The presence of boulders can then be assigned a risk rating across the site. Risk is typically calculated by assessing the impact, the consequence that encountering the hazard would have, and the likelihood of encountering the hazard. Hazards may be split into subcategories. In this example the risk level associated with boulders of different sizes is presented (Table 4). As the risk level impacts individual engineering methods differently, a method specific strategy is then required to mitigate the risk (Burley et al., 2023).

Table 4. Example of a typical risk register.

Boulder size [m]	Impact	Likelihood	Risk
0.2 – 0.5	Very Low	High	Low
0.5 – 1.5	Low	High	Medium
1.5 – 2.0	High	Low	Medium
> 2.0	Very High	Low	High

This simplistic risk register can be expanded further by considering size (dimensions) alongside density (distribution) and location (seabed or buried).

These three attributes are relevant to most engineering activities associated with wind farm development, and the constraints on each activity. By considering the contribution of each attribute to the risk register allows for a more thorough analysis and more specific mitigation.

As the impact of the boulder attributes are different for each engineering activity, the quantification of boulder risk should be tailored to the specific task.

Knowledge of the constraints for each task can then directly link to the risk value. Using an example of cable installation constraints (Table 5), the risk register can be expanded and tailored to the given engineering task (Table 6). This quantified risk can then be assessed with assigned risk values within the five-step mitigation strategy (Figure 1) for the most appropriate action (Burley et al., 2023).

Table 5. Relating boulder hazard to cable design constraint.

Individual Boulders	Boulder Fields	Constraint Level	
Size [m]	Density		
< 0.5	Low	Soft Constraint	Low
0.5 - 1.5	Medium		Medium
1.5 - 2	High		High
> 2	-	Hard Constraint	

Table 6. Example of an expanded risk register, for the installation of subsea cables.

Boulder Attribute		Impact	Likelihood	Risk
Size [m]	< 0.5	Low	High	Low
	0.5 – 1.5	Medium	High	High
	1.5 – 2.0	High	Low	Medium
	> 2.0	V. High	Low	High
Density	Low	Low	Medium	Low
	Medium	Medium	High	High
	High	High	Medium	High
Location	Seabed	High	Medium	High
	Sub-seabed	Medium	Low	Low

This type of analysis is well suited to risk-mapping. As the boulder attributes are spatially variable, so too is their risk. Risk-mapping can delineate and present the lateral variability of each attribute, allowing the complexity of the risk to be properly captured, and representing the geological conditions across the site. This method is particularly useful to delineate areas of boulder field, which are commonly encountered in previously glaciated terrains.

Illustrative maps presenting the risks of boulder size, density, and location, for the installation of subsea cables across a site, are presented as a series of figures below. Boulder size risk and its constraint on installation tools is presented in Figure 2 as a series of colour coded exclusion zones. Boulder density risk is presented in Figure 3, and boulder location risk as a function of the depth below seabed of interpreted boulder bearing units is presented in Figure 4.

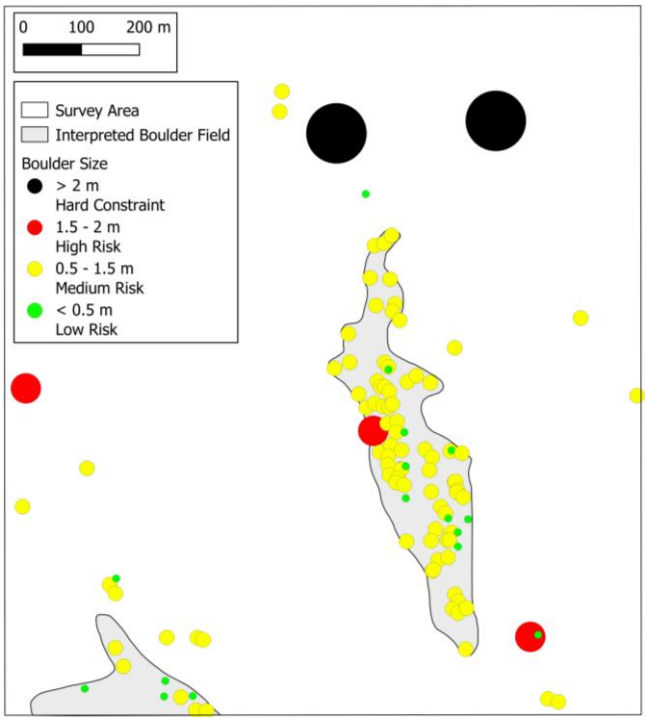

Figure 2. Lateral distribution of boulders and size dependant risk.

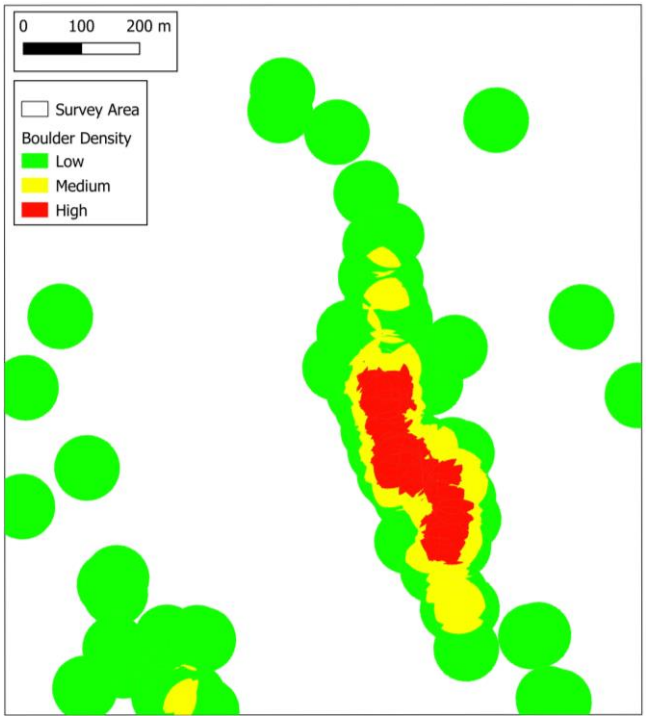

Figure 3. Density of interpreted boulders for a specified area.

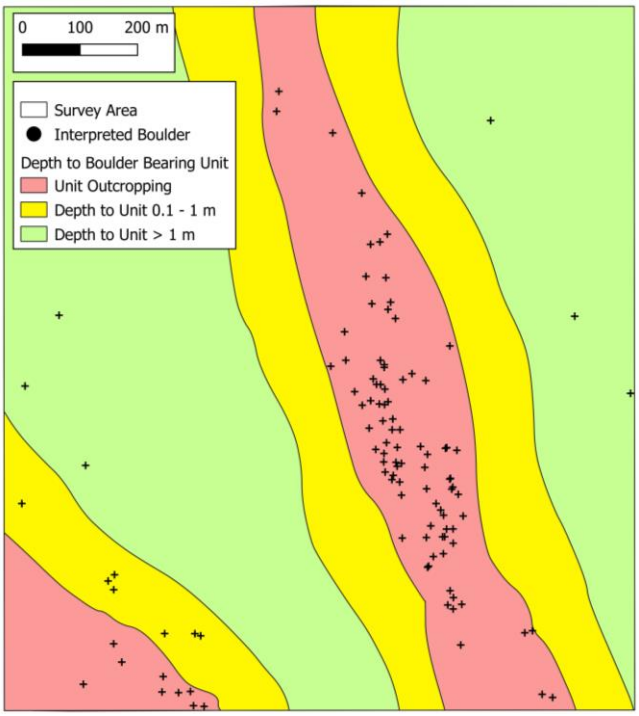

Figure 4. Risk of boulders as a function of location, through mapped boulder bearing geological units.

4 CONCLUSIONS AND OPPORTUNITIES

Boulder risk mitigation is not a new process, however this paper seeks to describe a systematic and best practice approach to the first stage of the risk mitigation process, by highlighting areas of potential optimisation and improvement.

By beginning the risk analysis process early in a development's schedule, survey campaigns can be designed and specified to identify the hazards that constrain engineering activities. This risk-based approach then defines the success of a campaign as achieving the level of understanding needed to mitigate against the risks. Engagement in risk-based thinking at an early stage may also provide additional efficiencies throughout the development cycle. Data acquired at an early stage of a project can be specified to meet the requirements of risk considerations that may not become relevant until later stages of a project. Conversely, this approach can also ensure surveys are not over specified, preventing time and resource from being spent on acquiring information that will never be used.

By increasing our understanding of the risks from boulders and how they can vary across a site, the mitigation strategies proposed can be more effectively planned. Identification of high risk or hard constraint areas can reduce the risk to engineering activities and increase the efficiency of installation.

Emerging technologies such as automated boulder interpretation, and synthetic aperture sonar may be influential in facilitating this growth of understanding, but are not a substitute for careful planning, detailed quality assurance, and well understood survey requirements. Which can be packaged into a bespoke, precise survey, detection, and quantification workflow, which can ultimately save a client time, resources, and money over the lifetime of a development.

ABSTRACT: The energy crisis presently faced in the world and particularly in Europe, is raising alarm for the transition from fossil fuels to sustainable and renewable energy resources. It is in this light that low enthalpy geothermal energy is increasingly getting attention, in the heating and cooling sectors. With diversified technologies of geothermal extraction, it is important to choose the right technology for every situation considering both the economic and technical aspects. In the context of structural rehabilitation of buildings, micropiles stand as the optimum choice for retrofitting and underpinning of existing foundations. This technology could also be advantageously extended in the sector of energy rehabilitation, as the thermal performance of micropiles suitably equipped to allow heat exchange between the ground and the building has proven promising for use in heating, ventilation, and air conditioning systems. Although very similar to energy piles, the behavior of energy micropiles is expected to be different mainly due to the difference in sizes and spacing. As such, a comprehensive understanding of the thermo-mechanical behavior of energy micropiles is important in view of their application. To date, however, little research has been conducted on the subject. The paper introduces energy micropiles, discusses their thermal performance and thermo-mechanical behaviour, and describes a real case of energy micropiles application.

RÉSUMÉ: La crise énergétique à laquelle le monde est actuellement confronté, et particulièrement l'Europe, sonne l'alarme quant à la transition des combustibles fossiles vers des ressources énergétiques durables et renouvelables. C'est dans cette optique que l'énergie géothermique à basse enthalpie retient de plus en plus l'attention, dans les secteurs du chauffage et du refroidissement. Avec des technologies diversifiées d'extraction géothermique, il est important de choisir la technologie adaptée à chaque situation, en tenant compte à la fois des aspects économiques et techniques. Dans le contexte de la réhabilitation structurelle des bâtiments, les micropieux constituent le choix optimal pour la rénovation et la reprise en sous-œuvre des fondations existantes. Cette technologie pourrait également être avantageusement étendue au secteur de la réhabilitation énergétique, car les performances thermiques des micropieux convenablement équipés pour permettre l'échange thermique entre le sol et le bâtiment se sont révélées prometteuses pour une utilisation dans les systèmes de chauffage, de ventilation et de climatisation. Bien que très similaire aux pieux énergétiques, le comportement des micropieux énergétiques devrait être différent principalement en raison de la différence de dimension et d'espacement. Alors, une compréhension complète du comportement thermomécanique des micropieux énergétiques est importante en vue de leur application. Mais à ce jour, peu de recherches ont été menées sur le sujet. Cet article présente les micropieux énergétiques, discute de leur performance thermique et de leur comportement thermomécanique, et décrit une étude de cas réel d'utilisation des micropieux énergétiques.

Keywords: Energy micropiles; rehabilitation of buildings; thermal performance.

1 INTRODUCTION

In response to the 2022 energy crisis in Europe, the European Commission announced the joint action plan REPowerEU, aiming to reduce Russian gas consumption in the EU by 2/3 by the end of 2022 and phase it out by 2027. One of its focuses is "clean energy transition" with the goal of increasing the EU's 2030 renewable energy target from 40% to 45%. This crisis has boosted interest of geothermal energy across Europe.

Wells were the only methods used to harness geothermal energy until energy geostructures were introduced in the 1980s. Energy geostructures interact with the soil combining the conventional structural role with the energy one. They include foundations (piles, slabs), retaining walls (diaphragm walls, sheet walls), tunnels. Energy foundations with a specific heat flux typical between 20W/m and 80W/m (Brandl, 2006), are widely used today (Loveridge et al., 2020). Successful implementation of these foundations has been recorded (Sani et al., 2019). Diaphragm walls,

typically used as retention systems, offer a long-term exchanged power per square meter of about 15-20W/m2 (Bourne-Webb et al., 2016; Di Donna et al., 2017). Tunnels provide a larger volume of ground and surface for heat exchange. The heat exchanged can be directly utilized by adjacent buildings and integrated into district heating and cooling systems (Barla and Di Donna, 2018). The specific heat exchange power obtained from energy tunnels can range from 10 – 20 W/m2 in the absence of groundwater flow and 50-60 W/m2 in the case of relevant groundwater flow (Barla and Insana, 2023).

Heat transfer between the ground and the structure occurs through plastic pipes within the geostructure, where a heat exchanger fluid, like water, water + glycol, or a saline solution, circulates. Energy geostructures are cost effective and eco-friendly, and require no new infrastructure compared to energy wells, with a comparable thermal performance. Among them, micropiles, commonly used for structural retrofitting and rehabilitation of buildings, could be an appropriate solution for heating and cooling existing buildings with minimal available space.

This paper introduces the concept of micropiles, followed by the energy micropiles. The thermal performance and the thermo-mechanical behaviour of energy micropiles are discussed. Finally, a real case study involving the utilization of energy micropiles is presented.

2 ENERGY MICROPILES

Micropiles are smaller – diameter (usually less than 30 cm), drilled and grouted non-displacement piles that are usually reinforced. Micropile installation involves drilling a hole, placing reinforcement, and grouting the hole. In addition to this conventional type, steel micropiles and self-drilling micropiles are available today. These smaller piles may be feasible under the following constraints (Sabatini et al., 2005):

- Limited access or location in remote areas.
- Need for a support system in close proximity to existing structures.
- Difficult ground and drilling conditions (such as karstic areas, uncontrolled fills, boulders, etc).
- Requirements for minimizing noise and vibration.

Micropiles can be used for both in-situ reinforcement and structural support. Extending their application to provide heating and cooling to buildings could be very useful in many cases.

2.1 Thermal performance of energy micropiles

Ronchi et al., (2018) carried out numerical simulations for a conventional grouted micropile in summer conditions. Results of the numerical study show that a thermal power of about 30W/m was obtained after a 6-month period. In wet sediments, up to 111W/m of thermal power was obtained from the self-drilling grouted TITAN 73/53 energy micropile (Ischebeck, 2015). These values are comparable to those of energy piles, signifying the promise of energy micropiles as a technology for heating, ventilation, and air-conditioning systems.

Pipe length, concrete thermal conductivity and pipe diameter are the most important parameters in maximising the thermal efficiency of energy micropiles (Cecinato and Salciarini, 2022). However, the small section of micropiles poses a challenge when considering the pipe arrangements commonly employed in larger piles such as the W, spiral, partly W and the double-U shape. In literature, two primary pipe configurations stand out for energy micropiles, the single-U and the coaxial. Due to the greater possibility of interference in small sizes micropiles with U-pipes, it is predicted that the coaxial pipe configuration should be the most suitable for energy micropiles. Moreover, with the large volume of water in the annular space of the coaxial pipe arrangement, the micropile can serve as a storage tank, as water has a high specific heat capacity. However, the intrusion of grout in the annular space could reduce the thermal potential of the micropiles in the long term and should therefore be investigated.

In addition, increasing the number of micropiles in a group will increase the overall heat exchange rate of the system, although it reduces the average heat exchange rate of individual micropiles (Kong et al., 2021). The spatial arrangement of energy micropiles within a group exhibits minimal or negligible influence on the average heat exchange rate of each micropile (Kong et al., 2021). However, closely spaced thermally activated micropiles should be avoided as thermal interference can result in a significant loss of function (Lupattelli et al., 2023) with time. When the fluid inlet velocity and/or the inlet temperature of the heat exchange fluid are increased, the pile temperature also increases (Kong et al., 2021). Consequently, meticulous design considerations are imperative to ensure the structural integrity of the energy micropile system remains uncompromised.

2.2 Review of the thermo-mechanical behavior of energy micropiles

Although the energy micropile system and the energy pile system are quite similar, their behavior cannot be assumed to be similar both mechanically and

thermally, as the former has negligible end bearing capacity and smaller dimensions (Ronchi et al., 2018). Unlike energy piles, very little research has been done on energy micropiles. It is important to note that due to poor cleanout at the toe of micropiles, the side shear resistance largely controls the restraint for thermal expansion and contraction of energy micropiles (Casagrande et al., 2022).

For micropiles installed in granular soils and subjected to cyclic thermal loading, (Lupattelli et al., 2023) observed the development of irreversible settlement during the initial cooling cycles. However, these settlement values were deemed negligible and could be disregarded during the design process. When installed in stratified soil, the behavior of energy micropiles becomes a little more complex and needs more attention. (Casagrande et al., 2022) carried out TRT tests to understand the impact of different soil layers on the thermomechanical response of EMPs. An interesting finding was the development of plastic strains which occurred only in the organic clay layer after a certain amount of heating, while all the other layers (silty sand and sand soil) kept the thermo-elastic behavior. Furthermore, it was observed that the mobilized coefficient of thermal expansion decreased following each successive heating cycle. This reduction was associated with an increase in side shear resistance, thereby increasing restraint along the pile's length induced by heating. Additionally, variations in the coefficient of thermal expansion were noted across different soil layers, with the lowest value recorded in the organic clay soil layer.

Just like energy piles, thermal axial stresses are induced by thermal loading in energy micropiles. These stresses increase both with the inlet fluid temperature (Kong et al., 2021) and the number of loading cycles (Casagrande et al., 2022). Significant compression stresses were observed for long, slender micropiles (Lupattelli et al., 2023). Therefore, thermal stresses should also be considered during the structural design process. These observations highlight the complexity of the thermo-mechanical behavior of energy micropiles. The observations discussed in this section pertain to micropiles with a U-pipe configuration. However, to the best of the authors' knowledge, no study on the thermo-mechanical behavior of coaxial energy micropiles has been conducted. Thus, further research is essential for an appropriate design of these small piles.

3 REAL CASE OF ENERGY MICROPILES APPLICATION

Europe's first zero energy parking, Toriparkki, is situated underneath the Turku market square in Finland (Figure 1). The 30.000 m^2 parking produces 100% of the heat energy used by combining solar energy, district heating, geothermal energy and underground thermal storage. The geothermal system comprises of 561 steel energy small diameter piles amongst the 2000 piles installed. The micropiles lengths range from 15 to 45 m, with diameters of 14 cm and 17 cm (Lautkankare et al., 2020). Inside the 40 mm U-tube polyethylene pipes, water circulates. The ground being constituted of clay is appropriate for thermal energy storage.

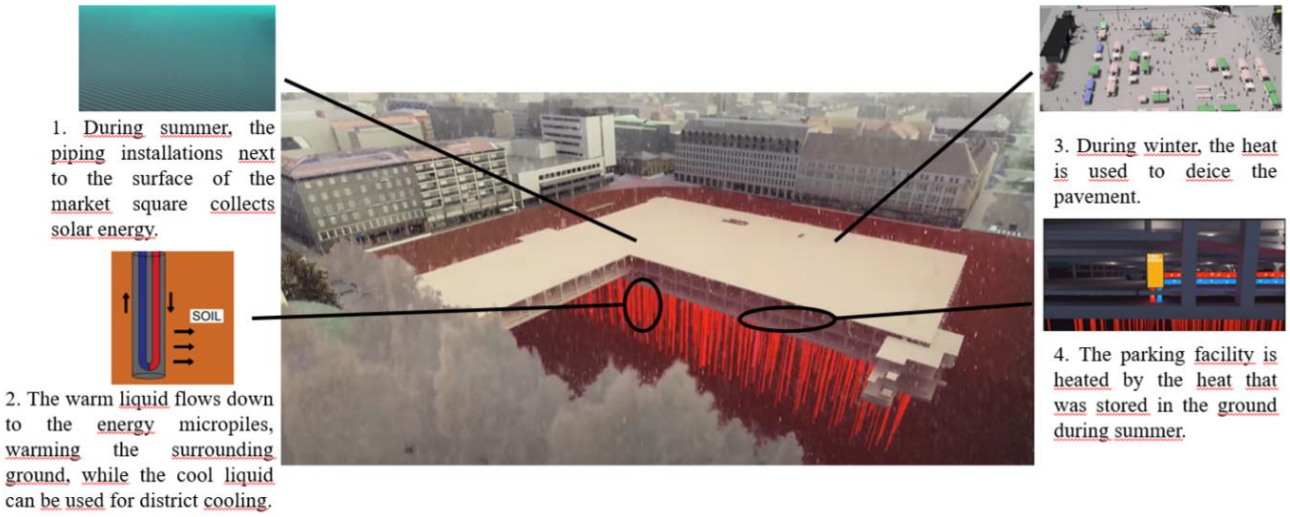

Figure 1. Illustration of the Toriparkki parking facility during winter. Adapted from (NollaE, 2019).

In summer, the surface of the market square is heated by the sun and the warm liquid flows underground through the piping system to the energy piles, warming the surrounding ground to a maximum depth of 50 m. The storage capacity and the heating power of the heat storage system are about 11.2 GWh and 6.6 M respectively. As autumn arrives, the thermal energy storage reaches its peak warmth, and the heated ground starts to release heat to the liquid in the energy piles. This warmed liquid then flows back up to the surface piping. Throughout winter, the heat stored underground is utilized to deice the pavement and heat the parking facility. As time progresses, the stored heat gradually diminishes, allowing the cool liquid in the system to be utilized for district cooling during spring. This heating system reduces CO2 emissions annually by about 950 tons compared to a heat pump facility.

4 CONCLUSIONS

Energy geostructures such as energy piles, slabs, walls, and tunnels, are efficient in providing renewable and clean energy for heating and cooling of buildings. However, their widespread adoption faces a common challenge in densely populated cities, where space constraints make it difficult, if not impossible, to implement individual geothermal systems. Micropiles, mostly used in structural retrofitting and rehabilitation, hold promise for providing sustainable energy for heating, ventilation, and air conditioning of existing buildings. Recent research has shown that the thermal performance of energy micropiles is comparable to that of energy piles. However, the small section of micropiles poses some challenges both in the thermal efficiency and thermo-mechanical behaviour. Nevertheless, it is predicted that the coaxial pipe configuration could be the most suitable pipe configuration for energy micropiles. In conclusion, more research should be carried out on energy micropiles for an appropriate thermal and thermo-hydro-mechanical design.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to FRIEDR. ISCHEBECK GMBH for providing information and data on Titan micropiles and for organizing site visits.

ABSTRACT: The global soil stabilisation market is forecast to grow to $35 billion by 2027 driven primarily by infrastructure and construction activities and exacerbated by the increasingly urgent need to adapt to climate change. Naturally sourced biopolymers are a promising low carbon 'green' stabilising agent, achieving higher strength in stabilised soils than cement and at similar cost. However, widespread uptake of biopolymers is impeded by the fact that they typically suffer from (a) poor water resistance and (b) poor resistance to biodegradation over time. This paper presents interim results from a research study into novel biopolymer treatment processes which are applied at or subsequent to the soil/biopolymer mixing stage with the aim of enhancing resistance to water and biodegradation while involving the addition of only small volumes of natural materials. The specific approach described in this paper aims to minimize the interaction of vulnerable hydrophilic functional groups in the biopolymers with water through acetylation, whereby the hydrophilic groups are replaced by natural hydrophobic acetyl groups. Three mixing protocols are proposed and this paper examines the first protocol where the acetylation agents are added at the same time as the biopolymer is added to the soil. While this is the simplest process procedurally, results demonstrate that the strength on wetting is lower than non-acetylated chitosan treated soil. Improved performance is anticipated for the other protocols.

RÉSUMÉ: Le marché mondial de la stabilisation des sols devrait atteindre 35 milliards de dollars d'ici 2027, principalement en raison des activités d'infrastructure et de construction, et exacerbé par le besoin de plus en plus urgent de s'adapter au changement climatique. Les biopolymères d'origine naturelle constituent un agent stabilisateur "vert" prometteur, à faible teneur en carbone, qui confère aux sols stabilisés une résistance supérieure à celle du ciment, pour un coût similaire. Cependant, l'adoption généralisée des biopolymères est entravée par le fait qu'ils souffrent généralement (a) d'une faible résistance à l'eau et (b) d'une faible résistance à la biodégradation au fil du temps. Cet article présente les résultats provisoires d'une étude portant sur de nouveaux procédés de traitement des biopolymères appliqués au stade du mélange sol/biopolymère ou ultérieurement, dans le but d'améliorer la résistance à l'eau et à la biodégradation tout en n'impliquant l'ajout que de faibles volumes de matériaux naturels. L'approche spécifique décrite dans cet article vise à minimiser l'interaction des groupes fonctionnels hydrophiles vulnérables des biopolymères avec l'eau par acétylation, les groupes hydrophiles étant remplacés par des groupes acétyles hydrophobes naturels. Trois protocoles de mélange sont proposés et cet article examine le premier protocole dans lequel les agents d'acétylation sont ajoutés en même temps que le biopolymère est ajouté au sol. Bien qu'il s'agisse du processus le plus simple d'un point de vue procédural, les résultats montrent que la force de mouillage est inférieure à celle d'un sol traité au chitosane non acétylé. Des performances améliorées sont attendues pour les autres protocoles.

Keywords: Biopolymer; soil stabilisation; chitosan; water resistance.

1 INTRODUCTION

The global soil stabilisation market is expected to experience substantial growth, increasing from $25 billion in 2019 to an estimated $35 billion by 2027 (Emergen Research, 2020) with soil-chemical stabilisation, anticipated to be the fastest-growing sector. This growth is primarily attributed to heightened infrastructure and construction activities,

further fueled by the urgent imperative to address climate change, flood risk, and rising sea levels.

Despite this growth, there are environmental concerns associated with conventional commonly used chemical additives such as cement and lime. Biopolymers have been advocated as an alternative low-carbon sustainable stabilisation agent (Chang et al., 2020). Existing research has demonstrated that biopolymers can acheive considerable soil strength improvements with low additive dosage compared to traditional stabilisers such as cement or lime, while at similar cost. The potential for biopolymers to naturally degrade over time may also be seen as beneficial for temporary and semi-permanent works (lifetimes of decades), however there is a need to develop robust controls on the degradation process.

Key to this is to address the issues of biodegradation and strength reduction on exposure to water. This paper describes a systematic approach for improving the water/biodegradation resistance of biopolymer stabilised soils and reports intial results from an 18-month UK EPSRC funded research project.

2 BIOPOLYMER SOIL STABILISATION AND INFLUENCE OF WATER

Typically, biopolymers are dissolved in water, forming a viscous fluid, before thorough mixing with soil. On drying, the functional groups on the long chain structure can bind with other biopolymer molecules or soil particles giving rise to a significantly improved strength and stiffness after drying. Additions of 1-3% biopolymer by weight have been shown to give rise to strengths exceeding those achieved by e.g. addition of 8-10% of cement (Chang et al., 2015 and Muguda et al., 2017).

Biopolymer stabilisation will significantly depend on the mineralogy of the soil and the properties of the biopolymer involving either direct biopolymer-soil binding or physical coating of soil particles by biopolymer and biopolymer-biopolymer binding.

However some of these binding mechanisms can be weakened/outcompeted by water molecules. Experimental measurements on xanthan gum stabilised soils have previously demonstrated a loss of compressive strength upon exposure to water (Chang et al., 2015, 2020). Biopolymer tensile strength and stiffness can diminish significantly with increased water content (Yakimets et al., 2007). Elsewhere the addition of de-acetylated chitin has been shown to improve the mechanical properties of clay-based soils, however this effect is significantly reduced in the presence of water (Hataf et al., 2018).

3 DESIGN APPROACH

The approach described in this paper has been previously described in Smith et al. (2023) and is briefly summarized here. It is hypothesised that the biopolymer functional groups within a stabilised soil which may otherwise preferentially bind to water, can be treated post mixing to negate their vulnerability to water and biodegradation without affecting the soil-biopolymer binding. In this paper the conversion of 'vulnerable' functional groups utilising acetylation is examined.

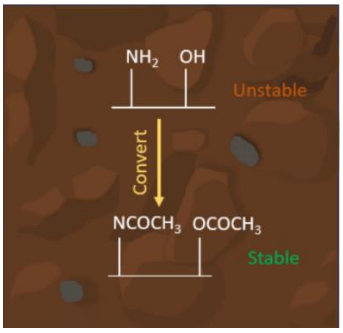

Figure 1. Enhancing biopolymer resistance to water and biodegradation through acetylation (after Smith et al., 2023).

Acetylation is a chemical process that has seen success as a non-toxic and environmentally friendly timber treatment technology (Mantanis, 2017). It involves replacing vulnerable hydrophilic functional groups with natural hydrophobic acetyl groups (shown in Figure 1). Re-acetylation can typically be carried out through the addition of acetic anhydride.

While this paper reports interim results based primarily on macro-geotechnical results from unconfined compression tests, and initial FTIR studies, additional studies will be carried out using XRD, GPC, zeta potential, TGA, and SEM to identify and characterize the binding and chemical reactions that occur.

Treatments agents will include various acetylation agents. In the wider project, three treatment protocols will be investigated:

1. Acetylation of the dissolved biopolymer immediately prior to soil mixing.
2. Mixing of the dissolved biopolymer with the soil followed by acetylation but prior to sample curing.
3. Mixing of the dissolved biopolymer with the soil followed by acetylation after sample curing.

It is anticpated that better performance will be seen in Protocols 2 and 3, however these will be more complex to apply in the field. This paper reports results from the evaluation of Protocol 1.

4 EXPERIMENTAL STUDY

4.1 Materials

Silica sand sourced from Cheshire, UK was puchased from Minerals Marketing Ltd, and was chosen for its local abundance. The particle sizes ranged between 0.06-0.5mm and the chemcial composition is listed in Table 1.

Table 1. Chemical composition of soils.

Chemical composition	Typical (%)
SiO2	94.68
Fe2O3	0.28
Al2O3	2.52
K2O	1.47
LOI	0.24

Chitosan biopolymer was utilised for the current study. Chitosan was selected due to its significant strengthening potential in soil stabilisation (Hataf et al., 2018; Adamczuk and Jozefaciuk, 2022), and its production route via de-acetylation of chitin, a material used by insects and crustaceans for exoskeletons and which has inherent water resistant properties. Chitin itself is a significant bi-product of the food industry. It is hypothesised that re-acetylation of chitosan, post soil treatment, will revert chemical bonds unused for soil binding to the chitin form and benefit from its associated properties such as high stability. The chitosan used in the study was purchased from Acros Organics, having a molecular weight ranging from 100000-300000 Da.

4.2 Sample preparation

The sample preparation process was divided into four stages: 1) preparation of the chitosan solution; 2) addition of the acetylation agent; 3) mixing with soils; 4) compaction into cylindrical specimen for testing.

Chitosan itself is insoluble in water, therefore the chitosan solution was prepared by dissolving chitosan powder in a 0.1M aqueous acetic acid solution. Following this, the acetylation agents were mixed in after a period of 5 minutes followed by mixing with the soils. 50 grams of final soil-biopolymer mixture was compacted into 38 mm diameter cylindrical hollow mould by a tamper to produce final specimens of 38 mm diameter and 25 mm height for testing. The samples were then cured by air drying in the laboratory over a 24 hour period at an average relative humidity of 50% and average temperature of 20°C.

Initial test sets utilised 25 mm height specimens to permit greater throughput of samples for parametric studies while providing semi-quantitative data. Verification of identified optimal treatment processes will be undertaken with 76 mm height samples in the future.

The chitosan to soils ratio was set at 1% by mass. The control test involved 1% chtiosan treated soils without any acetylation agent (`1%CS‘). Two different aceytlation approaches were involved in the study: (a) `1%CS-MeOH-Ac2O`: the addition of methanol (MeOH) with acetic anhydride (Ac2O), allowing acetyl groups to replace only the amino groups on the chitosan chain (Lavertu et al., 2012). This method is a common way to transform the structure of chitosan into chitin; (b) `1%CS-Ac2O`: the addition of Ac2O alone for uncontrolled acetylation.

4.3 Test program

The test programme was designed to assess the mechanical behaviour, water resistance and mechanical recovery after wetting of chitosan treated specimens following different treatments.

The mechanical behaviour of specimens was primarily evaluated through unconfined compression testing using a loading rate of 0.2 mm/min.

Water resistance was gauged through a simple water immersion test. The initial tests reported here utilised a two-hour immersion as an initial indicator of behaviours following water exposure. Specimens then underwent unconfined compression testing directly after the 2-hour immersion. Additionally, specimens subjected to a 2-hour wetting immersion followed by curing were tested to further assess their ability to recover mechanical properties post-wetting.

5 INITIAL RESULTS

5.1 Mechanical behaviours under dry condition

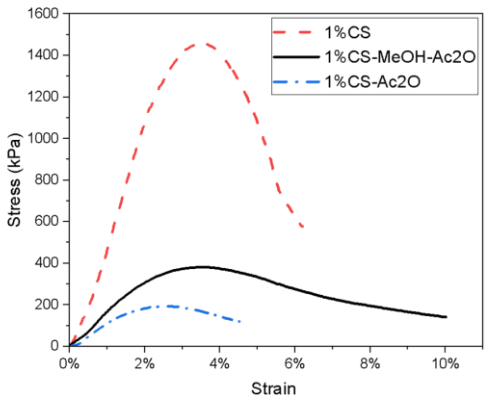

Figure 2. Stress-strain curves of 1% chitosan treated soil following 24 hours curing.

Figure 2 illustrates the stress-strain curves for specimens treated using the two reacetylation approaches following curing. The current reacetylation processes appear to reduce the strength of chitosan-treated soils, but this reduction is partly mitigated by approach (a) with the inclusion of methanol. This phenomenon could be attributed to the introduction of inactive acetyl groups, which may weaken the interactions between the biopolymer and the soil particles.

5.2 Water resistance

To assess water resistance, samples were immersed in water for 2 hours, and the results are shown in Figure 3. Both the 1%CS and 1%CS-MeOH-Ac2O specimens retained their shape in water, while the 1%CS-Ac2O specimen disintegrated. The resilience of 1%CS in water within the initial 2 hours can be attributed to the low solubility of chitosan, which only dissolves under acidic conditions. In contrast, the 1%CS-MeOH-Ac2O specimen absorbed a significant amount of water, behaving like a soft clay. While this reacetylation approach for this specimen should revert chitosan back to chitin, it may lead to randomly distributed acetyl groups (Gatto et al., 2019) that could lead to different characteristics compared to the original chitin, such as water absorbancy.

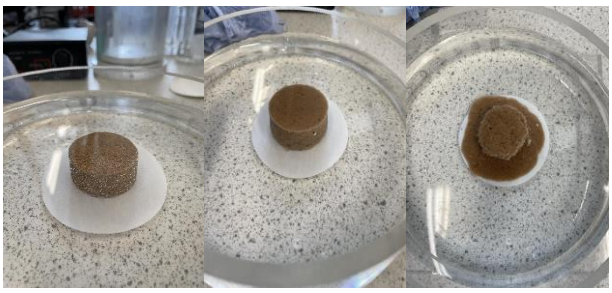

Figure 3. Specimens after two-hour water immersion test (a) 1%CS; (b) 1%CS-MeOH-Ac2O; (c) 1%CS-Ac2O.

Figure 4 presents a comparison of the unconfined compressive stress-strain responses of specimens after curing, wetting for 2 hours by immersion in a water bath, or wetting for 2 hours followed by a further curing stage. Both 1%CS and 1%CS-MeOH-Ac2O exhibit the ability to closely recover their stress-strain response after a single wetting and drying cycle. However, the failure modes of 1%CS and 1%CS-MeOH-Ac2O differ significantly as illustrated in Figure 5. While 1%CS experiences a compressive shear failure indicative of a peak material strength, 1%CS-MeOH-Ac2O displays a bulging response similar to a soft clay.

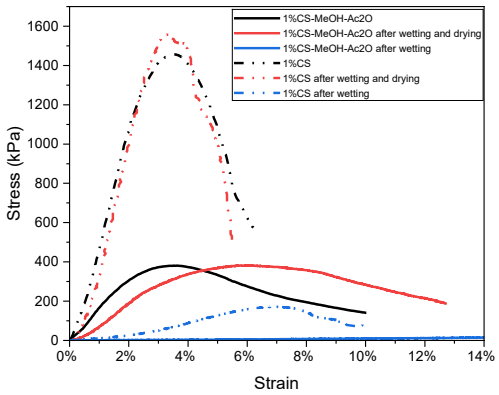

Figure 4. Stress-strain curve of specimen after drying, 2h wetting, 2h wetting and drying.

Figure 5. Failure mode of specimen after wetting (a)1%CS; (b)1%CS-MeOH-Ac2O.

6 DISCUSSION

FTIR results on pure re-acetylated chitosan samples have indicated the introduction of acetyl groups within the chitosan structure, and thus that the process appears to be able to regenerate the chitin structure (though with possible defects, Siripanich, 2023); however, the current mechanical testing indicates that it falls short of replicating certain anticpated properties. Notably, the water absorption ability increases, and the texture becomes softer upon exposure to water.

The initial re-acetylation methodology (Protocol 1) reported in this paper, while simple in operation suffers from the disadvantage that all agents are mixed together and that the reacetylation process may occur more rapidly than soil/biopolymer or biopolymer/biopolymer binding thus reducing strength gains. Further work will focus on the other staged protcols that provide more time for binding to develop before acetylation treatment.

7 CONCLUSIONS

The transformation of 'vulnerable' hydrophilic functional groups within a biopolymer through acetylation is hypothesised to hold significant promise in augmenting the biopolymer's resistance to both biodegradation and water. Three protocols are proposed:

1. Acetylation of the dissolved biopolymer immediately prior to soil mixing.
2. Mixing of the dissolved biopolymer with the soil followed by acetylation prior to sample curing.
3. Mixing of the dissolved biopolymer with the soil followed by acetylation after sample curing.

Results from initial studies on chitosan treated sandy soils reported in this paper focused on Protocol 1. While this is the simplest protocol operationally, the results were negative and indicated that while samples can retain their integrity on wetting they do not maintain their strength. On drying the strength characteristics are recovered. It is hypothesised that reacetylation process may occur more rapidly than soil/biopolymer or biopolymer/biopolymer binding thus reducing strength gains. Further studies will investigate Protocols 1 and 2 which are anticipated to provide improved performance.

Mechanical characteristics of non-cohesive soil improved by fibre and cement addition

Caractéristiques mécaniques des sols non cohésifs améliorées par l'ajout de fibres et de ciment

ABSTRACT: The work aimed to show changes in the mechanical characteristics of gravelly sand characterized by a lack of fines after adding dispersed reinforcement. Tests were conducted on natural non-cohesive soil or improved with a 1.5% cement additive. 18 mm long fibres were used, which were added in amounts of 0.1%, 0.2%, and 0.3% to the dry mass of compacted soil. The gravelly sand was compacted at the optimum water content to the maximum dry density by the Standard Proctor energy. The soil was sheared in triaxial conditions. The addition of fibres changed the sample behaviour on more plastic. The fibre content increases the maximum shear strength but it is obtained at greater relative strain. The cement lightly bound soil failure mode is diagonal through the failure plane, as in the case of semi-brittle material. Whereas the plane of destruction in the soil sample improved with cement and fibre addition is close to horizontal, which signifies that fibre-reinforced material entered its plastic zone.

RÉSUMÉ: Les travaux visaient à montrer l'évolution des caractéristiques mécaniques des sables graveleux caractérisés par un manque de fines après ajout de renforts dispersés. Les essais ont été réalisés sur sol naturel non cohésif ou amélioré avec un additif cimentaire à 1,5%. Des fibres de 18 mm de long ont été utilisées, qui ont été ajoutées en quantités de 0,1%, 0,2% et 0,3% à la masse sèche de sol compacté. Le sable graveleux a été compacté à la teneur en eau optimale jusqu'à la densité sèche maximale par l'énergie Standard Proctor. Le sol a été cisaillé en conditions triaxiales. L'ajout de fibres a modifié le comportement de l'échantillon sur davantage de plastique. La teneur en fibres augmente la résistance maximale au cisaillement mais elle est obtenue avec une déformation relative plus élevée. Le mode de rupture du sol légèrement lié du ciment est diagonal par rapport au plan de rupture, comme dans le cas d'un matériau semi-fragile. Alors que le plan de destruction dans l'échantillon de sol amélioré par l'ajout de ciment et de fibres est proche de l'horizontal, ce qui signifie que le matériau renforcé de fibres est entré dans sa zone plastique.

1 INTRODUCTION

Stabilization with hydraulic binders is an effective way to increase the stiffness of base and subbase layers and to improve the rutting of the subgrade. Another way to improve the soil properties is to use fibre-reinforcement. Scientists agree that fibre content is a recognized method for improving the shear strength and ductility of the stress-strain response of natural (Correia et al., 2021) or hydraulically bonded cohesive soils (Yang et al., 2022) but also natural (Michalowski and Čermák, 2003) and cemented non-cohesive soils (Consoli et al, 1998; Asghari et al., 2004; Haeri et al., 2005). The most used content of fibres to the dry mass of soil is 0.1−0.5%. Binder additives are used in various proportions, and the most common content of lime or cement is 2-10%. Cohesive soils are reinforced with fibres due to their brittleness after cementing or the possibility of cracking when drying. In the case of non-cohesive soils, silty sands are most often reinforced to improve mechanical properties. However, in recent years, research has also been carried out on gravelly sands with poor grain size characteristics, which require improvement due to low compaction possibilities.

The study aimed to investigate the influence of the addition of minimum cement content and polypropylene fibres on the compactibility and mechanical characteristics of post-glacial gravelly sand.

2 MATERIALS AND METHODS

The tested material is a Pleistocene glaciofluvial soil consisting of well-rounded quartz crumbles, as well as angular grains, with a considerable addition of lytic

particles and feldspars (Zabielska-Adamska et al. 2021). According to EN ISO 14688-1 standard, the tested soil is gravelly sand (grSa) with a median particle diameter D_{50} of 1.0 mm and the absence of fines (f_c = 0%). The soil is a poorly graded material with uniformity and curvature coefficients equalled 5.27 and 0.91, respectively. The unit weight, γ_s, is 26.0 kN/m^3.

Laboratory tests were conducted on samples of gravelly sand and gravelly sand with 1.5% 42.5R Portland cement addition to the dry mass of soil, and their mixtures with 0.1, 0.2 and 0.3% of the polyamide fibres with a length of 18 mm. The soil and polypropylene fibres are shown in Figure 1.

Figure 1. The polypropylene fibres with 18 mm longest and soil mixed with 0.3% of the fibres.

Compaction parameters, maximum dry density, $\rho_{d\,max}$, and optimum water content, w_{opt}, were found by the Standard Proctor method. The soil or soil and cement were mixed with polypropylene fibres using a laboratory mechanical stirrer, which is of great importance for the homogeneity of the tested samples (Zabielska-Adamska et al., 2023a).

Mechanical characteristics were performed in the triaxial test apparatus with a pneumatic way of applying the confining pressure and axial load. The cylindrical reconstituted samples were prepared in a bipartite mould by dynamic tamping of the material at w_{opt} into three layers to obtain $\rho_{d\,max}$ value from the Standard Proctor method. The diameters of the samples were about 70 mm, and the height was about 140 mm. The samples were tested directly after compaction (unstabilized hydraulically), and after 28 days of curing in constant temperature and humidity, wrapped in foil to avoid drying. All samples were tested with the ratio of shearing 0.1 mm/min by the CD method recommended for non-cohesive (ASTM D7181-20). Samples were not saturated to recreate the conditions prevailing in the pavement subgrade material but their degrees of saturation were about 0.80. After isotropic consolidation samples were sheared under confining pressure $\sigma_3' = 50$, 100 and 150 kPa.

3 TEST RESULTS AND ANALYSIS

3.1 Compaction results

The fibre addition results in an optimum water content decrease and a maximum dry density increase in both uncemented and cemented samples (Figure 2). Increasing fibre content from 0.2% to 0.3% practically does not influence the compaction parameters of gravelly sand and its mix with cement.

The cement addition to the gravelly sand increases the $\rho_{d\,max}$ value while decreasing the w_{opt}.

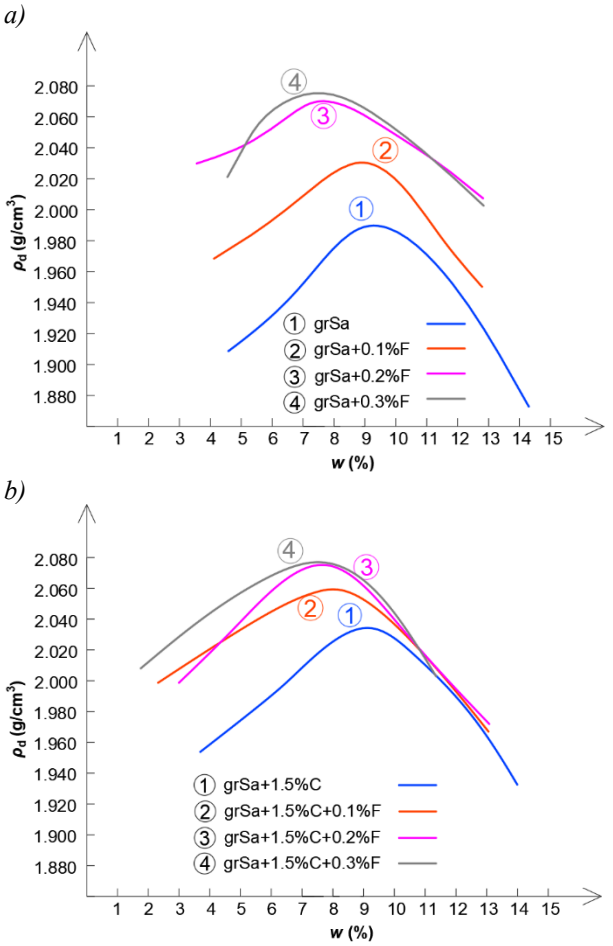

Figure 2. Compaction curves of tested materials with fibres: a) gravelly sand, b) sand and 1.5% of cement.

3.2 Triaxial test results

Test results for uncemented (Figure 3a) and lightly bound samples (Figure 3b) show that 1.5% cement addition increases twice the strength of tested samples that rises with the increase in confining pressure for each soil. The samples exhibit a gentle peak behaviour. The test results, presented in Figs. 3c-d, show the behaviour of the uncemented and cemented gravelly sand is changed by fibre addition. The peak strength and ultimate strength have increased whereas the initial strength is unchanged. The addition of fibres

proportionally changed the sample behaviour on more plastic and the maximum shear strength was obtained at greater relative strains.

Stiffness assessed by the E_{50} module decreases with fibre content (Tab. 1), both for uncemented and cemented samples. The addition of 1.5% cement practically does not improve it, which was also stated for greater cement addition (Du et al., 2020).

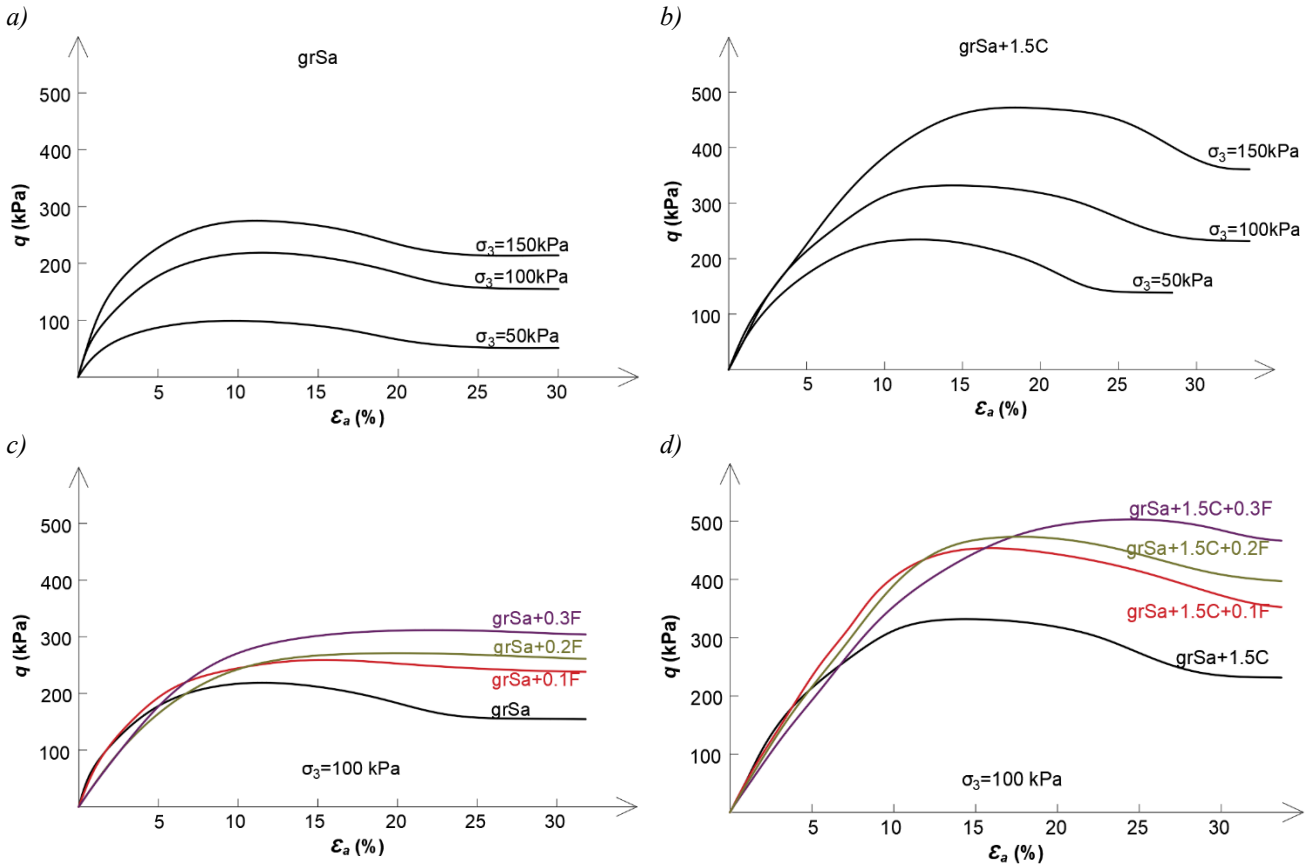

Figure 3. Results of CD triaxial tests shown as half of the deviator stress-strain curves for $\sigma_3' = 50$, 100 and 150 kPa for gravelly sand (a) and sand with 1.5% of cement addition (b), and 100 kPa for sand mix (c) and sand/cement with 0.1, 0.2 and 0.3% of fibres.

Table 1. Mechanical parameters of materials, where C – cement, and F – fibre content.

C	F	E_{50}	Shear strength parameters			
			Peak		Residual	
			ϕ'	c'	ϕ'	c'

The addition of cement and fibre improves shear strength parameters, both peak and residual (Tab. 1). Fibre content (0.1−0.3%) influences an increase of the effective angle of internal friction of natural grSa from 40.3° to 44.5°. In the case of stabilized soil, this increase is not so large and equals only 1.1°. Cohesion resistance grows significantly with the addition of fibres, both for natural and bounded materials. 1.5% of cement improves values of the angle of internal friction, but first of all – cohesion resistance.

Figure 4 shows various failure modes of samples damaged during the compression triaxial test. The sheared gravelly sand sample is characterized by the barrelling mode with a diagonal failure plane. The cement-bound soil failure mode is a typical single failure plane, obtained for semi-brittle material, whereas the plane of destruction in the uncemented and cemented samples improved with cement and fibre addition is close to horizontal. The horizontal failure plane signifies that fibre-reinforced material entered its plastic zone. In earlier research (Zabielska-Adamska et al., 2023b) carried out on grSa+1.5C with larger density (compacted by modified method) the

failure mode was vertical through failure plane as in the case of brittle material.

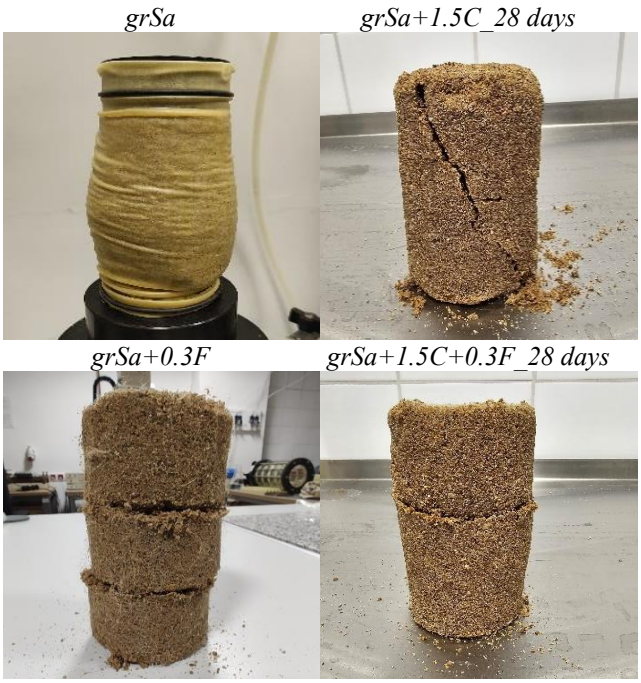

Figure 4. Views of sheared samples under $\sigma_3' = 100$ kPa.

4 CONCLUSIONS

1. The addition of 1.5% cement to gravelly sand increases peak and residual shear strength parameters, but practically does not impact on stiffness estimated by the E_{50} module.
2. Fibre reinforcement changes the behaviour of uncemented and slightly cemented gravelly sand. The peak and ultimate shear strength increased while the initial strength was the same. The peak and residual parameters increase, but the E_{50} module decreases.
3. The addition of 0−0.3% fibres regularly changed the behaviour of gravelly sand and its mix with cement on more plastic and where the peak strength was obtained at greater relative strain.

Evaluation of PFOS contamination in aquifers under single lined landfills

Evaluation de contamination d'aquifères par PFOS sous dépotoirs à revêtement composite singulier

ABSTRACT: Perfluorooctane sulfonic acid (PFOS) is among the most concerning types of a large group of compounds called per- and polyfluoroalkyl substances (PFAS). PFOS has captured significant attention due to its persistence in the environment and negative effects on human health. Landfills are a major source of PFOS to the surrounding aquifer and usually require composite liner systems for hydraulic and chemical containment. However, knowledge of the transport of PFOS through liner systems remains limited, and relevant numerical simulations are scarce. The paper reports an evaluation of PFOS contamination in the aquifer under a standard, single-liner, barrier system in a landfill, conducted using a 2D finite-element model of advective-diffusive PFOS transport. Three different levels of construction quality assurance (CQA) for the liner system are investigated. It's concluded that the advection process dominates PFOS transport through the liner system over molecular diffusion and mechanical dispersion. A considerable level of contamination for a scenario with excellent CQA indicates that a single composite liner may not be adequate to mitigate PFOS impact on an aquifer below or close to a municipal solid waste landfill.

RÉSUMÉ: Le perfluorooctane sulfonique (PFOS) est l'un des polluants les plus graves parmi le groupe des substances per- et polyfluoroalkyl (PFAS). Le PFOS a suscité l'intérêt en raison de sa persistance dans l'environnement et de ses effets néfastes sur la santé humaine. Les centres de décharge de déchets (dépotoirs) constituent une source majeure de PFOS pour les aquifères voisins et nécessitent un système de revêtement pour l'isolement hydraulique et chimique. Cependant, la connaissance de la migration du PFOS à travers les systèmes de revêtement des dépotoirs est limitée, et les simulations numériques du problème sont rares. Cette publication présente les résultats préliminaires d'une série de simulations en éléments finis en 2D du transport par diffusion-advection du PFOS à travers le dessous d'un dépotoir pourvu d'un revêtement composite singulier. Trois niveaux de qualité de construction de revêtement sont considérés. Les simulations tiennent compte des meilleures estimations de la distribution de probabilité des propriétés des matériaux, des variables environnementales et des taux de contaminants dans les déchets, afin de calculer des distributions de probabilité de la concentration maximale de PFOS dans l'aquifère. Les résultats des simulations révèlent que le processus d'advection est dominant par rapport à la diffusion moléculaire et à la dispersion mécanique. Le risque de contamination reste élevé, même dans un scénario de qualité de construction excellente, ce qui indique qu'un revêtement composite singulier n'est probablement pas suffisant pour protéger les aquifères situés sous les dépotoirs de déchets municipaux.

Keywords: PFOS; liner system; landfill; finite element method; construction quality assurance.

1 INTRODUCTION

Per- and polyfluoroalkyl substances (PFAS) are a diverse group of synthetic organic compounds with thermal stability, chemical inertness, and significant surfactant properties. They have been widely used since the 1950s in both consumer products and industrial applications (Renner, 2001), leading to their extensive detection in the environment, wildlife, and humans. Perfluorooctane sulfonic acid (PFOS, C_8F_{17}-SO_3H) is one of the most problematic PFAS compounds. Although the production of PFOS and its precursors ceased in the United States in 2002 (USEPA, 2000), PFOS remains notable in the environment due to its historical use (Paul et al., 2009),

continued precursor presence (Rhoads et al., 2008), and identification as an end product in PFAS environmental transformations (Bouazza, 2021). As the destination for most consumer products and industrial wastes containing PFAS, landfills are a major source of PFAS, including PFOS, to the environment. PFOS is widely detected in landfill leachates at ng/L to µg/L levels (Zhang et al. 2023). Meanwhile, the health advisory standard for PFOS in drinking water varies by jurisdiction, such as 70 ng/L for Australia (NHMRC, 2022), 600 ng/L set by Health Canada (2018), 4 ng/L set by the US Environmental Protection Agency (USEPA, 2023), and 100 ng/L for Europe (EurEau, 2018).

Geosynthetic composite liner systems are widely used in landfills to mitigate contamination and protect surrounding groundwater (Giroud and Bonaparte, 1989; Rowe, 1998, 2005, 2012; Rowe et al., 2004; Bouazza, 2002). A single composite liner system typically comprises a geomembrane (GMB), a geosynthetic clay liner (GCL) or a compacted clay liner (CCL), and an underlying attenuation layer. Hence investigating PFOS interactions with liner components to determine relevant material properties is necessary for evaluating PFOS's environmental impact in landfills equipped with liner systems.

While some studies have estimated key transport properties of PFOS in lining systems (Di Battista et al., 2020; Rowe et al., 2023; Rowe and Jabin, 2021; Bouazza, 2021; Schaefer et al., 2019), there have been very few attempts to numerically simulate the migration of PFOS in a liner system, partly because of limited data.

Rowe and Barakat (2021) examined the transport of PFOS in a municipal solid waste landfill lined by a single composite liner, which was numerically analysed using a 1½-D model finite-layer method (Rowe and Booker, 1984, 1985; Rowe et al., 1997; Rowe and Booker, 2004; Rowe and Abdelrazak, 2019) which considered the downward advective-diffusive-dispersive migration through periodically spaced wrinkles to an aquifer that was modelled as a boundary condition with horizontal flow. It was concluded that the no-leakage, pure-diffusion case can in principle maintain acceptable concentrations in the aquifer. However, with leakage through a reasonable number of holes in the geomembrane for landfills with a single liner system containing significant concentrations of PFOS in the leachate, there was likely to be a significant impact on a shallow underlying aquifer.

The present study uses a 2D finite element method (FEM) model to simulate the leakage of leachate and the migration of PFOS through a typical single-liner system while considering the full 2D effects of a series of leaks in the lining system.

The primary advantage of a 2D model over the 1½-D model used by Rowe and Barakat (2021) is the ability of the 2D model to examine migration downgradient of the landfill and the impact of monitoring points away from the landfill.

2 METHOD

2.1 Problem description

The 2D model of a municipal solid waste (MSW) landfill simulated in the study is shown in Figure 1, where PFOS transport involving both advection and diffusion occurs. The landfill is 400 m long in the direction of flow in the underlying aquifer and 100 m wide in the direction normal to the plane of the diagram. The landfill base is equipped with a single composite liner which is comprised of a 1.5 mm-thick HDPE GMB, a 7 mm-thick GCL, above a 3.743 m-thick attenuation layer (AL) and a 3 m-thick aquifer (AQ). The combined thickness of the clay liner and attenuation layers is selected according to MoE (1998). If the unlikely condition of no defects on GMB is assumed, the advective PFOS transport is eliminated and the leakage rate q_a is nil, giving a pure-diffusion problem. Selected input variables related to material properties, dimensions, and boundary conditions have been estimated, and are shown in Table 1.

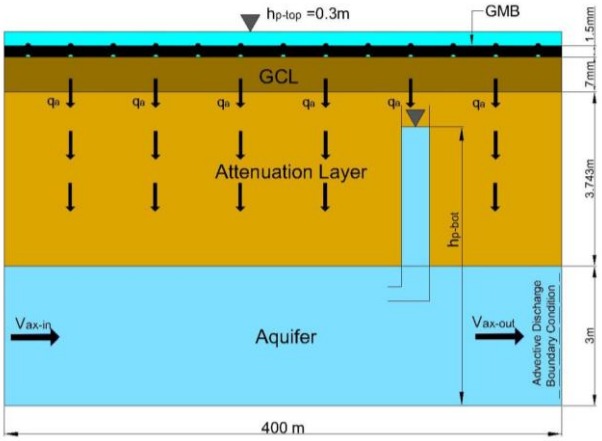

Figure 1. Schematic of the liner-subsoil system for "good CQA and with ELLS": holed wrinkles of 325 m/ha, corresponding to 13 leaks per 400 m. Not to scale.

Input parameters used in the simulations have been obtained based on an extensive review of the literature, data study and expert judgement. In addition, calibration on data from landfill cells where there is good construction quality assurance (CQA) and a dipole method electrical leak location survey (ELLS) gave an estimation of 325 m/ha for the holed wrinkle length per hectare (Rowe and Zhao, 2023). Two other levels of CQA are also investigated in this study, i.e.,

"good CQA and no ELLS" corresponding to 475 m/ha and "excellent CQA" corresponding to 75 m/ha.

Table 1. Input parameters.

Parameters	Symbols	GM estimations
Total hydraulic head drop across the model	ΔH	1.05 m
Length of holed wrinkle per hectare for "good CQA & no ELLS", "good CQA & with ELLS", and "excellent CQA"	L_w	475 m/ha, 325 m/ha, and 75 m/ha
Wrinkle width	$2b$	0.2 m
PFOS concentration in landfill leachate	C_0	900 ng/L
PFOS mass per unit waste mass	p_0	1800 ng/kg
Inward horizontal groundwater Darcy velocity in the aquifer	$V_{ax\text{-}in}$	0.95 m/a
Transmissivity	θ	1.0315×10^{-3} m^2/a
Hydraulic conductivity of GCL in contact with GMB	k_a	9.4×10^{-4} m/a
Hydraulic conductivity of GCL below holed wrinkles	k_b	7.52×10^{-3} m/a
Hydraulic conductivity of AL	K(AL)	1×10^{-7} m/s
Dispersivity of AL	α(AL)	0.052 m
Transverse dispersivity of AQ	α_T(AQ)	0.1 m
Longitudinal dispersivity of AQ	α_L(AQ)	2 m

2.2 Analysis method

The migration of PFOS within the investigated landfill model occurs in tandem with the flow of leachate, which is governed by the semi-coupled steady-state saturated water flow equation and time-dependent reactive diffusion-advection equation (RDAE) representing the transport of solutes. A specified mass of PFOS is applied at the top of the model's domain hence allowing for decline of PFOS concentration in the waste as is removed through leachate drainage and/or migration into the subsurface. The numerical simulations are conducted using the Soil Pollution Analysis System (SPAS), a multi-purpose finite-element method simulation software specifically tailored to lining systems (El-Zein, 2008; El-Zein and Balaam, 2012). Maximum concentration of PFOS anywhere in the aquifer, at any time, C_{max}, is computed by SPAS and used to characterise the level of contamination. The point in space and time at which maximum concentration is found is given by x_{max} and t_{max} (low transverse dispersivity in the aquifer leads to low dispersion of contaminants in the vertical direction and hence contaminants reaching the aquifer largely remain at the upper aquifer and reach their maximum concentrations at the top).

3 RESULTS AND DISCUSSION

Table 2 summarizes results of the simulations. C_{max} for the pure-diffusion case is 0.55 ng/L (occurring at 580 years), which is around two to three orders of magnitude lower than those of the advection-diffusion cases and occurs at much later time (Table 2). Such a contrast suggests that advection is the dominant process in PFOS transport through the liner system and causes the vast majority of its impact in the aquifer, while diffusion has a much smaller effect. Meanwhile, comparing the C_{max} value of 0.55 ng/L to four drinking water standards, namely 4 ng/L (USEPA), 70 ng/L (Australia), 100 ng/L (Europe), and 600 ng/L (Canada), indicates that a single-liner system with an intact GMB may serve as an effective barrier to PFOS.

Table 2. Summary of leakage rate and PFOS contamination.

Case	L_w (m/ha)	q_a (Lphd)	C_{max} (ng/L)	t_{max} (yr)	x_{max} (m)
Pure diffusion	0	0	0.55	580	400
Good CQA and no ELLS	475	300	508	145	391
Good CQA and with ELLS	325	197	403	155	386
Excellent CQA	75	46	176	145	335

However, even with high-quality ELLS and an excellent CQA, holed wrinkles in the GMB are inevitable, hence generating both advection and diffusion. Some landfills are designed with the leachate level below the potentiometric surface in the underlying aquifer which induces a "hydraulic trap" (Rowe, 1988; Rowe et al., 2000, 2004). In these cases, the flow through the holes in the geomembrane will be inward. However, when the leachate level is above the potentiometric surface in the underlying aquifer, leakage through holes will be downward. It is this latter case that is examined in this paper.

Figure 2 shows the horizontal variation in concentration at the top of the aquifer at 150 years. The overall rising trend of concentration is mainly attributed to the PFOS transport caused by the horizontal groundwater flow. Meanwhile, the "waves" in curves reflect the effect of leakage spikes under GMB defects.

Figure 3 shows PFOS concentration versus time at the point of highest concentration in the aquifer below the landfill. Contamination levels in the aquifer first increase to a peak before gradually declining. Under

the premise of good CQA, applying ELLS reduces the density of defects on the GMB, the leakage rate (q_a, reducing from 300 Lphd to 197 Lphd), and the peak PFOS concentration in the aquifer (C_{max}, declining from 508 ng/L to 403 ng/L). Under an excellent CQA, q_a and C_{max} will be reduced to 46 Lphd and 176 ng/L, respectively. This indicates that, as expected, a higher level of CQA can contribute to limiting PFOS contamination in the aquifer.

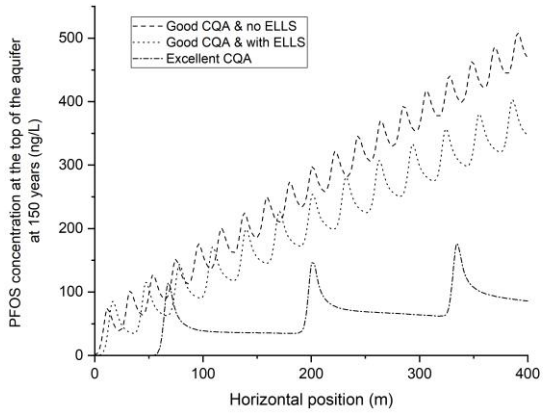

Figure 2. Change in PFOS concentration at the top of the horizontal direction in the aquifer at 150 years.

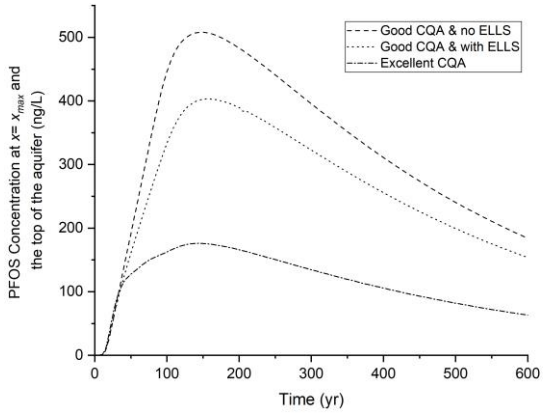

Figure 3. PFOS concentration over time at x= x_{max} and the top of the aquifer.

However, in all 3 cases considered, C_{max} remains higher than some of less stringent standards (i.e., 70 ng/L for Australia and 100 ng/L for Europe), and significantly higher than the strictest ones (4 ng/L for USEPA). Even the most lenient standard (600 ng/L for Canada), is approached by C_{max} under a good CQA. This is consistent with and adds support to the findings of Rowe and Barakat (2021) and suggests that single lining systems, even under high quality construction, may not be sufficient to protect groundwater from PFOS contamination under landfills unless the PFOS concentration in the landfill is substantially lower than that assumed or there is a substantially higher level of natural attenuation than that considered in this study. However, the simulations presented here are based on deterministic analyses for a single representative case under various assumptions of construction quality. In reality, there is significant uncertainty in input data and a more thorough assessment of the adequacy of different lining systems needs to take these uncertainties into account.

4 CONCLUSIONS

This study is the first to conduct a 2D finite element simulation of PFOS migration through landfills with a single composite lining system into underlying aquifers. The study's findings must be qualified by a number of limitations. These include the assumption of steady-state flow and full saturation, no adsorption or biodegradation of PFOS, and input parameters obtained based on limited information.

Despite these limitations, the study's key finding is noteworthy, indicating that, while high construction quality reduces the contamination level, single lining systems in MSW landfills may not be sufficient to prevent PFOS contamination in aquifers. Further investigations are required to assess the necessity of double composite lining systems to mitigate PFOS contamination in similar contexts. In addition, it is important to take into account data uncertainty in future analyses by estimating probability distributions of key input variables and conducting probabilistic simulations of PFOS contamination.

Effect of saturation conditions on thermal properties of sands

Effet des conditions de saturation sur les propriétés thermiques des sables

Z. Zhou*, A. Diambra, T. Liu

ABSTRACT: Soil thermal conductivity, diffusivity and heat capacity are critical parameters that govern the design of specific geotechnical infrastructure including energy piles, high-voltage cables and pipelines. The presence and flow of water are of particular importance as it dominates the conduction and convection hear transferring mechanisms, leading to a global increase in heat conduction ability by replacing air within the multi-phased soil system. This paper presents preliminary results from an experimental programme that aims to characterise the effects of saturation conditions on the thermal properties of a siliceous sand. Thermal conductivities were investigated for samples prepared to varied relative densities and degrees of saturation by two methods: (I) sand-water mixed at specific water contents and moist-tamped in moulds to the target densities; (II) cycles of wetting-draining applied to initially dry specimens through a customised test set-up. Thermal needles were employed that trigger transient heat source and monitor temperature variations. Significant differences were observed in the thermal conductivities between the Method I specimens and the Method II specimens in the first saturation stage. However, the differences diminished in the subsequent infiltration cycles. Overall, the results confirmed strong dependency of sand's thermal conductivity on saturation conditions as the presence of water envelopes and bridges sand particles in heat conduction.

RÉSUMÉ: La conductivité thermique, la diffusivité et la capacité thermique du sol sont des paramètres critiques qui régissent la conception d'infrastructures géotechniques spécifiques, notamment des pieux énergétiques, des câbles haute tension et des pipelines. La présence et le flux d'eau revêtent une importance particulière car ils dominent les mécanismes de transfert de chaleur par conduction et convection, entraînant une augmentation globale de la capacité de conduction de la chaleur en remplaçant l'air au sein du système de sol multi-phasique. Cet article présente les résultats d'un programme expérimental visant à caractériser les effets du degré de saturation sur les propriétés thermiques du sable siliceux. La conductivité thermique a été étudiée sur des échantillons préparés à des densités relatives et des degrés de saturation variés selon deux méthodes: (I) mélange de sable et d'eau à des teneurs en eau spécifiques, tassé humide dans des moules jusqu'aux densités cibles; (II) cycles d'humidification-drainage appliqués à l'aide d'un dispositif d'essai personnalisé. Les conductivités thermiques des échantillons ont été mesurées par des aiguilles thermiques déclenchant une source de chaleur transitoire et surveillant les variations de température. Des différences significatives ont été observées dans les conductivités thermiques des échantillons de la Méthode I par rapport à ceux de la Méthode II lors de la première étape de saturation. Cependant, ces différences se sont atténuées au cours des cycles d'infiltration ultérieurs. Dans l'ensemble, les résultats du programme d'essais préliminaires confirment une forte dépendance de la conductivité thermique du sable aux conditions de saturation et à la présence du film d'eau qui enveloppe et relie les particules de sable dans la conduction de chaleur.

Keywords: Thermal conductivity; saturation condition; high-voltage cables; porous media.

1 INTRODUCTION

Soil thermal properties dictate the storage and movement of heat in soils (De Vries, 1963) and govern heat transfer processes in various applications, including oil and gas pipelines, buried high-voltage (HV) electrical cables, agriculture, shallow geothermal system, thermal energy storage and nuclear waste disposal facilities (Gera et al., 1996; Malek et al., 2021; Nixon et al., 1991; Zhang and Wang, 2017). Thermal conductivity of soils is affected by a range of variables, for examples mineralogy, density, stress level and saturation conditions. The degree of saturation is a also crucial factor as it affects the transition of heat transfer from the solid phase to the liquid phase and the coupled process of heat conduction and moisture movement under various temperature gradients (Farouki, 1981).

Characterising thermal properties of partially saturated soil is crucial for onshore HV cables (Salata et al., 2015) and the landing parts of offshore HV cables, especially in regions where water tables may fluctuate daily or seasonally. Systematic investigation of soil's thermal conductivities in these application scenarios is required. This paper reports preliminary findings from an experimental programme that

investigates the impact of sample formation and saturation methods, wetting-draining cycles, and water level fluctuation on the thermal conductivity of granular soils.

2 MATERIAL AND METHODS

2.1 Soil tested

Leighton buzzard fraction B sand was used for this testing programme. It features a mean grain size d_{50} = 0.88 mm, coefficient of curvature C_c = 1, coefficient of soil uniformity C_u = 1.88, specific gravity G_s = 2.65, maximum and minimum void ratios e_{max} = 0.84 and e_{min} = 0.53, respectively (de Leeuw et al., 2021).

2.2 Sample preparation Method I

Method I for sample preparation was based on the conventional moist tamping method. Sand and water were mixed thoroughly at target water contents and filled in five layers into a cylindrical mould with an internal diameter of 50 mm and height of 130 mm. Each layer was tamped to achieve target void ratio and relative density. The adopted sample size followed the recommendation by ASTM (2022) and was compatible with the size of the thermal needle (2.4 mm diameter and 100 mm length) employed in the study (details see Section 2.4).

2.3 Sample preparation/saturation Method II

This method employed moulds of the same size as used in Method I. The specimen was initially prepared by pluviating dry sand to a target void ratio (relative density). Subsequently, water was percolated from the specimen base, and multiple saturation-desaturation cycles were applied through the inflow and outflow reservoirs, as shown in Figure 1. Specimen mass and its variations were measured by a digital balance placed beneath the sample, enabling continuous monitoring of the specimen's global water content and degree of saturation. In contrast to Method I, Method II enabled the application of wetting-draining cycles and simultaneous thermal conductivity measurements.

2.4 Equipment and test programme

The conventional transient thermal needle method was adopted in this study. The thermal unit was consisted of a single thermal needle (TR-3) and the TEMPOS thermal analyser supplied by the METER Group. The equipment allows thermal conductivity measurements in the range of 0.1-4 $W \cdot m^{-1} \cdot K^{-1}$ with an accuracy of ±10%. A 3-D printed top cap was designed to guide the needle's penetration from the centre of the specimen's top surface. Silicon grease was applied to the needle surface to enhance its contact with soil particles and improve the needle's sensitivity in capturing temperature variations (ASTM, 2022). Thermal tests were performed directly on the specimens prepared by Method I. Combinations of four relative densities (0%, 25.8%, 51.6%, 77.4%) and five degrees of saturation (0, 10%, 20%, 50%, 100%) were explored. The specimens prepared by Method II covered the same relative densities as those in Method I but with finer considerations of the degree of saturation.

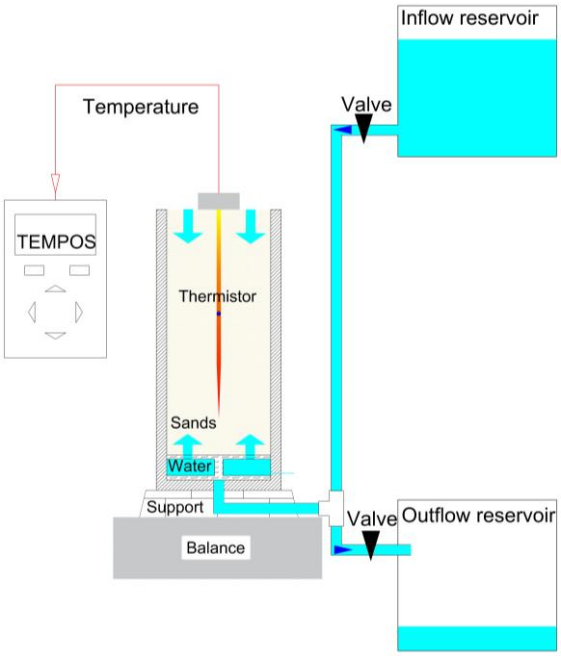

Figure 1. Schematic representation of the Method II set-up.

3 RESULTS AND DISCUSSION

3.1 Results from Method I

Figure 2 shows the variations of thermal conductivity against the degree of saturation (S_r) for the sand specimens prepared with Method I. Nominal trends are indicated with dashed straight lines. Under identical saturation level, specimens prepared at the lowest relative density, D_r = 0% ($e = e_{max}$) manifested lowest thermal conductivities. Higher-density specimens develop greater particle contact areas and therefore greater heat conduction capacity (Abu-Hamdeh, 2003). Sharp increases in thermal conductivity can be observed over the low S_r (<10%) range, followed by gradually increasing trends as S_r increased further.

The observed trends corroborate previous findings by Smits et al. (2010). Water surrounding sand particles enhances heat conduction through connected water channels, which act as a conduit for heat

exchange, noting the thermal conductivity of water (≈0.598 $W \cdot m^{-1} \cdot K^{-1}$) is significantly greater than that of air (≈0.02 $W \cdot m^{-1} \cdot K^{-1}$) (Aljundi et al., 2024). As the degree of saturation increased further, thermal conductivities rose only modestly as the main substitution processes of air by infilling water were largely completed at this stage.

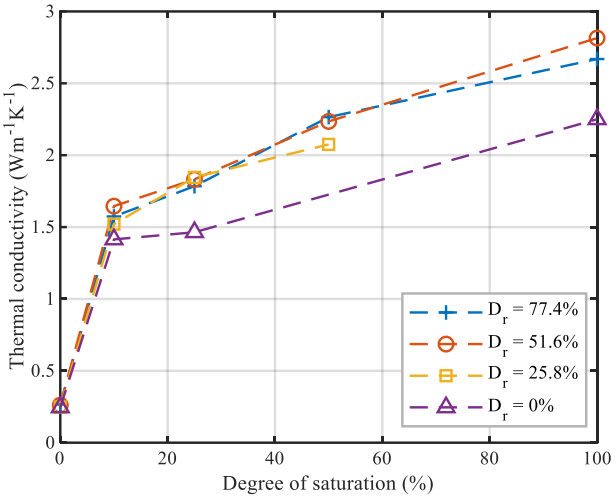

Figure 2. Measured thermal conductivities against degrees of saturation for specimens prepared by Method I.

3.2 Results from Method II

Figure 3 plots thermal conductivities against apparent degrees of saturation (S_r^*) for specimens prepared with Method II. Noting the progressive change in water level during the wetting-draining cycles and the non-uniform nature of the saturation process (especially in the 1st injection stage), apparent degrees of saturation (S_r^*) were computed based on the mass variations measured by the scale to represent the specimens' global saturation states.

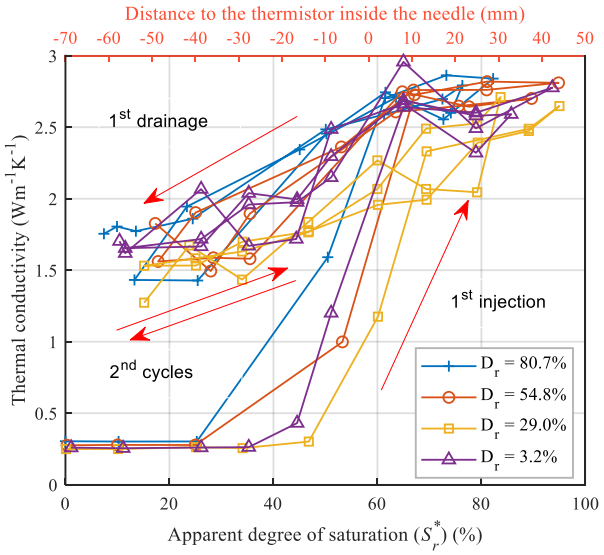

Figure 3. Measured thermal conductivities in two wetting-draining cycles for specimens prepared by Method II.

Figure 3 also plots on the upper x-axis distances between the estimated water levels and the thermistor positioned in the middle of the needle (see Figure 1) during the wetting-draining cycles. Water levels were approximated by assuming full saturation in the wetted zones, neglecting any capillary rise for the relatively coarse-grained uniform (d_{50} = 0.88 mm and C_u = 1.88) sand tested. Much more uniform distributions of water were expected in the subsequent draining-re-wetting cycles.

The measured thermal conductivities in the 1st percolation stage primarily relied on the water level relative to the thermistor. As water percolated into the lower part of the initially dry specimen, the water level remained below the thermistor level. The apparent degree of saturation (S_r^*) remained relatively low (< 30%) and the measured thermal conductivities largely represented those of dry specimens. Marked increases in thermal conductivities occurred as the water level ascended and S_r^* increased further to ≈70%.

Consistent and broadly linear trends can be observed in the subsequent desaturation and re-saturation cycles over the S_r^* range of 10-70%. Thermal conductivities appear to reach plateaux as S_r^* exceeded 70%. It is noted that natural gravity cannot de-saturate the specimens further to S_r^* <10% due to the presence of residual water.

An advanced multi-needle system is being developed at the University of Bristol that captures the distribution and evolution of thermal conductivity in unsaturated sands accurately.

3.3 Comparative analysis

Trends of thermal conductivity for the specimens prepared with Methods I and II are compared in Figure 4 for the first saturation stage and Figure 5 for the subsequent draining-wetting stages. Markedly different patterns are evident under relatively low S_r (or S_r^*) conditions of <60%. The results become more consistent under higher and more uniform saturation conditions in which the needle sensor was sufficiently immersed. Further increases in S_r^* resulted in relatively minimal increases in thermal conductivities, regardless of the specimen preparation method used.

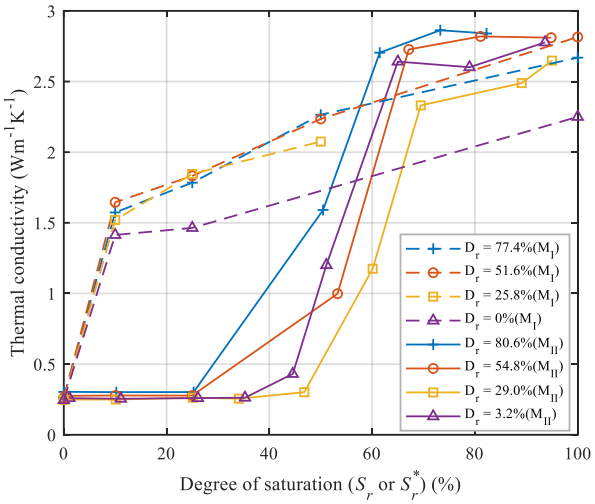

Figure 4. Comparison of measured thermal conductivities in the first saturation stage.

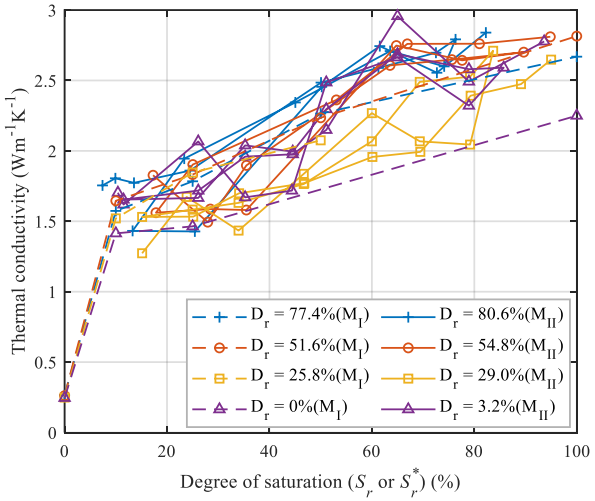

Figure 5. Comparison of measured thermal conductivities in the subsequent wetting-drying stages.

Compatible trends were observed in the subsequent wetting-drying cycles, despite the different specimen formation and saturation procedures employed (Figure 5). Saturating histories appear to yield only minor effects. Sand's thermal conductivity is primarily affected by its degree of saturation, although the water percolation process and any thermal coupling effects may also result in variations in the thermal conductivities of specimens prepared by Method II.

4 SUMMARY AND CONCLUSIONS

This paper presents preliminary results from an experimental programme designed to investigate the effects of saturation conditions on the thermal conductivity of silica sands. Two specimen preparation and saturation methods were employed: (a) a conventional method mixing sand and water at specified water content and tamping to target relative density; and (b) a customised experimental set-up that applied wetting-draining cycles and monitored water inflow and outflow. The measured thermal conductivities for the two methods exhibited significant disparities in the first saturation stage but became much more compatible in the subsequent de-saturation and re-saturation cycles. Further experimental study using an advanced multi-needle system is underway to investigate the potential effects of large number of wetting-draining cycles as well as coupled conduction-convection heat transfer process.

Validation of a sulfide soil landfill numerical model

Validation d'un modèle numérique de décharge pour sols sulfurés

ABSTRACT: Due to their silty texture and high organic content, sulfide soils are typically unsuitable for use as a foundation for construction projects. In most cases, excavation and replacement with other construction materials are needed to ensure the structural integrity of building or infrastructure. Landfills are commonly used for the disposal of excavated sulfide soil. Because of the chemical properties of these soils and the risk of acidification, these landfills need to be kept saturated to limit oxygen diffusion. However, the long-term behaviour of these landfills is not yet fully understood, highlighting the need for further research to investigate the fluctuation of the degree of saturation in the soil, under different conditions. This study examined the effect of seasons on the degree of saturation in sulfide soil landfills and its effect on oxygen transport. The objective of the current study was to validate a numerical model of a sulfide soil embankment, done using SEEP/W software, with data from the monitoring of a sulfide soil landfill, in Northern Sweden. A one-dimensional numerical model of the landfill was created using laboratory measurements of hydraulic conductivity and water retention capacity. This model was then validated by comparing it with data from installed sensors. The numerical model accurately predicted the degree of saturation changes over time in the landfilled soil. These findings allow engineers to optimize design and predict long-term performance under different environmental conditions. The study highlights the importance of numerical modelling in predicting long-term hydrological behaviour and offers valuable insights into sulfide soil landfill behaviour.

RÉSUMÉ: En raison de leur texture limoneuse et de leur forte teneur en matière organique, les sols sulfurés sont généralement inadaptés dans les fondations des projets de construction. Dans la plupart des cas, il est nécessaire de les remplacer par d'autres matériaux de construction pour garantir l'intégrité structurelle des bâtiments ou des infrastructures. Les sols sulfurés excavés sont couramment mis en décharges. En raison de leur propriétés chimiques et du risque d'acidification, il est nécessaire de maintenir ces décharges saturées pour limiter la diffusion de l'oxygène. Cependant, le comportement à long terme de ces décharges n'est pas encore pleinement compris, soulignant la nécessité de recherches supplémentaires pour étudier leurs fluctuations du degré de saturation dans différentes conditions. Cette étude a examiné l'effet de la consolidation et des saisons sur le degré de saturation des décharges de sol sulfuré, avec un accent particulier sur le transport de l'oxygène. L'objectif de cette étude était de valider numériquement un modèle de digue en sol sulfuré en utilisant le logiciel SEEP/W, avec des données provenant d'une installation de capteurs dans une décharge de sol sulfuré, dans le nord de la Suède.Un modèle numérique unidimensionnel de la décharge de sols a été créé en utilisant des mesures de laboratoire de la conductivité hydraulique et de la capacité de rétention d'eau. Ce modèle a ensuite été validé en le comparant aux données des capteurs installés.L'étude a montré que le modèle numérique prédisait avec précision les variations du degré de saturation au fil du temps dans le sol. Ces résultats permettent aux ingénieurs d'optimiser la conception des digues et d'en prédire les performances à long terme dans différentes conditions environnementales. L'étude met en évidence l'importance de la modélisation numérique pour prédire le comportement hydrologique à long terme et offre des informations précieuses sur le comportement des décharges de sol sulfuré.

Keywords: Sulfide soil landfill; numerical modelling; SEEP/W; saturation degree; oxygen transport.

1 INTRODUCTION

Sulfide soil contains high concentrations of mainly iron sulfides (e.g., pyrite). These minerals naturally occur in certain geological formations found worldwide, including tropical regions, Australia, and coastal areas of Sweden and Finland. Disturbing these soils through excavation or construction exposes the sulfide minerals to oxygen, leading to oxidation. This can create acidic conditions, lowering soil pH which leads to dissolved sulfate and metals released into water bodies, impacting aquatic life and infrastructure.

Sulfide soils are often silty and water-rich, and pose risks of settlement, soil failure, and frost heave in cold

regions. Therefore, they are often excavated and replaced with more construction-suitable soil types. The urbanization and construction of infrastructure in sulfide soil regions in sweden have heightened the demand for soil management alternatives e.g. disposal. Due to the soil's chemical properties, its disposal is complex, requiring measures to prevent oxidation and acidification. Hence, these soils must be deposited while remaining saturated to prevent environmental hazards.

Creating optimal conditions for sulfide soil is expensive and restricts landfill capacity. To expand landfill capacity and prevent oxidation, it is vital to understand the hydrological properties of sulfide and silty soils in unsaturated conditions. Some software, including one-dimensional (1-D) and two-dimensional (2-D) flow models, have been employed to help in the design and evaluation of soil covers such as VADOSE/W and SEEP/W(Song & Yanful, 2008). SEEP/W has been commonly used to simulate water infiltration in unsaturated systems e.g. (Aubertin et al., 2009; Bréard Lanoix, Pabst, & Aubertin, 2017; Bussière, Aubertin, & Chapuis, 2003; Cifuentes, Aubertin, Chapuis, Bussière, & Molson, 2006; Fala, 2003; Gwendoline, Bruno, Pabst, Émilie, & Roy, 2020; Martin, 2003).

This study aims to predict the behaviour of sulfide soil landfills under various conditions and identify short and long-term influencing parameters by validating a numerical model using SEEPW with on-site measurement data.

2 MATERIAL AND METHODS

2.1 Description of test plots

The test area is a sulfide soil landfill where fresh soil was recently deposited. A 60 cm layer of till covers the entire site, while the depth of the sulfide soil deposition exceeds 3 metres (Figure 1).

2.2 Field measurements

The installation of sensors for measuring temperature, water matric potential (WP), and volumetric water content (VWC), was carried out in the sulfide soil layer and cover in May 2022. Table 1 lists the depth of installation of instrumentation. It is important to note that additional sensors were installed in this case study; however, the data from these additional sensors has not been presented in this paper.

2.3 Finite element modelling

Hydrogeological numerical simulation was conducted using SEEP/W 2021. The sulfide soil landfill analyzed in this study is composed of two primary layers (cover and sulfide soil) based on the test plot. Specifically, the cover layer surface is represented as a distinct 60 cm layer with a finer mesh to reduce convergence challenges when modelling infiltration events into the arid ground, and to incorporate the impact of surface drying and desiccation.

In this study, the measured data from sensors were employed to verify the numerical model. The initial case was the same as the test plot case to verify the performance of the numerical model.

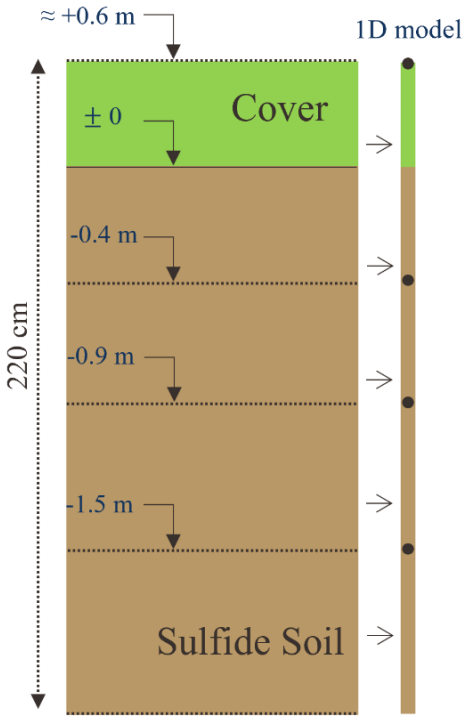

Figure 1. Soil layers and 1D model.

Table 1. Sensor installation position.

Layer	Depth (m)	Monitoring points	Sensors
Cover	≈ +0.6	Point 1	VWC & WP
	+0.1	-	
Sulfide soil	-0.1	-	
	-0.4	Point 2	VWC
	-0.9	Point 3	VWC
	-1.5	Point 4	WP

2.4 Input data

When conducting simulations of soil layers using SEEP/W software, it is essential to ensure that all necessary input data is included in the model. These input data including material properties, boundary conditions, and initial conditions are critical to the accuracy and reliability of the simulation results.

2.5 Material properties

The material properties of the soil layers must be accurately defined, including soil water characteristics curve (SWCC), and hydraulic conductivity. These parameters will play a significant role in determining the flow of water within the sulfide soil layers. The SWCs of material including air entry value (AEV) were derived from a pressure plate test conducted in the laboratory for the material used for the test plot. The SWCCs were fitted with theoretical curves using Van Genutchen model.

The saturated hydraulic conductivity (HC) was measured using permeability tests. The results then were used to predict unsaturated hydraulic conductivity using SEEP/w. The unsaturated hydraulic conductivity function is challenging to measure directly, and prediction methods are commonly used instead. In this study, Van Genutchen model was used to estimate unsaturated hydraulic conductivity of soil as a function of matric suction. The material properties used in the numerical modelling are summarized in Table 2.

Table 2. material properties.

Soil	Porosity	AEV (kPa)	HC (m/s)
Cover	0.3	50	10^{-7}
Sulfide soil	0.4	20	$5e10^{-7}$

2.6 Boundary and initial condition

The boundary and initial conditions must be properly defined to provide a comprehensive understanding of the water flow into and out of the soil layers. A Land Climate Interaction (LCI) boundary condition was applied to the top of the domain. The LCI boundary condition requires weather information, including air temperature, relative humidity, wind speed, and precipitation, which is essential for calculating infiltration and flux in the system caused by rainfall, snowmelt, evaporation, etc. This data was obtained from the Swedish Meteorological Institute website using a weather station at Umeå airport from May 2022 to September 2023. The bottom boundary was considered an open boundary condition, representing both inflow and outflow of water, depending on the local hydraulic gradients and other boundary conditions. The initial water table level was set at the cover surface level, and all soil layers were considered fully saturated at the first step of the simulation. This assumption was based on the water level measured at the site and measurements from samples taken from the site. The saturation water content was determined based on the maximum and minimum density of the soil at the site.

3 RESULTS

The study presents data collected between May 2022 and September 2023, which were used to evaluate the validation of a numerical model simulation for a sulfide soil landfill. The data consist of soil layer temperature, volumetric water content, and water flux in the soil layers. To compare the simulation results with measured data, three sensors were selected at points 1, 2 and 3 for volumetric water content and temperature and two sensors (point 1 and 4) for water flux to compare results from the numerical model and landfill case study, as indicated in *Table 1*.

In Figure 2, a comparison is made between temperatures in different soil layers and the air temperature. Notably, the temperature in the soil layers did not drop below freezing, despite sub-zero air temperatures during the winter. This phenomenon is attributed to the insulating effect of snow covering the soil surface, which prevents the soil layers from freezing. This observation is crucial when considering the potential impact of frost depth on the hydraulic conductivity of the soil layers and water flow. Figure 3 presents a comparison between measured and numerically calculated volumetric water content. Initially, differences in the results were observed due to sensor placement in disturbed soil following the excavation of a ditch in the soil layers to be able to install sensors. This led to significant fluctuations in soil volumetric water content.

Over time, the system reestablished equilibrium, and the results of the numerical model began to align with the observed trend. It is shown that during winter when the soil surface was covered by snow the soil layers, including sulfide soil remained saturated.

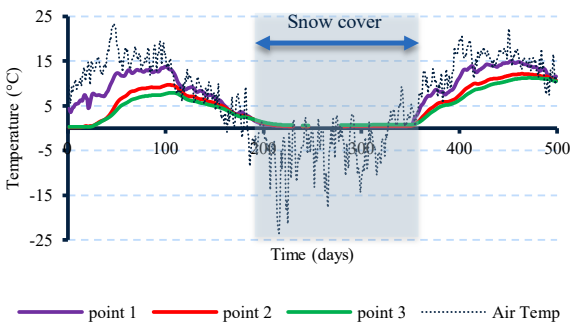

Figure 2. Comparing soil layer temperatures to air temperature.

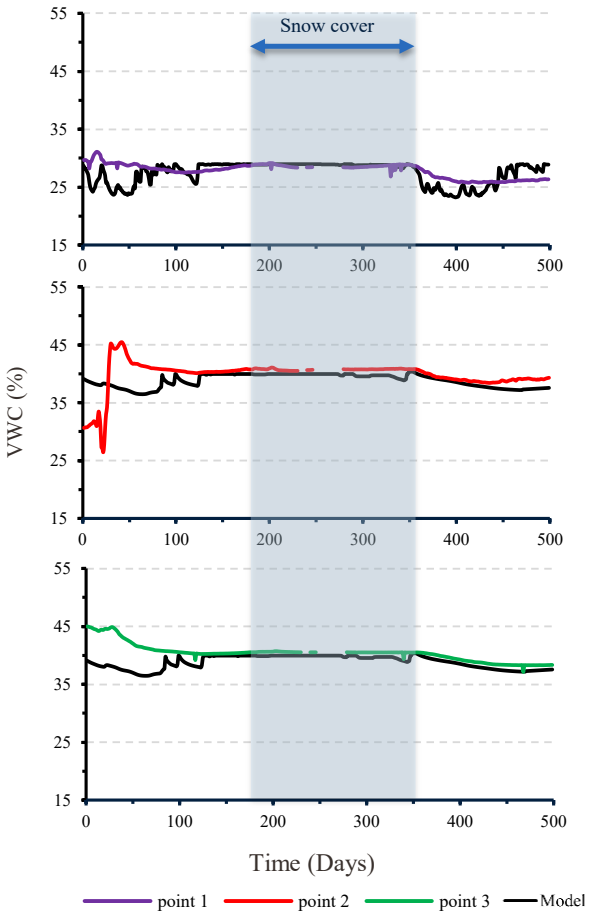

Figure 3. comparison measured and predicted VWC.

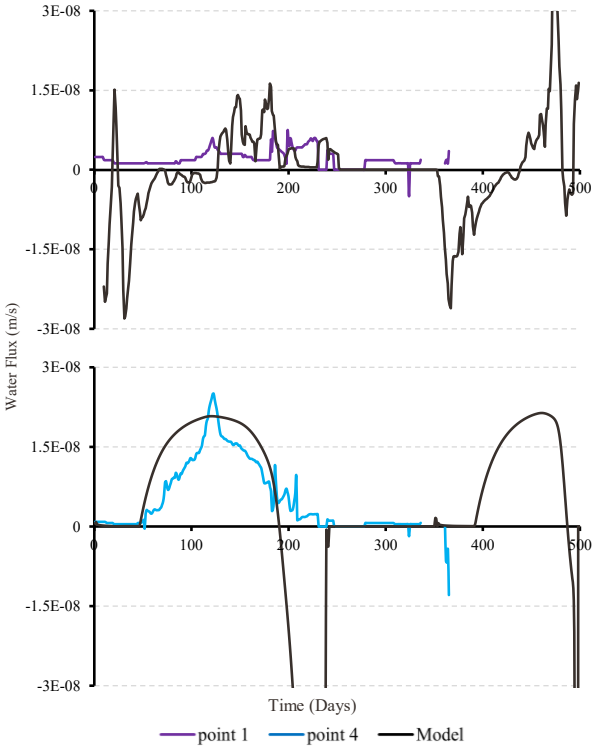

Figure 4. comparison measured and predicted water flux.

Figure 4 provides a depiction of water flux at specific points within the soil layers. These graphs are based on data recorded by water potential sensors. Unfortunately, these sensors only collected data for approximately 400 days, and not for the entire monitoring period until September 2023. Fluctuations in water potential reflect the dynamic movement of water into and out of a system. An increase in water potential signifies water entering or becoming more available within the system, often due to factors like rainfall, irrigation, or root water uptake. Latter is not the case in this specific case. Conversely, a decrease in water potential indicates water leaving the system, through processes such as evaporation, transpiration, or drainage. Water flux based on water potential can be calculated using Darcy's Law, where the flux equals the product of hydraulic conductivity and the negative gradient of water potential, providing a straightforward method for comparison between software outputs and calculated water flux values.

Water movement direction is indicated by positive or negative flux values in this paper. Positive flux signifies water moving towards the surface, such as during summer from days 0 to 200 due to higher temperatures and evaporation. With lower temperatures and autumn precipitation starting from day 120 to 200, the positive flux decreases, indicating slower water flow towards the surface and less water exiting the system. Negative flux denotes water moving away from the surface, potentially due to precipitation and snow melting in the springtime beginning from day 400. During the snow season, roughly between days 250 to 350, the flux is zero, likely due to snow covering the soil surface and preventing water from entering or leaving the system. Initial discrepancies between measured and predicted data may result from soil disturbance during sensor installation, but consistency improves over time, particularly between days 50 and 200.

At Point 4, there is a negative flux predicted just before the snow season, which is not reflected in the measured data. Similarly, there is negative flux occurring between approximately after snow season, which is also not found in the predicted data. In summary, differences exist between the measured data and the results of the numerical modelling.

These differences can be explained by the position of the water table and its fluctuations. However, it's important to note that the available data on water table fluctuation at the site is limited and hasn't been integrated into the model. Additionally, the properties of the soil are closely related to its density and water retention capacity. For this specific soil, further tests are necessary to measure its water retention capacity and hydraulic conductivity at various densities. The

changes in density over the monitoring period are also unknown. To enhance the accuracy of the model's predictions, it is beneficial to determine the consolidation properties of this soil and assess potential changes over the monitoring period.

Finally, it's crucial to acknowledge that the climate data used in this model is not specific to the site. Differences in temperature, precipitation, and other climate variables may introduce variations that impact the modelling results.

4 CONCLUSION

This study aimed to validate a numerical model for a sulfide soil landfill, with the objective of enhancing understanding of water movement and seepage in sulfide soil layers. The goal was to predict the behavior of these soil layers over an extended period. The numerical model successfully predicted the volumetric water content in various layers of the sulfide soil landfill. Additionally, the study compared the results of water flux from both measured and predicted data.

This comparison revealed that, although the prediction results came close to estimating the flux in the soil layers, disparities between the measured and improved data were evident. These differences may be attributed to inaccuracies in material properties, climate data, and the fluctuations of the water table under real conditions. To enhance prediction accuracy, it is essential to define more precise boundary and initial conditions for the model.

Continuing this research requires obtaining more comprehensive data on the material properties of sulfide soils in general, including their consolidation properties. Furthermore, accurate data on the density of soil layers at the specific landfill site is necessary, which can be acquired through borehole sampling. In addition, identifying the parameters that influence the saturation degree of sulfide soil landfills and quantifying the impact of each parameter through numerical analysis is crucial for further advancements in this field.

Reinforcement of a coarse granular aggregate with microgrids: Influence on packing

Renforcement d'un agrégat granulaire grossier à l'aide de micro-grilles: Influence sur le paquetage

ABSTRACT: Micro-reinforcement using engineered fibres or particulate inclusions, such as strip fibres, has potential for improving the performance of coarse granular aggregates, such as materials for road bases or railway ballast. During loading, the aggregate particles move, and the soil skeleton is rearranged. Recent studies have shown the effectiveness of fibre reinforcement of soils and coarse granular aggregates. Usually, the fibres are mixed randomly within the soil skeleton, with consequences on packing. Fibres can be considered micro-reinforcements, as these are inclusions at the particle scale. Alternatively, other forms of micro-reinforcements can be used. Small elements of geogrids, herein designated microgrids, are alternative forms of micro-reinforcement. Their inclusion may also affect the packing of the particles of aggregate, as the presence of the reinforcement my affect the displacement and rotation of the adjacent particles. In this paper, the influence of microgrids on the packing of a coarse aggregate is analysed. For that, a container with two transparent faces was used. The aggregate and the micro-reinforcement elements were mixed at a predetermined volumetric ratio, placed in the container, and submitted to compaction. The addition of microgrids disrupted the natural grain packing, and corresponding increases in e_{max} and e_{min} were observed. For the microgrid with higher anchorage length, non-natural void formation was observed due to microgrid-microgrid interaction rather than microgrid-grain interlocking.

RÉSUMÉ: Le micro-renforcement à l'aide de fibres artificielles ou d'inclusions particulaires, telles que les fibres en bandes, peut améliorer les performances des agrégats granulaires grossiers, tels que les matériaux pour les bases routières ou le ballast des voies ferrées. Pendant le chargement, les particules d'agrégats se déplacent et le squelette du sol est réorganisé. Des études récentes ont montré l'efficacité du renforcement des sols et des agrégats granulaires grossiers par des fibres. En général, les fibres sont mélangées de manière aléatoire dans le squelette du sol, ce qui a des conséquences sur le paquetage. Les fibres peuvent être considérées comme des micro-renforts, car il s'agit d'inclusions à l'échelle des particules. D'autres formes de micro-renforts peuvent également être utilisées. Les petits éléments des géogrilles, appelés ici micro-grilles, sont d'autres formes de micro-renforcement. Leur inclusion peut également affecter le paquetage des particules de l'agrégat, car la présence du renforcement peut affecter le déplacement et la rotation des particules adjacentes. Dans cet article, l'influence des micro-grilles sur le paquetage d'un agrégat grossier est analysée. Pour ce faire, un conteneur à deux faces transparentes a été utilisé. L'agrégat et les micro-éléments de renforcement ont été mélangés selon un rapport volumétrique prédéterminé, placés dans le conteneur et soumis au compactage. L'ajout de micro-grilles a perturbé l'empilement naturel des grains, et des augmentations correspondantes d'e_{max} et d'e_{min} ont été observées. Pour la micro-grille ayant une longueur d'ancrage plus élevée, on a observé une formation de vides non naturels due à l'interaction micro-grille-micro-grille plutôt qu'à l'imbrication micro-grille-grain.

Keywords: Micro-reinforcement; packing; coarse aggregates; scaled-ballast.

1 INTRODUCTION

For the past two decades, researchers (Lirer et al. 2011; Michalowski & Čermák, 2003; Soriano et al. 2017) have tried to reinforce soils, mostly sands, with random micro-reinforcements, such as discrete fibres. The shear strength of the resulting composite material is governed by the micro and the macromechanical characteristics of both fibres and soil particles (Lirer et al. 2011). Discrete fibres play a significant role in increasing the overall shear strength and ductility of sands (Michalowski & Čermák, 2003). Because of the effectiveness of fibre reinforcement, the approach has been extended to coarse granular aggregates such as railway ballast.

Railway ballast is a coarse granular aggregate, generally obtained by quarrying high quality rock, used as a load bearing layer. The ballast layer supports the track superstructure and transfers the load generated at wheel-rail interface to the sub-base and the underlying soil. Laboratory testing of full-size ballast is difficult, expensive, and time-consuming. Thus, testing scaled-down ballast is an attractive solution for understanding the mechanics of full-size ballast (Sevi, 2008).

Ajayi et al. (2017a) studied the behaviour of 1/3 and 1/5 scaled ballast reinforced with randomly distributed strip fibres and analysed the influence of the fibre dimensions and fibre content. Ajayi et al. (2017a) observed that, in monotonic triaxial tests, fibre-reinforced gravels exhibited decreased dilation, increased ductility and increased peak deviator stress. Within the framework of classic soil mechanics principles, reduced dilatancy is consistent with higher ductility, but neither is consistent with an increased deviator stress. Thus Ajayi et al. (2017a) proposed a three-phase model for the grains, fibres and voids, with the fibres considered explicitly as a separate phase:

$$\upsilon = \frac{V_s+V_f+V_v}{V_s} = 1 + e + V_{fr} \qquad (1)$$

where υ is the specific volume of fibre-reinforced soil, V_s is the volume of solids, V_f is the volume of fibres, V_v is the volume of voids, e is the void ratio of the soil (considering soil particles only) and V_{fr} is the volumetric fibre ratio (V_f/V_s). This framework has the advantage of considering the fibres independently of the natural soil matrix (solids particles and voids).

Ajayi et al. (2017a) expressed the fibre dimensions normalised with respect to the effective diameter corresponding to 50% of soil particles, D50. LN is the normalised fibre length (= Lf/D50) and WN the normalised fibre width (= Wf/D50), where Lf is the fibre length and Wf is the fibre width.

For the case of 1/3 scale ballast reinforced with strip fibres, the minimum normalised fibre dimensions giving an effective improvement of the monotonic response were: LN = 7.1 and WN = 2.5 (Ajayi et al. 2017a). The volumetric fibre ratio, Vfr, is the ratio in Eq.1 that accounts for the presence of fibres in the soil matrix. For a given Vfr, as the grain size increases, the number of fibres required to develop similar grains–fibre interactions decreases. Thus for scaling purposes, Vfr is not a sufficient measure for representing the fibre content. When considering the mechanical behaviour of fibre reinforced granular materials across different grain size ranges, the number of fibres available for fibre-grain interaction is also important and can be defined by the fibre-grain ratio Nfg. For a given fibre length and width, Nfg is the ratio between Nf, the number of individual fibres in a fibre reinforced specimen and Ng the number of grains in a fibre reinforced specimen. Ng can be estimated using two different approaches: Approach 1, which assumes that all grains are approximately spherical with a diameter equal to D50 (Ajayi et al. 2017b); Approach 2, which divides the weight of the ballast specimen by the average weight of a single grain (Ferro et al. 2023).

Ferro et al. (2022) studied the ability of randomly distributed fibres to reinforce full-size ballast using packing tests and full-scale cyclic laboratory tests (single sleeper bay section of railway under plane strain conditions). From the full-scale tests, the authors concluded that the effectiveness of fibres in reducing the settlement of traditional railway track depends not only on their ability to increase the material shear resistance, but also on how little they influence the packing of ballast grains. To assess the effect of fibre reinforcement on the long-term settlement of ballast after cyclic load, Ferro et al. (2022) proposed an alternative measure of the propensity to pack of the fibre-reinforced composite, IDr:u which is the ratio of the range of reinforced void ratios (emax and emin, maximum and minimum void ratio of unreinforced ballast) to the corresponding range the unreinforced material (e^U_{max} and e^U_{min}, maximum and minimum void ratio of unreinforced ballast, respectively). For full-size ballast IDr:u should be smaller than 1.05 (Ferro et al. 2022).

The form of the reinforcement will result in different mobilisation mechanisms. Discrete fibres oriented horizontally can sustain tensile forces generated at the grains level (Soriano et al. 2017), while microgrids will tend to generate additional interaction mechanisms such as local interlocking. Indraratna et al. (2018) analysed geogrid reinforcement of railway ballast and defined a range for the geogrid aperture size, A, that maximise bearing capacity of the ballast layer, while reducing track settlement. The aperture size should not be smaller than 0.9D50 and larger than 1.2D50.

In this paper, two forms of microgrid were studied, particularly their effect on the packing of a coarse granular aggregate. Unreinforced and reinforced specimens were compacted using a shaking table and the effect of compaction on the grain packing was analysed.

2 MATERIALS AND METHODS

2.1 Materials

Freshly quarried gneiss granular aggregate was obtained from *Irmãos Cavaco* quarry (Aveiro, Portugal). This coarse material corresponds to a 1/3 scale representation of the full-size ballast used on Portuguese railways (BS EN 13450: Aggregates for Railway Ballast, 2013). The particle size distribution of the aggregate is shown in Figure 1. G_s is the aggregate specific gravity, C_u is the uniformity coefficient and *FI* the flakiness index. *FI* informs about the percentage by weight of an aggregate with an aspect ratio less than 0.6 times their mean size. The natural effective angle of shearing resistance (effective angle of friction), ϕ', of the coarse granular aggregate is 39°.

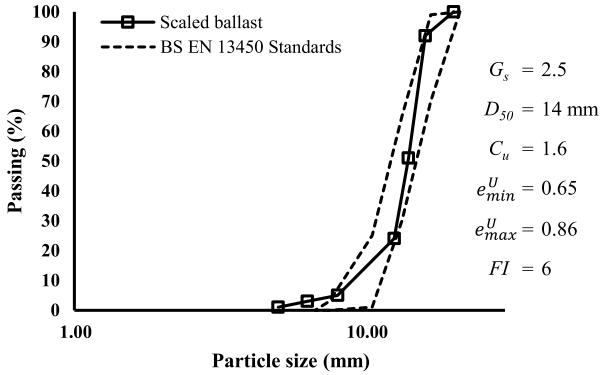

Figure 1. Aggregate particle size distribution and additional properties.

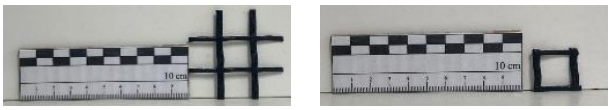
The microgrids were obtained from a commercially available geogrid by cutting pieces to a predefined geometry. Two different microgrid shapes were considered (Figure 2). The normalised dimensions of the microgrids are given in Table 1.



a) *b)*

Figure 2. Microgrids studied: a) MG1, b) MG2.

Table 1. Microgrids volume and normalised geometry: length, width, and aperture size.

Normalised dimensions	MG1	MG2
Volume of a single element (cm^3)	0.554	0.238
L_N (-)	3.9	1.8
W_N (-)	3.7	1.6
A/D_{50} (-)	1.1	1.1

The central element of MG1 and MG2 is the same (an opening of 16 mm × 16 mm). The difference between MG1 and MG2 is that the former includes additional elements beyond the central element (Figure 2). Thus, the normalised length and width of MG1 are nearly double of MG2. The normalised aperture size (A/D_{50}) of the microgrids is within the range proposed by Indraratna et al. (2018). However, the normalised length (L_N) and width (W_N) of the microgrids do not meet the optimum dimensions proposed by Ajayi et al. (2017a), for strip fibres.

2.2 Packing test

To assess the effect of the microgrids on the packing of the 1/3 scale ballast grains, packing tests were carried out. Two different plywood boxes were used: Box 1, cubic box with internal edges of 300 mm (all faces made 16 mm thick plywood); Box 2, cubic box with two 8 mm thick plexiglass faces, which allow for visual inspection of the particle movement during compaction, with longitudinal internal edges (268 and 300 mm). The boxes were stiff enough to ensure plane strain conditions. The packing tests were carried out in Box 1, and visual observation of the packing using Box 2.

For each packing test, Box 1 was filled manually and weighed. Loose conditions were obtained by placing the aggregate gently into the box. Dense conditions were obtained using a shaking table, with a frequency of 50 Hz and amplitude of 0.8 mm. Three episodes of shaking (approximately 300 seconds each) were applied after placing each layer of material (100 mm high) into the box, with a total of 3 layers. The box was slightly overfilled and the final top surface levelled by adding and removing individual grains. For the dense condition, the final level was obtained by hand-pressing the lid against the aggregates while vibrating. This process, described by Ferro et al. (2022), allows the maximum density to be achieved without grain breakage. Once the specimen had been levelled, the lid was placed on top of it and the actual height of aggregate was measured.

The packing tests (Box 1) were carried out for a predetermined volumetric fibre ratio of 3.2%, identified by Ajayi et al. (2017a) as the optimum Vfr for a coarse granular aggregate with grain dimensions similar to that used herein. The volume of microgrid reinforcement was calculated from the volume of solid particles and the bulk density of the specimen. Mineral particles were hand-mixed with microgrids on a specimen by specimen basis to ensure a random distribution of the microgrids within the grains.

For each condition (unreinforced, U; reinforced with microgrid 1, R MG1, and with microgrid 2, R MG2), 6 packing tests were carried out; 3 for the loosest (emax) and 3 for the densest (emin) condition,

resulting in a total of 18 tests. One additional packing test per condition was carried out in Box 2 (3 tests in total).

3 RESULTS AND DISCUSSION

3.1 Fibre-grain ratio

To assess the fibre-grain ratio, N_{fg}, it is necessary to estimate the number of grains per specimen. Table 2 summarises the estimates of the number of grains average value for 3 specimens per condition tested, N_g, using Approaches 1 (Ajayi et al. 2017b) and 2 (Ferro et al. 2023), described in section 1.

Table 2. Number of grains, N_g, and fibre-grain ratio, N_{fg}, for the specimens tested, using Approaches 1 (Ajayi et al. 2017b) and 2 (Ferro et al. 2023).

Nomenclature	U	R MG1	R MG2
V_{fr} (%)	-	3.2	3.2
N_g (-) Ajayi et al. (2017b)	11675	9914	10422
N_g (-) Ferro et al. (2023)	12175	10339	10867
N_{fg} (%) Ajayi et al. (2017b)	-	9.8	21.7
N_{fg} (%) Ferro et al. (2023)	-	9.4	20.8

Approach 2, proposed by Ferro et al. (2023), leads to higher number of grains per specimen (by ~4%) than the method proposed by Ajayi et al. (2017b). The different estimates of N_g influence the fibre-grain ratio, which are related to the volume of a single fibre. To better understand those relations, Figure 3 shows the influence of the volume of a single fibre on the fibre-grain ratio, N_{fg}. (for a constant volume of solids, V_s = 0.017 m^3, and volumetric fibre ratio, V_{fr}). As the volume of a single fibre increases, the number of grains that potentially can be engaged by each fibre decreases. The average volume of a single fibre MG1 and MG2 is, respectively 0.554 cm^3 and 0.238 cm^3. The differences in N_{fg} between the two approaches are small (Table 2, Figure 3). This is related to the shape of the aggregate particles studied: a reduce flakiness index, $FI \leq 15\%$, indicates that most grains have a reasonably spherical shape. For materials with higher FI, the approach proposed by Ferro et al. (2023) will tend to be more realistic.

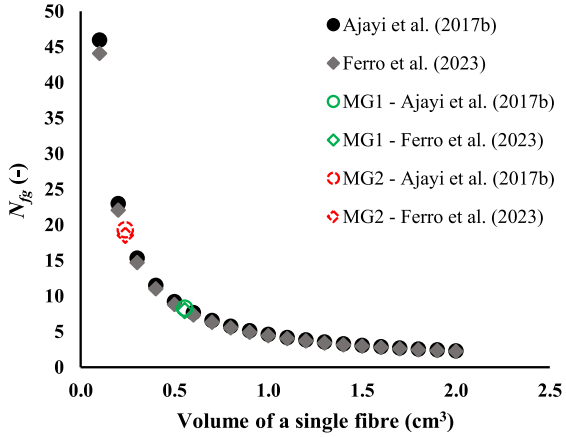


Figure 3. Variation of the fibre-grain ratio with the volume of a single fibre.

3.2 Packing

Table 3 summarises the packing test results (average for three specimens per condition); the maximum and minimum void ratio (e_{max} and e_{min}) and the ratio of the range of reinforced void ratios to that of the unreinforced material ($I_{Dr:u}$).

Table 3. Packing test results (average for 3 specimens per condition), maximum (e_{max}) and minimum (e_{min}) void ratio, standard deviation (σ), and grains packing disruption analysis ($I_{Dr:u}$).

Nomenclature	e_{max} (-)	σ (-)	e_{min} (-)	σ (-)	$I_{Dr:u}$ (-)
U	0.86	0.01	0.65	0.01	-
R MG1	1.42	0.02	0.93	0.02	2.25
R MG2	1.12	0.01	0.86	0.01	1.20

The addition of microgrids at V_{fr} = 3.2% led to an increase in both the maximum and the minimum void ratio of the mix relative to the unreinforced aggregate. For MG1, e_{max} increased by 64% and e_{min} by 33%; for MG2, this effect was less pronounced, with increases of 29% for e_{max} and 24% for e_{min}. Both microgrids interfered significantly with the natural packing of the aggregate grains, as $I_{Dr:u} > 1.05$. MG1, owing to its form and greater length than MG2, caused greater disruption to the natural packing with $I_{Dr:u}$ = 2.25.

The packing tests carried out in Box 2 allowed observation of the relative positions of the microgrids and grains, and changes during loading. Figure 4 shows cross sections of specimens, unreinforced and reinforced with MG1 and MG2, at different stages of the test: initial state, t = 0 s; half way through compaction, t = 150 s; and after compaction, t = 300 s. The distribution and arrangement of the microgrids on horizontal cross sections was also observed on

disassembling the boxes following the end of each test (plan view, Figure 4g and k).

The inclusion of microgrids MG1 and MG2 influenced the packing of the aggregate (Figure 3a, d and h). Particularly for MG1, the number and dimension of the voids in the vicinity of MG1 is important. Although the specimen R MG1 (as indicated by the values of emax and emin, Table 3) densified during compaction, the process did not eliminate such voids. Thus MG1 clearly disrupted the natural packing of the aggregate. For MG2, this was less evident, indicating that the form of MG2 is more easily accommodated by the aggregate particles than that of MG1.

Microgrid segregation was observed in both cases, and was more pronounced for MG1 than MG2. Again, this can be explained by the different forms of the microgrid reinforcements.

The results (Table 3) and the observations of the disrupted packing (Figure 4, with fibre overlapping) indicate that V_{fr} = 3.2 % is not optimum for this type of micro-reinforcement. However, this value was proposed by Ajayi et al. (2017a) for strip fibres not for microgrids. Thus further studies to optimise the form and the corresponding content of microgrids are needed.

During filling of Box 2 and at the start of the packing tests, it was evident that some microgrids were vertically oriented along the plexiglass. For this reason, at the end of the test the box was emptied carefully, in layers, to check if this was a boundary effect. The microgrid elements were found at both horizontal and vertical positions in all plan sections of the specimens (Figure 4). This is likely a consequence of the stabilisation effect that microgrids have, as they tend to lock-in aggregate particles in their vicinity and rotate along with grains.

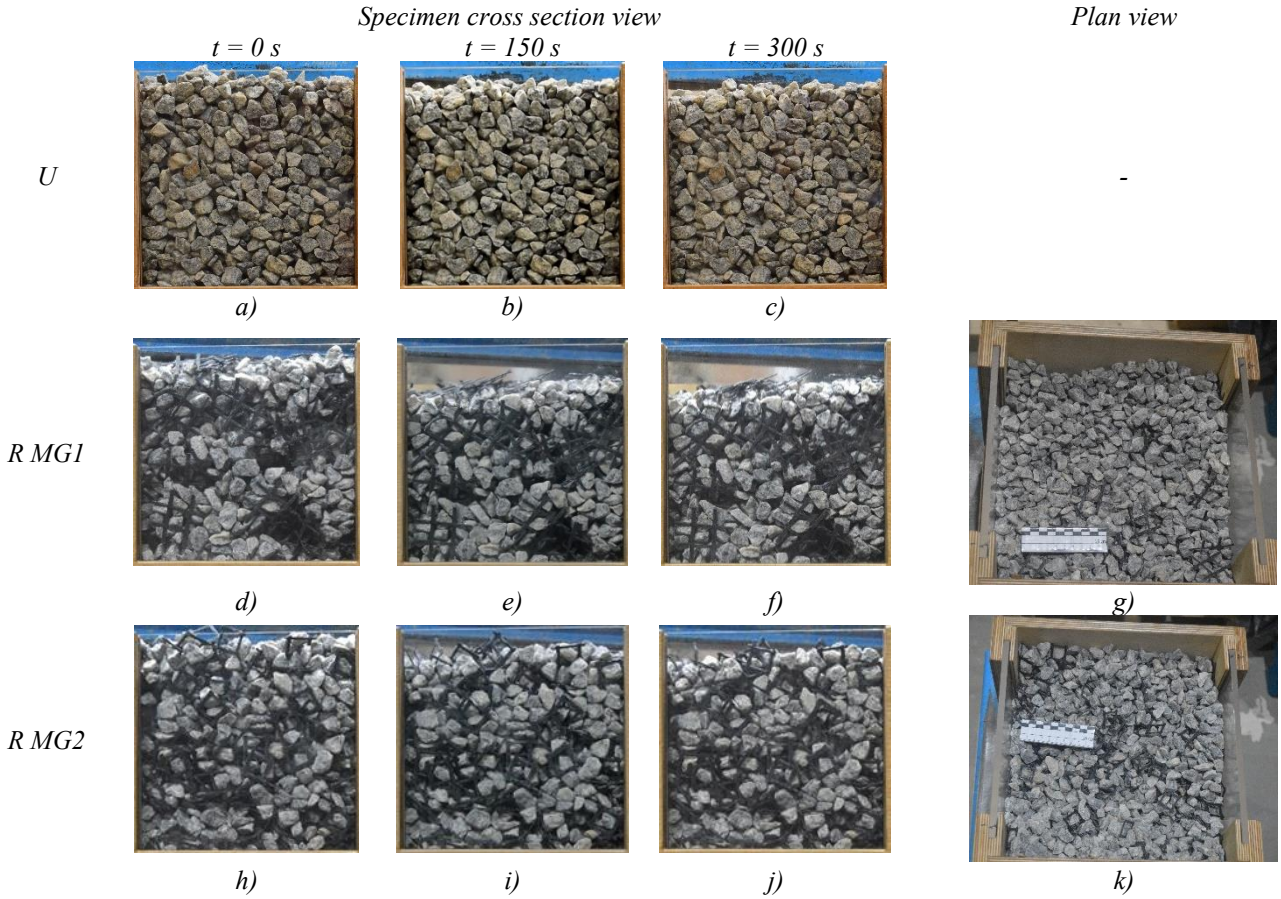

Figure 4. Cross section view of the packing tests (Box 2) at different moments: initial state (t = 0 s) a) U, d) MG1, h) MG2; after half way through compaction (t = 150 s) b) U, e) MG1, i) MG2; after compaction (t = 300 s) h) U, i) MG1, j) MG2, Plan view of specimens after compaction (Box 2) showing microgrid orientation: g) MG1, k) MG2.

4 CONCLUSIONS

In this paper, the reinforcement of a coarse aggregate (1/3 scale railway ballast) with two different types of microgrid was investigated using packing tests. The fibre-grain ratio was estimated using two different approaches from the literature. Images taken during the packing tests were analysed, to better understand

how the microgrids influence packing of aggregate particles. The main conclusions from the study are:

1. The inclusion of the microgrids influenced the aggregate packing and increased the maximum and minimum void ratios of the mix relative to the unreinforced aggregate.
2. The form of the microgrids affected the degree of disruption; the smaller microgrid, with only a central square element, was less disruptive.
3. The approaches used to estimate the number of grains per specimen gave similar results (4% difference).
4. The optimum volumetric fibre ratio V_{fr}= 3.2% for strip fibre reinforcement of similar aggregates is not appropriate for the microgrid reinforcements studied.
5. In contrast to strip fibre reinforcement, which adopt a generally horizontal orientation, microgrids orientate both vertically and horizontally within the aggregate particles.

Additional studies are needed to determine the optimum volumetric fibre ratio for microgrids and to give a better understanding of the micro mechanical interaction between microgrids and grains. Optimisation of the form of micro-reinforcement seems possible and needs further investigation.

ABSTRACT: Studies on structured soils, including seismic metamaterials, have shown the existence of complex wave phenomena within and around the structured zone. The aim is to assess areas where seismic or vibratory energy is concentrated, and to decide whether it would be worthwhile to exploit them by judiciously placing piezoelectric energy sensors. The article presents what is already being done with vibration sensors implanted in civil engineering structures and shows the potential interest of seismic metamaterials in this context. The modification of the surface signal by both structured soil and surface resonators meets the challenges of Civil Engineering through the effects of soil-structure interaction. Seismic metamaterials can therefore not only be considered for building protection, lensing and minimizing the effects of potentially deleterious Rayleigh waves, but also have potential applications in energy harvesting using ambient seismic noise.

RÉSUMÉ: Les études sur les sols structurés, dont les métamatériaux sismiques, ont montré l'existence de phénomènes d'onde complexe à l'intérieur et autour du sol transformé. Il s'agit d'évaluer les zones de concentration d'énergie sismique ou vibratile et de décider de l'intérêt de les valoriser en plaçant judicieusement des capteurs d'énergie piézoélectriques. L'article présente ce qui se fait déjà avec des capteurs de vibrations implantés dans des structures de génie civil et montre le potentiel intérêt des métamatériaux sismiques dans ce contexte. La modification du signal en surface à la fois par le sol structuré et les résonateurs de surface rejoignent les enjeux du génie civil par les effets de l'interaction sol-structure. Les métamatériaux sismiques peuvent donc non seulement être envisagés pour la protection des bâtiments, les effets de lentille et la minimisation des effets des ondes de Rayleigh potentiellement délétères, mais ils ont également des applications potentielles dans la collecte d'énergie en utilisant le bruit sismique ambiant.

Keywords: Energy harvesting device; seismic noise; seismic metamaterials; structured soils; smart city.

1 INTRODUCTION

In recent years, there has been growing interest in finding new ways to produce clean, sustainable energy. A new type of devices has emerged. They are called Energy Harvesting Devices - EHDs (Khaligh et al., 2010). One of the most innovative and promising methods is to harvest energy from pedestrian or road traffic, for example.

2 REVIEW OF SOME TYPES OF ENERGY HARVESTING DEVICES

When people walk, run or climb stairs, they generate kinetic energy that can be converted into electricity using various energy harvesting technologies.

Among all the energy related human activities we can consider in urban environment, traffic is one of the most energy-expensive ones, and, furthermore, it is characterized by great waste. Only 30% of the fuel potential is used to transfer kinetic energy to the vehicle and the largest part of this energy is dissipated in decelerating phases by brakes and gases (Ye et al., 2010).

The use of speed bumps is basically to slow the vehicle in certain areas such as school, residential streets, dangerous corner, and near car park area such as a bus station and hypermarket. “Powerbumps” are innovative energy harvesting devices that reduce the speed of vehicles by converting the kinetic energy otherwise wasted by brakes into electricity (Pirisi et al., 2012).

The amount of energy that can be gained from pedestrians depends on several factors, such as the number of people walking, their weight, and the frequency and intensity of their footsteps.

Piezoelectric tiles are one of the most common technologies used to harness energy from pedestrian traffic. These tiles are embedded in the ground and generate electricity when they are compressed by the weight of people walking on them. They can be installed in public spaces such as parks, plazas, and sidewalks to generate electricity that can be used to power lights, sensors, and other low-power devices.

Kinetic pavements are similar to piezoelectric tiles but designed to generate more energy. They use a more advanced technology that allows them to generate energy not only when compressed, but also when flexed. Kinetic pavements are typically made of a composite material that contains piezoelectric fibers.

The stairs generate electricity through the kinetic energy produced by people walking up and down them. The energy is then stored in batteries and used to power the station’s lighting system.

An energy harvester can be constructed by combining a mechanical structure with an energy transducer. The former commits itself to capture the mechanical energies and regularizing them into internal strain energy or kinetic energy of relevant components. Then, the transducer converts regularized energies into electricity to power low-consumption devices (Yin et al., 2023). The harvester system (figure 1), by means of the piezoelectric effect, converts the mechanical energy of the human being walking, running or jumping, in exploitable electric energy.

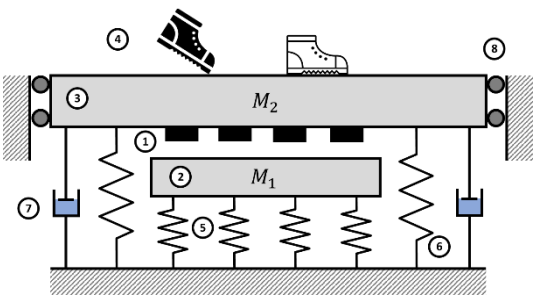

Figure 1. Schema of the harvester system (adapted from Malki et al., 2020). Legend: 1– piezoelectric patches, 2 – mass M_1, 3 – plate (mass M_2), 4 – pedestrian steps, 5 – substrate springs, 6 – centered springs, 7 – dashpot, 8 – sliding device.

3 HUGE OSCILLATORS IN THE CITY AND METACITY

Metacity was a concept first put forward in the late 1980s on the basis of experimental observations of soil response and its devastating effects. It has been known since the 1950s that the natural frequencies of any man-made structure are influenced by soil-structure interaction, particularly on soft soils, and that the presence of structures on the surface of a homogeneous half-space can significantly modify ground motion (Clouteau and Aubry, 2011; Guéguen et al., 2000; Trifunac, 1972; Wong et al., 1977). Most of the time, the problem of ground response is disconnected from that of the resonant response of buildings or group of buildings (figure 2a).

On the basis of studies carried out on the interaction of cities with the seismic signal (what could be viewed as a form of multiple scattering similar to that in Phononic Crystals PCs), some authors propose further extensions of this concept (Wirgin and Bard, 1996) based on analogies with electromagnetic and seismic metamaterials (Kadic et al., 2013; Merrit and Housner, 1954). This theoretical approach is consistent with studies of several authors on the influence of the trees of a forest on the surface waves (Maurel et al., 2018).

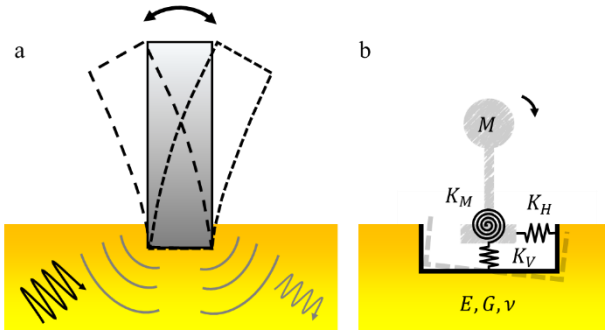

Figure 2. (a) The building vibrates as a result of seismic waves, then through inertial effects, becomes a secondary source of vibration itself. (b) Soil-foundation interface is modelled here in the case of three degree of freedom with analogic Maxwell models (K_H, K_V, respectively horizontal and vertical stiffnesses, K_M is the rotational stiffness of the model).

The concept here is to position sensors in areas where vibratory motion is amplified by surface resonators (Brûlé et al., 2019; Brûlé et al., 2020). Seismic metamaterials come into play by virtue of their ability to concentrate the mechanical energies of seismic waves and seismic ambient noise. It should be noted that seismic metamaterials were first studied in the case of earthquakes (Brûlé et al., 2014). City vibrations are also of interest to researchers, who are using the fiber optics (D.A.S. – Distributed Acoustic Sensing) already installed in cities as a gigantic

network of seismic sensors (Rodet et al., 2022). Distributed Acoustic Sensing is a technology that enables continuous, real-time measurements along the entire length of a fiber optic cable. For example, each building can be modeled as an oscillator with soil-foundation interface conditions. These interfaces can be represented by rheological models with several degrees of freedom (figure 2b).

4 ROLE OF SEISMIC METAMATERIAL

The main paradigm shift lies in the search for the specific modal signatures of all these objects (structured soils, foundations, etc.), which requires the implementation of specific material means in the field (seismic sensors, sensor density, etc.) and also analysis tools to extract the data of interest (Brûlé et al., 2024).

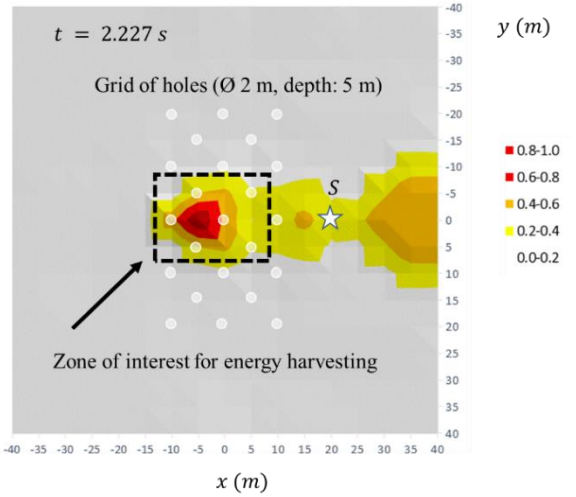

Figure 3. Example of a staggered hole pattern (20 – 40 m). The impact source (S) is located at 10 m from the long side. The energy scale is arbitrary and normalized. The figure shows energy concentrations at locations of interest for positioning vibration sensors (Brûlé et al., 2020).

The transposition of the principles of periodic media to materials as specific as terrestrial materials requires rigorous definition of the validity conditions. In particular, these conditions are the strain range of the soil making possible the justification of an elastic behavior and a thick and homogeneous sedimentary site to limit the reflection effects of the underlying geological layers of contrasted impedance.

The interpretation of the measurements is carried out from the perspective of the physical phenomena expected in periodic media. The seismic lenses tested (Brûlé et al., 2024) are explored as phononic crystals and metamaterials. By the effects observed, we point out the diffraction including Bragg reflection and double image of the source as a result of the negative refraction of a flat lens.

However, a metamaterial is defined as an artificial composite material made from the assembly of resonators of smaller dimensions, whose wavelength at resonance is much larger than their physical dimension. These possibilities of local resonances are verified for Helmholtz resonators or very soft soils with rigid inclusions. On a macroscopic scale, a metamaterial is likely to exhibit properties that are not found in nature, such as negative refractive index. In addition to these early interpretations, there is an analysis of the modification of the polarization of surface waves. This new reading of the data opens the discussion on other descriptions of phenomena such as the existence of local resonances of rigid elements placed in a soil, and no longer of empty cylinders, as well as on static or dynamic homogenization approaches, dynamic anisotropy, transformational optics, surface resonators, etc.

The modification of the signal by the fact of a structured soil and surface resonators are the link with Civil Engineering and the soil-structure interaction practiced in Earthquake Engineering (figure 3). Research subjects converge in seismology and on the effects of secondary sources generated by surface buildings.

5 SEISMIC AMBIENT NOISE

In urban areas and for the frequency range of interest for civil engineering structures (0.1 Hz to 30 Hz), the orders of magnitude for particle velocities at ground level are 10^{-6} to 10^{-5} m/s. For accelerations, values are of the order of 10^{-5} to10^{-3} m/s^2.

The rapid development of sensor sensitivity, miniaturization, falling costs and energy storage capacities will make it possible to exploit seismic ambient noise excacerbated by structured materials (in the ground or in buildings).

6 DISCUSSION AND CONCLUSIONS

The development of building construction is steadily moving towards smart buildings and cities. All free energies will be exploited: solar, geothermal, wind energy, seismic ambient noise, etc. A decisive turning point in the evolution of seismic metamaterials is their ability to create energy channels - rather chaotic, but potentially profitable for installing sensing devices.

ABSTRACT: In contexts where empirical methods support decision-making, the need for organized information, often in a 'Just in Time' manner, is crucial. In such situations, machine learning (ML) and artificial intelligence (AI) based methods can play a significant role in offering meaningful solutions. Data must fulfil predefined criteria and be stored in structured databases. Quality of information and its organization are essential factors for predictive and decision-making algorithms. This paper will introduce essential database criteria and provide an example of data analysis for a case study to offer effective decision-making support for an underground construction project in an urban environment. In NATM (New Austrian Tunnelling Method) works, there is a heavy reliance on continuous monitoring and observation. Particularly in linear excavations, work cycles follow each other rapidly, often operating 24/7. The constant decision-making required for the progress of each daily cycle demands continually updated information that is readily available and presented in a clear and precise format for quick and rigorous interpretation.

RÉSUMÉ: Dans les contextes où les méthodes empiriques soutiennent la prise de décision, le besoin d'informations organisées, souvent en mode 'juste à temps', est crucial. Dans de telles situations, les méthodes basées sur l'apprentissage automatique (ML) et l'intelligence artificielle (IA) peuvent jouer un rôle significatif en offrant des solutions significatives. Les données doivent respecter des critères prédéfinis et être stockées dans des bases de données structurées. La qualité de l'information et son organisation sont des facteurs essentiels pour les algorithmes de prévision et de prise de décision. Cette communication introduira des critères essentiels pour les bases de données et fournira des exemples d'études de cas d'analyse de données afin d'offrir un soutien efficace à la prise de décision pour un projet de construction souterraine en milieu urbain. Les travaux réalisés selon NATM (New Austrian Tunneling Method) reposent largement sur la surveillance et l'observation continues. Particulièrement dans les excavations linéaires, les cycles de travail se succèdent rapidement, souvent en fonctionnement 24/7. La prise de décision constante nécessaire à l'avancement de chaque cycle quotidien exige des informations continuellement mises à jour, disponibles rapidement et présentées dans un format clair et précis pour une interprétation rapide et rigoureuse.

Keywords: Business intelligence; advanced data analysis; machine learning; Python; NATM; tunnels.

1 INTRODUCTION

The organization of data enables the search for predictive models, supports decision-making through algorithms, which can be established by AI, with the ultimate goal of automating processes.

Relational database technology has been adopted since the late 1970s (Vaisman and Zimániy, 2017). However, despite not being a new tool, some industries have not fully embraced the advantages it offers. Organized and structured information simplifies data analysis process.

Construction sector data management will improve with software like Building Information Modelling (BIM).

Efforts need to be made to evolve Big Data and AI strategies to achieve predictive algorithms.

This paper deals with underground excavation information from Circular Line construction contract of Metro do Porto (MdP) in progress, and some

hypothesis to data organization, management and analysis. It is an approach by construction site engineers, looking for decision-making tools.

2 BACKGROUND

Briefly, significant research and applications exist related specifically to data analysis through advanced algorithms to infer characteristics, predict trends, support decision making, etc., related to geotechnics in general (Gomes Correia et al., 2023; Gomes Correia, et al., 2020).

The interest of the subject it is clearly shown among academics and professional bodies like Federation of International Geo-engineering Societies (FedIGS), through the organization of regular event International Conference in Information Technology in Geo – Engineering (ICITG), launched by Joint Technical Committee 2 (JTC2) dedicated to Representation of Geo-engineering Data in Electronic Format (Gomes Correia et al, 2020). Also, TC309–Machine Learning and Big Data in ISSMGE, represents the same interest, in: 1) benchmark datasets, 2) Big Data acquisition, 3) site investigations and geo-materials behaviour; 4) Design; 5) Construction and maintenance; 6) industry interaction, standards and guidelines, points out to ML supported in geo-data, learning and making previsions, supported in AI algorithms (Zili Li et al, 2023). More recently, The International Society for Intelligent Construction (ISIC) is also working in the same line to provide source of knowledge and information on intelligent construction technologies for public agencies, contractors, consultants, academia, etc. (Gomes Correia, et al., 2020).

When I&D turns to concepts like *distributed ledger technologies* (DLT) or *blockchain* and *data lakes* (e.g. Mourão, 2022), or when internet of things (IoT) bring us the idea to access Data directly from devices, equipment's and machines, it is difficult to accept that old relational data bases or data base management systems are still not fully implemented.

3 INFORMATION TECHNOLOGY IN MdP CIRCULAR LINE CONSTRUCTION CONTRACT

Construction sector has already implemented commercial software platforms to communicate and manage documentation, between different stakeholders, in many cases as a contractual obligation established by the owner and NP EN ISO9001, Quality System Management System, documents normalization and control, related to the operationalization process and quality.

More recently, BIM, promise to bring the expected digital revolution to the sector, together with proper and long expected Data management. However, this technology it is not fully implemented in Portugal, regulation by "Portaria n.º 255/2023", recognizes that BIM importance justifies its use in public works project design. MdP Circular Line it is supported in BIM as a constructor contractual obligation. Implemented under its full capacity it enables daily analysis of solutions compatibility.

In construction operations, processes are established by Quality systems of Contractor, and approved by Supervisor. This includes executing, measuring and monitoring, safety and health procedures, like normalizes documents in use. The information collected along the way, it is frequently compiled in datasheets obeying to established formats and organized in a set of digital directories like a hierarchical db. This manual compilation of information it is done, independently, by different stakeholders (Contractor, Supervisor and Owner).

The overall system works and data it is available and accessible, but some work it is redundant (different player's repeat data compilation with same data), in a manual, arduous and repetitive labour. This system assures access to information (Python routines have already successfully tested), but it is not optimized, neither in data management, nor in the quality data analysis that enables.

4 PROCESSES WORKFLOW, INFORMATION AND RELATIONAL DATABASE

Evaluate processes workflow it is a need to plan activities during construction. Through an entity relationship diagram, can be identified the information produced and necessary along the process (Figure 1). Include in such diagram, all the dimensions (quality, environment, health and safety,…) of a construction contract in public works, can be a complex and extensive task. Along the process, routines supported in different code languages can be used, like SQL and Python.

Frequently, digital information acquired automatically it is transformed in pdf files or even paper support data, and loaded by different stakeholders, in a redundant, monotonous, laborious and joyless task. Sometimes, to approach specific questions, some organizations, reload information to a new shape or format, wasting time and resources.

When the process it is well known and all the variables are identified, the structure of a relational database can arise. The model of a data base, through

an entity-relation diagram can establish the architecture constructed with SQL code. At that stage, data loading may begin. This phase, however unavoidable, at least to some extent, can be minimized through: 1) automatic data acquisition; 2) shared database (Contractor, Supervisor and Owner).

5 RAW DATA TO A DATABASE

The ideal or traditional formula for planning and architecting an appropriate database for a specific project is not always achievable, be it due to limited project resources or lack of long-term perspective in project, life-cycle, or asset management.

When there is not a proper database, but instead exists dispersed data, more or less organized, but without pre-established formats or key links, it is still possible to organize the information to allow data analysis, through successive stages: extract, transform and modelling data. Lower quality initial data, enhance data edition challenge.

Considering that data sources are adequate, exists commercial software to enable all the phases of the process: 1) extract; 2) transform; 3) modelling; 4) calculations; 5) visualization; 6) publishing. In different moments of the process, AI algorithms enables simplification and automatic decisions.

Power BI, supporting DAX and M languages, enables to extract and transform data, as a interactive business intelligence and data visualization tool with visually appealing reports, dashboards, data insights, and a user-friendly interface.

During construction works on the Circular Line of MdP, attempts were made to data analysis: 1) Python code enables data analysis relative to excavation with explosives, stored it in an external server, and presenting the results graphically and periodically reports; 2) data is stored in an external server and fed into a business intelligence report using Power BI.

As an example, Figure 2 shows a detail of a Power BI report related to the vibrations monitoring due to the use of explosives in an area classified by UNESCO, adjacent to the iconic Torre dos Clérigos, where this project imposed a Vmax<2,5mm/s, strincter than the regulations set by standard (NP2074, 2015), that establishes 3mm/s as the maximum value for sensitive buildings.

6 FINAL REMARKS

NATM relies on continuous monitoring and observation. Together with settlements, groundwater levels, convergences data, all the information on design and operations represents a large amount of data, which is not always easy to navigate through and interpret in order to support decisions just in time (JIT), if it is not properly stored and managed.

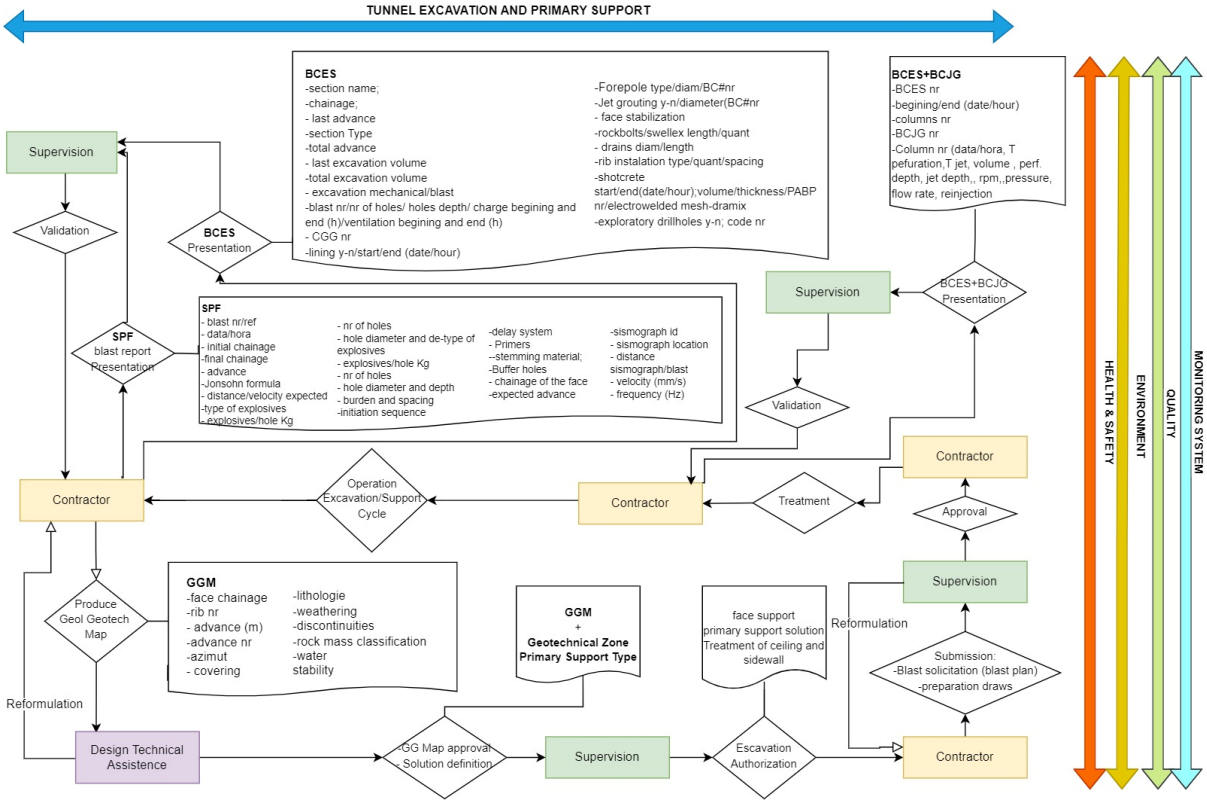

Figure 1. Tunnel excavation and primary supports processes workflow entity-relation diagram.

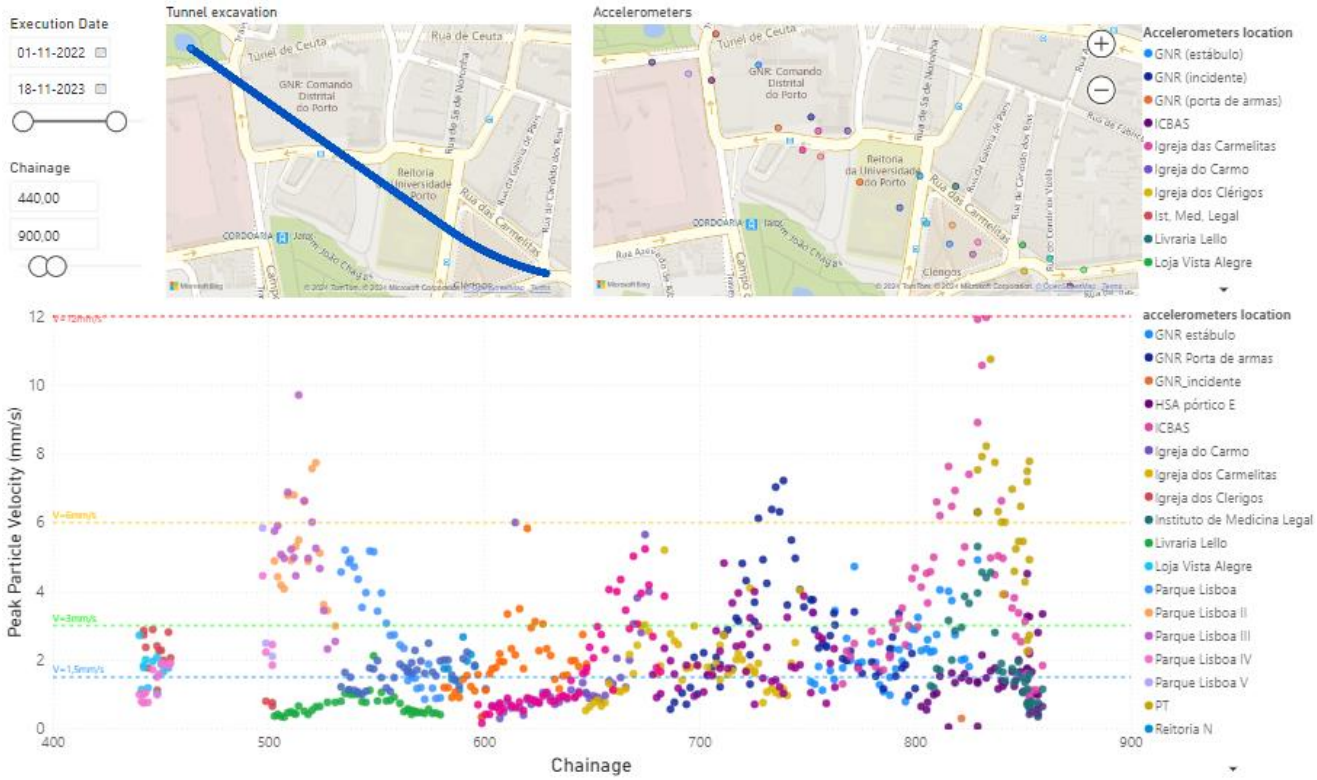

Figure 2. Blasting monitoring results data analysis.

In such environment, an attempt it being made to define a conceptual SQL database and to carry out data analyses on the real and existent hierarquical folders database, with Python code and Power BI.

Data and its management are critical for NATM construction operations, but must also remain available for the life-cycle and asset management.

This theme is in progress, as it addresses a subject still under study and which we hope to develop further in the future. Initially, this will involve data acquisition and storage methods, followed by the implementation of data analysis. At a more ambitious level, it encompasses the establishment of automated data analysis routines and decision support, involving artificial intelligence and machine learning algorithms.

ABSTRACT: The railway network in Europe spans approximately 200,000 km of track. Since 2012, a single interoperable European railway area facilitates the transportation of both passengers and goods across the continent. The needs for higher efficiency transportation modes are rapidly growing, and the shift towards rail in the EU is expected to accelerate because of its high environmental performance, sustainability, and safety. Meanwhile, the existing infrastructure is aging, with many assets being over a century old (earthworks, bridges, and tunnels). To meet these new challenges, modernization of the existing network is imperative. The regeneration of railway structures generally involves significant geotechnical engineering works due to the lack of available space or assets that are at the limit in terms of stability. These works are becoming increasingly complex and must be carried out with minimal traffic disruptions. In many countries, national guidelines have been published to assist engineers in the design and execution of geotechnical works near existing railway infrastructure. However, there are no European recommendations or standards. In order to discuss these national recommendations at the European level, this paper gives an overview of design, execution and control rules applied in France for geotechnical works on existing railway infrastructure. First, the characteristics of the French railway network are presented. Then, the main risks associated with geotechnical works close to railway traffic are identified. Finally, the implications of incorporating railway safety in the design and execution of works are highlighted.

RÉSUMÉ: Le réseau ferroviaire européen s'étend sur environ 200,000 km de voies. Depuis 2012, un espace ferroviaire européen unique et interopérable facilite le transport de passagers et de marchandises à travers le continent. Les besoins en modes de transport plus efficaces dans l'UE augmentent rapidement, et la transition ferroviaire devrait s'accélérer davantage en raison de ses performances environnementales, de durabilité et de sécurité élevées. Dans le même temps, l'infrastructure ferroviaire existante est vieillissante, de nombreux ouvrages ayant été construits il y plus d'un siècle (ouvrages en terre, ponts et tunnels). Pour répondre à ces nouveaux défis, la modernisation du réseau existant est impérative. La régénération des ouvrages ferroviaires implique généralement des travaux géotechniques importants en raison du manque d'espace disponible ou d'ouvrages à la limite en termes de stabilité. Ces travaux deviennent de plus en plus complexes et doivent être réalisés avec un minimum de perturbations pour les circulations. Dans de nombreux pays, des référentiels nationaux ont été publiés pour aider les ingénieurs à concevoir et à exécuter des travaux géotechniques à proximité des infrastructures ferroviaires existantes. Il n'existe cependant aucune recommandation ou norme européenne. Afin de présenter ces recommandations nationales au niveau européen, cet article donne un aperçu des règles de conception, d'exécution et de contrôle appliquées en France pour les travaux géotechniques sur les infrastructures ferroviaires existantes. Dans un premier temps, les caractéristiques du réseau ferroviaire français sont présentées. Ensuite, les principaux risques liés aux travaux géotechniques proches du trafic ferroviaire sont identifiés. Enfin, les implications de l'intégration de la sécurité ferroviaire dans la conception et l'exécution des travaux sont soulignées.

Keywords: Railway; safety; infrastructure.

1 INTRODUCTION

In Europe, the needs for higher efficiency transportation modes of passengers and goods across the continent are rapidly increasing. Transport by rail is viewed by many as a promising solution because of its high environmental performance, sustainability,

and safety. Growth of the railway industry is expected to accelerate in the future.

The rail network in Europe spans approximately 200 000 km of track. Since 2012, a single interoperable European railway area is established (Directives 2012/34, 2016/2370 and 2016/797 of the European Parliament). Infrastructure managers are required to grant non-discriminatory open access to railway infrastructure for domestic and international rail services. Meanwhile, the existing infrastructure in Europe is aging, with many assets being over a century old (earthworks, bridges, and tunnels).

To meet this future challenge of higher traffic and increased capacity, modernization of the existing European railway network is imperative. The regeneration of railway structures generally involves significant geotechnical engineering works due to the lack of available space or assets that are at the limit in terms of stability. These works are becoming increasingly complex and must be carried out with minimal traffic disruptions (Renard, 2011).

In many countries, national guidelines have been published to assist engineers in the design and execution of geotechnical works near existing railway infrastructure. However, there are no European recommendations or standards. The current technical specifications for interoperability (STI; EU regulation n°1299/2014) do not cover geotechnical works.

To discuss these national recommendations at the European level, this paper gives an overview of some design, execution and control rules applied in France for geotechnical works on existing railway infrastructure. First, the characteristics of the French railway network are presented. Then, the main risks associated with geotechnical works close to railway traffic are identified. Finally, the implications of incorporating railway safety in the design and execution of works are discussed.

2 OVERVIEW OF FRENCH RAIL INFRASTRUCTURE

The French railway network consists of 30 000 km of line, including 2 600 km of high-speed line, on which travel 15 000 trains per day. The map of the national rail network highlights the density of the tightly knit network in France (Figure 1).

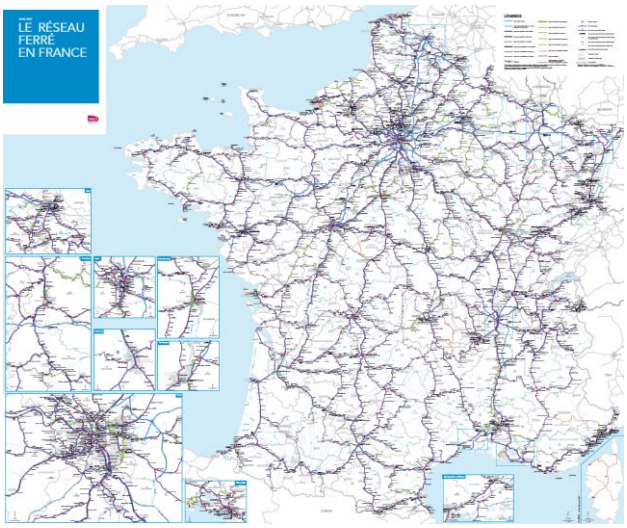

Figure 1. Map of the national rail network (from SNCF Réseau website).

Most main lines are standard UIC 1.435 m gauge, with only a few exceptions. A maximum permissible load of 22.5 tonnes per axle or 8 tonnes per linear metre is generally permitted.

The French railway network is composed of individual assets. The total number of earthworks is estimated at around 100 000 units, with a wide variety of structures (constitution, geometry, etc.) in many different environments (floodplains, rocky slopes, etc.). Over 32 000 rail bridges with a span greater than 2 meters were counted in a survey from 2018, with roughly 5 000 steel deck structures, 7 500 filler beams, 5 700 reinforced concrete or prestressed concrete bridges, 14 000 masonry bridges. There are approximately 20 000 retaining walls and 300 km of masonry covered slopes along the tracks in France. Lines pass through 1550 tunnels over a total length of 638 km, with an average tunnel span of 400 m (UIC, 2018).

Most of the assets were constructed 100 to 150 years ago during the industrial development of the second half of the 19th century. Structures are likely to deteriorate over time due to internal or external factors (Talfumière, 2011). These are mainly increase in traffic and loads and exposure to attacks from their environment (aggressive chemical conditons, erosion, submerssion, etc...). Degradations can lead to irreversible deformations with alterations of track geometry and/or more or less sudden failures in certain cases. A general lack of investment in maintenance and renewal projects over the years has resulted in poor track conditions in certain areas. Elsewhere, many assets have been reinforced at least once since their construction but these reinforcements are also aging and can become less efficient.

Geotechnical works carried out in operated railway environments are strongly impacted by the constraints

and risks brought about by train traffic. These specific risks are discussed in the following paragraph.

3 MAIN RISKS FOR GEOTECHNICAL WORKS NEAR OPERATED RAILWAYS

In addition to geotechnical hazards encountered in any ground engineering project, there are specific risks associated with works carried out near operated railway infrastructure. These are mainly related to:

- exposure of workers/equipment to moving trains / airflow effect
- exposure of workers/equipment to high voltage electrical installations
- potential damages to rail infrastructure with impact on traffic safety (disturbing signaling equipment, instability, and track geometry modifications)

In general, the closer the works are to the tracks, the greater the risks and the higher the costs of construction. Malfunction of signaling equipment can cause accidents such as train collisions. Damage to rail infrastructure caused by geotechnical works can have serious impacts on traffic safety. Overall stability must obviously always be guaranteed (equilibrium of the ground and of the structure at the Ultimate Limit State). Allowable displacements at the Serviceability Limit State (SLS) are often a major concern for projects near existing railway infrastructure. Indeed, unrestrained alterations of track geometry can ultimately lead to train derailment. Therefore, displacements are often a critical issue for projects.

The main risk treatment measures applied for the design and execution of geotechnical works in France to guarantee railway safety are presented in the following paragraph.

4 RAILWAY SAFETY IN DESIGN AND EXECUTION OF GEOTECHNICAL WORKS IN FRANCE

4.1 Standards and reference guides

Eurocodes are preferably applied for the design of geotechnical works on existing railway structures. However, there are instances where recent standards are difficult to apply, for example to justify the stability of old existing structures or for financial reasons. A risk tolerability principle known in France as GAME (*Globalement Au Moins Equivalent* meaning “globally at least as good”) is used as an alternative in some cases.

In addition, a complete collection of reference guides published by SNCF give further design prescriptions and most importantly guidance on execution of works near operated railway systems. Some important documents are in the reference list (IG90032; IG90033; MT40200; IN1226). The rules described in SNCF guidelines are applicable to works on the French railway network presented in paragraph 2. The purpose is to guarantee safe rail operations without unexpected traffic disruptions or accidents.

4.2 General risk treatment measures

4.2.1 Use of construction machinery near operated tracks

To mitigate the risks related to moving trains and electricity, safety perimeters for the use of construction machinery and equipment near the tracks are defined in IG90033 as protective measures. These perimeters apply to most machines used for geotechnical works such as mechanical excavators, piling and drilling rigs. When railway traffic is maintained while works are carried out, machines must under no circumstances enter the “Prohibited Zone” limited by a vertical plane 3 m from the track centreline or from any electrical installation (Figure 2). If there is a risk of accidental overturning of a piece of equipment, the limit of the prohibited zone is placed at 3 m from the nearest rail. Cranes and other lifting equipment can only operate outside a “Protection Zone” defined by a vertical plane 5 to 6 m from the axis of the track (included expected load sway). These limits also apply to boring rigs used for ground investigations.

Vibrations generated by powerful mechanical equipment (rotary hammer drills, hydraulic rock breakers, compactors, etc.) have the potential to cause significant disturbances to existing railway infrastructures. Continuous vibration monitoring is compulsory for works within 30 m of existing tracks. Allowable thresholds are set in SNCF standard IN1226 (2009).

Contractors are required to obtain specific qualifications from SNCF to be authorized to carry out works near operated tracks.

Various technologies exist to warn workers of approaching trains.

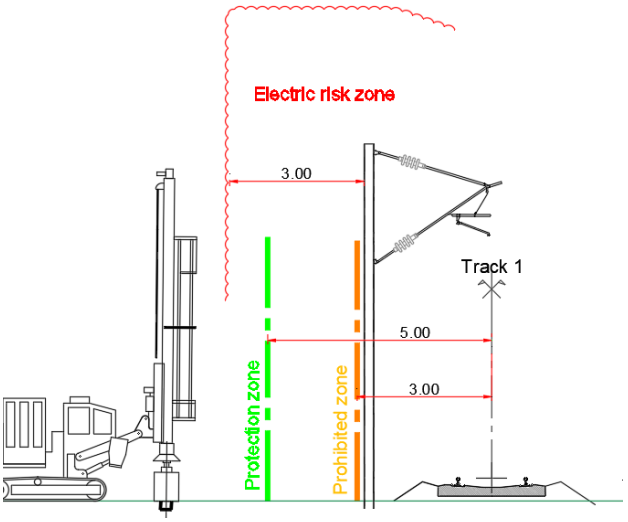

Figure 2. Zones for the use of construction machinery near the tracks following IG90033 (SNCF, 2018)

4.2.2 Track geometry quality

Settlements and displacements caused by geotechnical works are assessed in terms of track geometry. The main parameters used are (Figure 3):

1. Alignment
2. Track gauge
3. Cross level
4. Twist
5. Longitudinal level

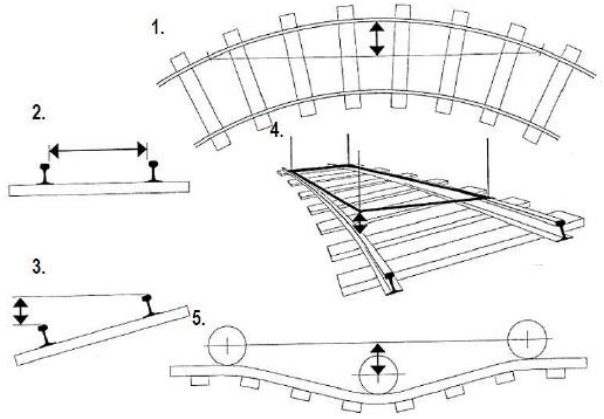

Figure 3. Schematic representation of principal track geometric parameters (Calon, 2016).

Maintaining the safety and regularity of railway operations requires that the characteristics of the traffic be considered (type, speed and frequency of traffic, importance of the line, etc.). For design, allowable track displacements depend on local conditions and vary depending on traffic speed: the faster the trains, the lower the allowable displacements. Limit values for tracks, switches and crossings in France are defined by reference guide MT40200. For each geometry parameter, the following thresholds are specified:

- Immediate Action Limit (IAL): Value which, if reached or exceeded, requires immediate measures to be taken to maintain track performance and guarantee traffic safety.
- Intervention Value (IV): threshold beyond which it is necessary to plan a short-term corrective intervention in order to avoid reaching the IAL.
- Alert value (AV): Alteration threshold beyond which specific monitoring should be carried out.

Examples of allowable longitudinal and cross levels against maximum train speed taken from MT40200 are presented in Figure 4 and Figure 5. Allowable longitudinal levels decrease linearly with traffic speed. Variations in allowable cross levels are less pronounced between 60 and 220 km/h, illustrating the higher risks for traffic safety in case of transverse default, even at moderate speed. Twist faults are of particular concern as they may cause the wheels to lose contact with the rail and derail the vehicle.

Integrating track geometry in design of geotechnical works often has important implications for projects. During initial design phases, it is recommended to limit anticipated track displacements below alert values (AV). When this is unachievable, different options are possible depending on local context:

- Reduce train speeds temporarily during works to maintain expected displacements below acceptable values,
- Perform frequent track geometry corrections by ballast maintenance to always guarantee satisfactory geometry during works,
- Carry out works during traffic interruptions (generally nights or weekends).

Such impacts on railway traffic must be anticipated. In France, traffic is planned 3 years in advance. Sufficient time must therefore be allowed between design and execution to allow for potential impacts on traffic to be incorporated in the transportation timetables. Selecting the most appropriate design option requires a global analysis balancing the potential benefits against costs and disadvantages (including operating losses for speed limitations and traffic interruptions).

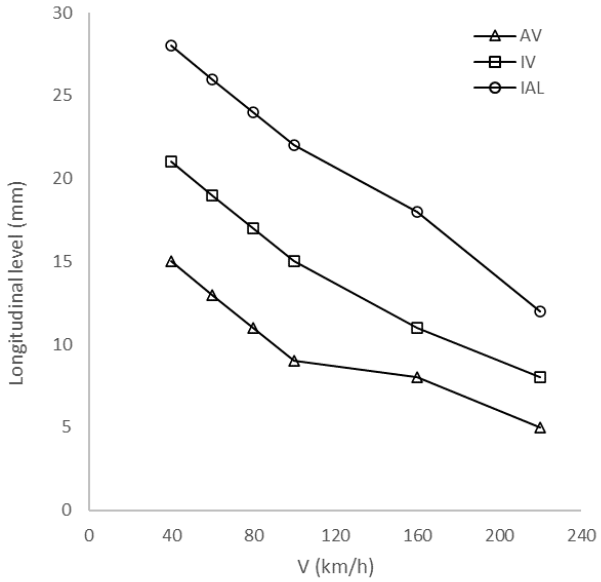

Figure 4. Examples of allowable longitudinal levels versus maximum train speed V (from MT40200 SNCF, 2021; measured over a wavelength of 15m)

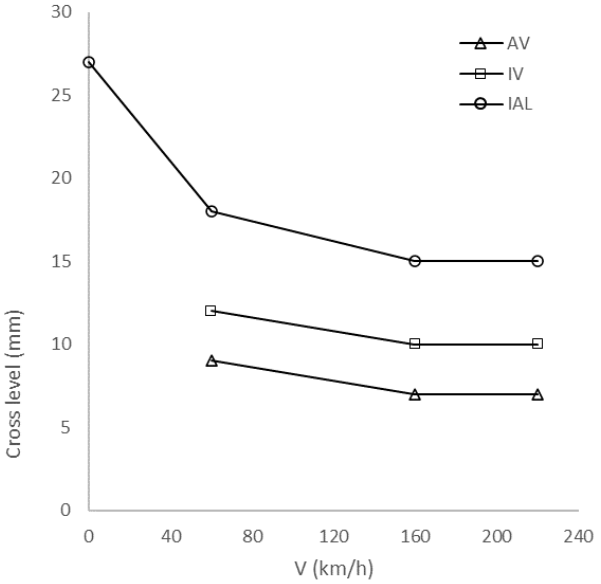

Figure 5. Examples of allowable cross levels versus maximum train speed V (from MT40200; SNCF, 2021)

It is important to note that the magnitude of allowable tracks displacements discussed above is millimetric whereas the commonly acknowledged precision for geotechnical settlement calculations is centimetric. Eurocode 7 asserts that understanding of the ground conditions depends on the extent and quality of the geotechnical investigations. Nevertheless, settlement calculations remain inaccurate and only give an approximate value. It is important that the uncertainties underlying settlement estimates be fully understood by all parties involved in such geotechnical projects (consultants, contractors, and infrastructure managers). In all projects with risks of track geometry modifications, it is appropriate to apply the approach known as "the observational method". The possibility for design adjustments during construction based on track geometry monitoring data must always be anticipated.

4.3 Excavations / retaining structures near operated tracks

According to reference guide IG90033, the effects of excavations near operated tracks must be considered when they are executed below a theoretical plane P0 inclined at 2 (horizontal direction) for 1 (vertical direction) and passing through a point located 3 meters from the axis of the track (Figure 6). Supports (i.e. retaining walls) are compulsory for excavations penetrating the theoretical plane P1 inclined at 3 (horizontal direction) for 2 (direction vertical) from the crest of the ballast.

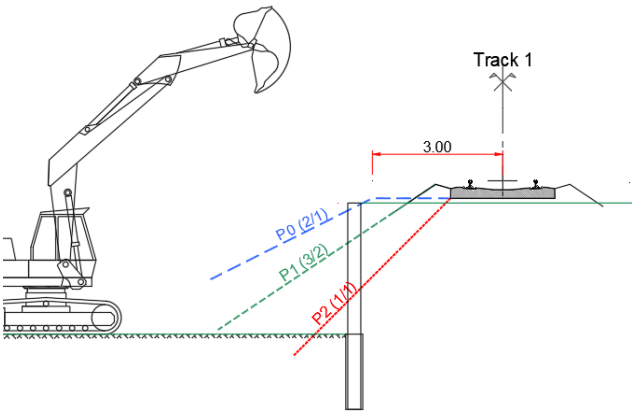

Figure 6. Excavation geometry near operated tracks from IG90033(SNCF, 2018)

Maximum allowable wall displacements are imposed in IG90033 based on the distance to the track and the depth of excavation. The displacements are also a function of the type of support and train speed, but do not depend on the surrounding ground conditions. The values were derived by SNCF from parametric studies on finite element models.

Figure 7 and Figure 8 present the theoretical example of an excavation located 5 m from an operated track. For both types of wall, allowable displacements decrease with traffic speed. Higher displacements are permitted for propped walls (Figure 8). Below 3 to 4 m, the allowable displacements decrease. This is asssumed to account for the greater risks associated with deep excavations.

Experience gained from imposing these thresholds for over 20 years in France has proven the

effectiveness of the method applied to maintain the geometry of tracks near open cuts.

In certain cases, it may be required to reduce traffic speed as a safety measure to increase admissible displacements for the design of retaining walls.

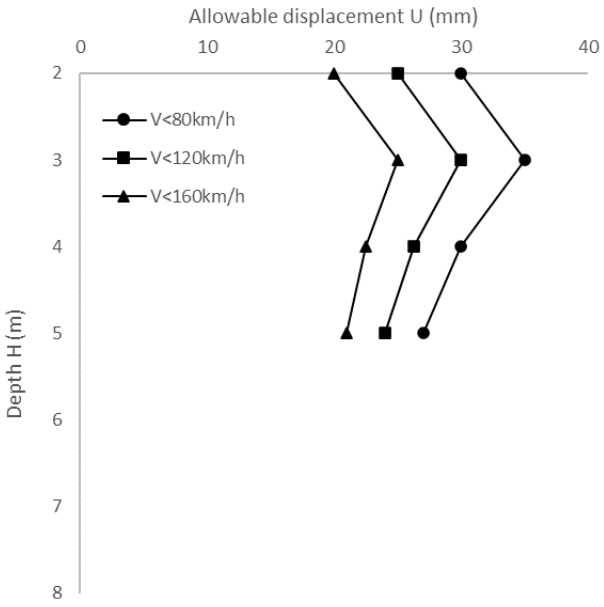

Figure 7. Example of allowable displacements for cantilever walls located 5 m from an operated track (IG 90033, Hécran=3m)

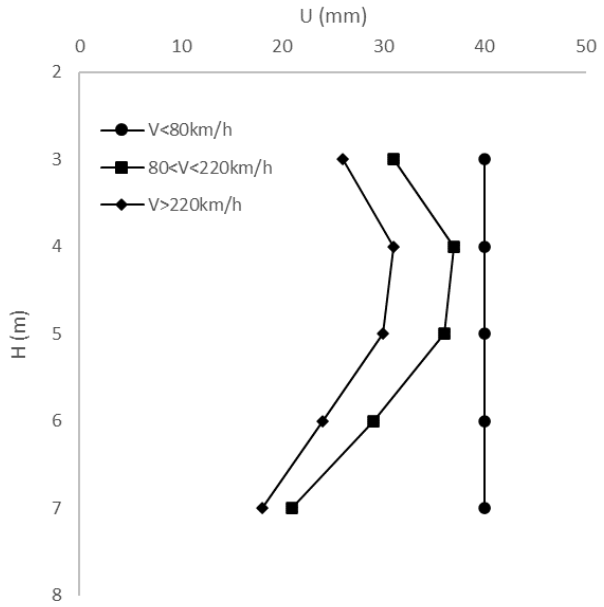

Figure 8. Allowable displacements of anchored/propped walls located 5 m from an operated track (IG90033; SNCF, 2018)

5 CONCLUSIONS

In this paper, specific risks for geotechnical works near operated railways are highlighted. In France, practice of railway safety measures is based on national reference guides validated by years of experience. Railway safety in projects can be achieved in part by takin into account traffic characteristics (especially speed) as design parameters. Geotechnical works will inevitably become more and more frequent within the interoperable European railway area. Hence, all infrastructure managers and operators would benefit from sharing local experiences and combining best-practices to guarantee a uniform level of safety everywhere in Europe.

Towards an open geotechnical data platform in France

Vers une plateforme de données géotechniques ouvertes en France

I. Halfon*, M. Beaufils
BRGM, F-45060 Orléans, France
i.halfon@brgm.fr

ABSTRACT: An important quantity of geotechnical data is constantly collected for all the new projects of civil engineering. This data includes generally core and destructive boreholes, in which samples are taken for laboratory testing and in situ geotechnical tests are performed. The density of geotechnical data is particularly high in urban areas. The data is collected by geotechnical engineering or drilling Companies for public or private owners. Data is essential to define the geotechnical conditions of a project and are obviously necessary for the geotechnical design of foundations or underground structures. However, most of the time, data is not accessible in a numerical format, and at the end of the project, is often forgotten, while it could be reused for neighbouring projects. It is a great loss of information and knowledge to the technical and scientific geosciences community, and it represents a significant cost for the country economy. In France, the BRGM (French geological survey office) is currently developing a new open access platform dedicated to the capitalization and accessibility of geotechnical data, compliant with the FAIR principles (Findable, Accessible, Interoperable and Reusable). This paper describes the challenges to overcome and the possible solutions, considering the high diversity of geotechnical tests, explains the need of keeping the exhaustive data set for each test, and describes the next stages of development.

RÉSUMÉ: Une quantité importante de données géotechniques est constamment collectée pour tous les nouveaux projets de génie civil. Ces données comprennent généralement des sondages carottés et destructifs, dans lesquels des échantillons sont prélevés pour des essais en laboratoire et des essais géotechniques in situ sont réalisés. La densité des données géotechniques est particulièrement élevée dans les zones urbaines. Les données sont collectées par des sociétés d'ingénierie géotechnique ou de forage pour le compte de maitres d'ouvrage publics ou privés. Les données sont essentielles pour définir les conditions géotechniques d'un projet et sont évidemment nécessaires pour la conception géotechnique des fondations ou des infrastructures. Mais la plupart du temps, les données ne sont pas accessibles sous format numérique, et à la fin du projet, elles sont souvent oubliées, alors qu'elles pourraient être réutilisées pour des projets voisins. C'est une grande perte d'informations pour la communauté technique et scientifique des géosciences, et cela représente un coût important pour l'économie du pays. En France, le BRGM (Bureau de Recherches Géologiques et Minières) développe actuellement une nouvelle plateforme de science ouverte dédiée à la capitalisation et à l'accessibilité des données géotechniques, conforme aux principes FAIR (Findable, Accessible, Interoperable and Reusable). Cet article décrit les difficultés techniques et solutions proposées, compte tenu de la grande diversité des essais géotechniques, explique la nécessité de conserver l'ensemble des données brutes pour chaque essai, détaille les différentes étapes du développement.

Keywords: Geotechnical data; open access; FAIR principles; standardization; data structuration.

1 INTRODUCTION

Geotechnical engineering encompasses the study of the mechanical properties of soils and rocks and their interaction with the structure or development to be built. The vast majority of geotechnical studies require the acquisition of a certain amount of data, including in particular the stratigraphic succession, the lithological description of the soils, the measurement of their identification parameters, the measurement of their mechanical behaviour parameters (resistance, deformability, consolidation, etc.). The density of geotechnical data is particularly high in urban areas.

The data includes generally core and destructive boreholes, with eventually samples for laboratory testing and in situ geotechnical tests.

For each project, one or more drilling contractors, laboratories and geotechnical engineers, acquire this data in one or more investigation stages as part of an order placed by the project owner.

The data is then analysed and interpreted by a geotechnical engineer. They produce a report, which presents the geotechnical model of the project derived from the investigations carried out, the geotechnical parameters interpreted and the various justifications for the geotechnical structure under investigation. The raw data is generally provided as an appendix to this report, in the form of borehole logs, photographs of

samples or cores, graphs, test reports, results tables, etc. This report and its appendices are attached to the tender documents for the works companies, who can also supplement them and make their own interpretations.

Once the work has been completed, the geotechnical reports and the data they contain are archived by the various parties involved. More often than not, if the structure does not behave abnormally, this data is never reused, or even forgotten altogether.

The advent of digital tools (databases, GIS, etc.) now makes it possible to capitalise on this data, and opens up the possibility of re-using it for neighbouring projects, for example, or quite simply to improve knowledge of the subsoil, facilitate and rationalise its development (Kokkala and Marinos, 2022), (Pando et al., 2022).

In France, the BRGM (French geological survey office) is currently developing a new open access platform dedicated to the capitalization and accessibility of geotechnical data, compliant with the FAIR principles (Findable, Accessible, Interoperable and Reusable).

2 ABOUT GEOTECHNICAL DATA

2.1 Nature, heterogeneity, provenance and reusability

Geotechnical data is both numerous and diverse in nature. It may be textual data (e.g. lithological descriptions or geotechnical classification symbols), single physical quantities (e.g. water content or density), pairs or groups of linked physical quantities (e.g. shear strength, which is made up of cohesion and friction angle), or temporal data (e.g. piezometric records).

It is also important to note the existence in geotechnics, as in other scientific disciplines, of a rich and sometimes ambiguous vocabulary to designate the different properties of soils and rocks, with terms of close physical meanings. For example, we speak of undrained cohesion, or undrained shear strength, or sometimes apparent cohesion, or even short-term cohesion. It is therefore essential to define a precise lexical reference system as part of a geotechnical data bank.

In addition, some geotechnical parameters are measured directly (e.g. the cone resistance of the static penetrometer). Others (most of them in fact) are the result of an in situ or laboratory test, involving raw measurements, parameters linked to the test or to the measuring device, intermediate calculations and interpretation by the engineer, leading in the end to interpreted parameters. For instance, in the Ménard pressuremeter test, the contextual data are the depth, the groundwater level, the probe characteristics and the calibration parameters. The raw data are the probe volume measurements at each step of pressure, and at different times. The intermediate parameters are the corrected pressure-volume measurements and the p_1 and p_2 pressures of the beginning and the end of the pseudo-elastic phase. And the final interpreted data are the net limit pressure (Pl*), the net creep pressure (Pf*) and the pressuremeter modulus (E_M).

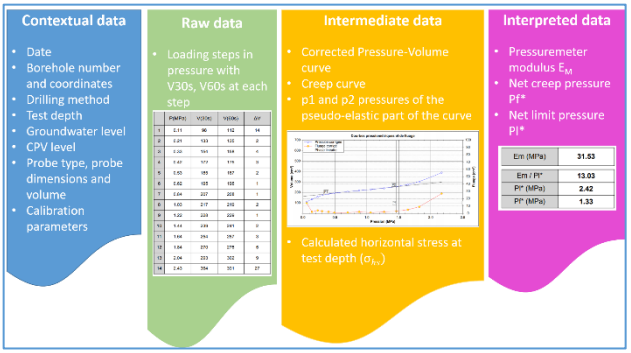

Figure 1. Different classes of data, example of the Ménard pressuremeter test (©BRGM).

The capitalisation of geotechnical parameters in a database therefore raises the question of what data do we want to store? One option would be to store only the final, interpreted data from a geotechnical test (e.g. Pl*, Pf* and E_M in the case of the previous example). However, this would appear to be a very restrictive choice: in fact, these parameters are of little use to the geotechnical engineer if he does not have all the contextual elements of the test (drilling method and diameter, probe dimensions and characteristics, volume-pressure raw data and curves, creep curve, etc.).

It is therefore essential to know and control the source of geotechnical data and, to do this, to be able to store in the database all the data from a geotechnical test: contextual data, raw measurements, curves, intermediate calculations and, of course, the interpreted values. This choice of exhaustiveness gives the engineer who re-uses the data the opportunity to assess the quality of the test and to make his own interpretation. On the other hand, this choice implies a number of constraints and requirements: the management of a large quantity of data, the use of a harmonised vocabulary for all geotechnical data, and the need of using structured and standardized data, i.e. data that obeys precise classification rules, and finally.

2.2 Data standardization and interoperability

Data structuration is a prerequisite for setting up a database. This essential step requires the use of an unambiguous vocabulary for the various physical properties that are stored. To ensure that this vocabulary is understood and shared by all geotechnical engineers, the logical choice is to draw on geotechnical standards (testing standards and Eurocode 7). Each term used for a physical quantity must be accompanied by a clear definition. Any synonyms must be listed and associated with this property.

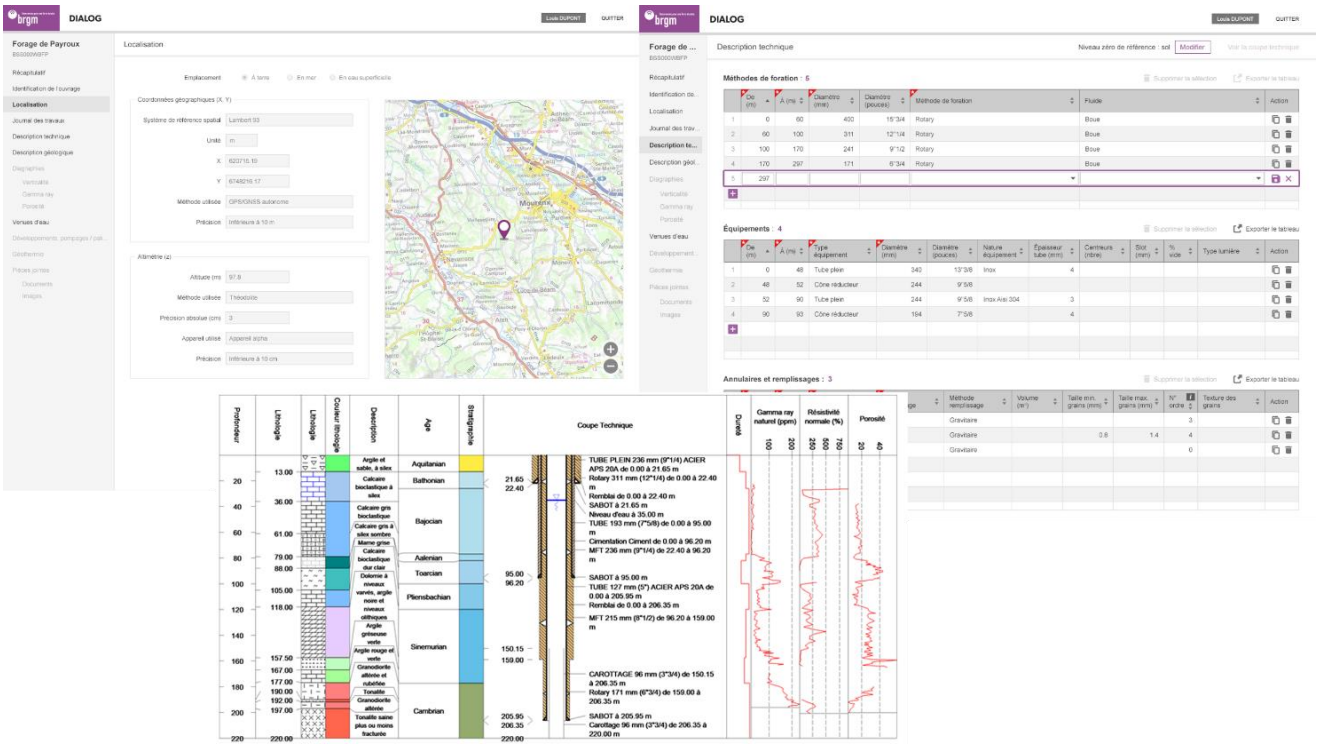

Figure 2. DIALOG web application screenshots (©BRGM).

In order to facilitate data description and to harmonise semantic, BRGM has established registers and acting as a reference point for geoscience vocabularies (https://data.geoscience.fr/ncl/). The registers published cover a wide range of earth sciences topics, including lithology, chronostratigraphy, fossils, minerals, as well as methods, observed properties and units of measurement. They include many entries relating to Geotechnics (in-situ tests, laboratory tests, geomechanical properties and associated units). Each register includes additional information such as synonyms, semantic relationships (hierarchies, equivalences, genealogies, etc.), as well as other useful information for subject specialists such as symmetrical relationships and replacements for obsolete terms.

For Geotechnics, the BRGM registry provides a list of ObservedProperties, Procedure. They have been drawn up as part of an open and collaborative science approach, so that any user can propose modifications or additions to the proposed definitions.

Interoperability is "the ability of a product or system, whose interfaces are fully known, to work with other existing or future products or systems without restrictions on access or implementation" (Wikipedia). Interoperability is also essential if data is to be easily exchanged, either to feed the database or to export data. It requires the development of data standards for all kind of geotechnical data, which is still not the case at present time.

2.3 Digital transition: BIM, Digital Twin, Geomodeling

Since 2018, BRGM has been looking to the issue of standardising geotechnical data. The opportunity to tackle this topic was offered by the national project MINnD, which main aim was to extend the capacities of OpenBIM standards, in particular the Industry Foundation Class (IFC) format from bSI, for describing infrastructures in their environment (Beaufils & al, 2020), (Rives & al, 2020).

For geotechnical engineering, the work was carried out in collaboration with several professional bodies in France, including ANDRA, CAN, CETU, EDF, EGIS, GEOLITHE, GEOS, SETEC, SYSTRA, TERRASOL and VINCI CONCESSIONS. There was a consensus to build the extension for geotechnics on existing

standards (e.g. NF P 94-500) or existing recommendations (e.g. AFTES GT32).

Having as a target the definition of a data exchange format with common semantics between GIS and BIM tools, the group focused on identifying the data exchanged, describing it and organising it.

The openGIS standards promoted by the Open Geospatial Consortium (OGC), used in particular for geology and hydrogeology, served as the basis for this work. Also the group was aware of the existence of the AGS/AGSi (Chadwick & al, 2019) and DIGGS (Bachus & al, 2020) standards and in February 2022 a project called the Geotech Interoperability Experiment was launched (Beaufils & al, 2022).

Again lead by BRGM, the project proposed to federate the geotech community around standards for BIM and GIS.

3 STATUS OF GEOTECHNICAL DATA MANAGEMENT IN FRANCE

3.1 Rules and laws

In France, geotechnical data is the property of the organisation that commissions and pays for it. French law, set out in the Mining Code, requires the declaration to the Authorities of any drilling deeper than 10 m, whatever its purpose (geological, hydrogeological, geotechnical, geothermal investigation, water pumping, etc.).

This declaration is made using a web application (DUPLOS) developed by BRGM. It must be made before the drilling is carried out. An identification number is then created by BRGM and sent to the organisation that made the declaration. The Mining Code also stipulates that all documents relating to the drilling can then be sent to BRGM. To this end, DIALOG, a web application has been developed to enable the lithological and stratigraphic description of the borehole, previously declared, to be entered. To date, this application cannot receive geotechnical properties, except a pdf file attachment.

3.2 BRGM Survey about a national geotechnical data base

Before starting to develop an open access national platform for geotechnical data, BRGM launched a survey to the French geotechnical community. The objectives of this survey were to: find out about the practices of French geotechnical engineers with regard to archiving and exchanging geotechnical data, assess the opinion of geotechnical engineers for data sharing, collect the expectations and needs of future users of the platform, and also their criticisms or warnings.

The survey took place in mid-2023. It was relayed by various geotechnical associations and more than 200 answers were collected A slight majority (53%) are representatives of geotechnical engineering companies, 20% are civil works or foundation contractors, 14% are engineers from public organisations, 6% are public owners. This high level of participation demonstrates the interest of French geotechnical community in this subject.

It appears that a large majority of respondents (85%) consult regularly or occasionally the BSS (subsoil database, which at date is a borehole database, with litho-stratigraphic data only).

With regard to archiving practices, digital archiving of geotechnical reports and data is widely used (92% for reports and 81% for geotechnical data). In the case of data, pdf format is used in the majority (53%). Re-usable formats (such as text, excel or csv) are used by 31% of respondents, and more structured formats (such as AGS, BIM or others) accounting for only 13%.

Support for the project from the geotechnical community is relatively good, as shown by the scores between 1 and 5 given to different proposals, presented in Figure 3. There is also a strong demand for all the raw values in order to be able to make full use of this database.

About a national openaccess geotechnical database, on a score from 1 (disagree) to 5 (agree), you would say	Score
This would make it easy to retrieve old data	4,6 / 5
This would make it possible to avoid carrying out (or repeating) investigations in areas where data is already available	3,6 / 5
This would help to better define new or future geotechnical investigations	4,6 / 5
This would be useful, provided that the raw data from the trials is accessible.	4,2 / 5
This is of limited use, as geotechnical investigation is always necessary anyway.	2,7 / 5
The benefits are limited, as we have no control over the quality or reliability of the tests carried out by others.	3,0 / 5
The benefits are limited, as it takes a lot of time to archive or consult data.	2,1 / 5
This is likely to reduce the market for geotechnical surveys.	2,5 / 5

Figure 3. Results of the BRGM survey about geotechnical database.

However, some concerns were expressed. For example the question of the reliability/quality of the data made available on the platform, and the risks of reducing the market for geotechnical surveys in France.

4 NATIONAL GEOTECHNICAL DATA PLATFORM – TECHNICAL ASPECTS

4.1 User profiles

Users of the platform will of course be geotechnical professionals (engineers, civil works contractors), but

also infrastructure project owners, teachers, students or simply individuals looking for information about the subsoil.

The data suppliers will be the public or private project owners who order for geotechnical investigations. They may delegate the supply of data files to their project managers or geotechnical sub-contractors.

4.2 Structured and unstructured data

The geotechnical data that will be collected can be classified into two categories: structured data and unstructured data.

Structured data is data that has already been organised in a digital format, which may be a proprietary format (for example the files used for acquisition equipment), a format specific to geotechnics (such as AGS or DIGGS), a format associated to the further application (ifc for BIM, or RESQML for geological modelling applications) or a csv or excel format with predefined fields. In order to be able to collect and store this structured data, it is necessary to make a mapping that provides the link between a given parameter in the database and the same parameter in the original file.

The unstructured data are the geotechnical test sheets only available in paper or pdf format. For these data, several possibilities will be provided: downloading the scanned document or pdf file, or manual entry of the test. Further developments based on AI are explored to extract key data in a pdf file.

4.3 Functionalities to develop

Data input interfaces will be developed, on the principle of the DIALOG application currently used to enter lithostratigraphic descriptions of boreholes. Ultimately, the goal is to welcome the largest possible variety of geotechnical tests. However, the tables for each type of test will be developed progressively so as to quickly have an operational tool for the most common tests (e.g. pressuremeter tests, which are very common in France), which will gradually be enhanced with the other types of test. As mentioned above, the content of these tables should include all the fields corresponding to contextual, raw, intermediate and interpreted data.

For users, the data will be accessible via a cartographic interface, with borehole points displayed, as in situ or laboratory tests are always attached to an investigation location. Data will be able to be exported in a variety of formats. Queries by geographical sector, by type of test or by geological unit will be developed.

Finally, connections with geotechnical tools and software are also envisaged: for example, with 2D or 3D geomodelling tools.

4.4 OpenGeotech: the project and its architecture

A pilot project, called OpenGeotech, is currently under development at BRGM. Aimed at giving substance to the standardisation work undertaken previously, it proposes to:

- extend the DIALOG application to the collection and description of geotechnical tests,
- have those data made available through an a standardized protocol called OGC SensorThings API, as recommended and promoted in the Geotech Interoperability Experiment.

In addition to illustrating and validating the standard activity previously mentionned, these two combined actions are done in order to facilitate the process of geotechnical data collection and also offer a „reward“ or „money back“ to the declarant by offering him the capacity to acess and reuse the declared data in other softwares (geomodeling, soil structure calculus or BIM tool) thanks to the interoperable API.

At the current stage of development, drilling parameters (instantaneous logs) and three types of test have been targeted: the Menard Pressuremeter test, the Standard Penetration Test (SPT) and the Cone Penetration Test (CPT).

The description of more tests is planned to be offered in the future, including Laboratory Tests and Samples / Specimen description. These actions will be carried on as part of a larger project in BRGM, currently known as the Geotech Information System project.

5 CONCLUSION AND PERSPECTIVES

Until now, in France, geotechnical data acquired during investigations is not usually reused. Although digital archiving is increasingly used by geotechnical engineers, the data is very rarely organised in a structured way.

The creation of a structured database enabling geotechnical data to be banked and shared with the public is a task that has been entrusted to BRGM by the authorities. It aims to enhance the value of the data acquired, to reduce the need to carry out new surveys unnecessarily, to better target the investigations to be carried out and to improve knowledge of the French subsoil.

A survey of French geotechnical professionals was launched in mid-2023. Most of them were in favour of the project, although they did express some concerns about the quality, reliability and confidentiality of the data.

From a technical point of view, the wealth and complexity of geotechnical data raises a number of questions about the choice of data to be banked, as well as the methods for feeding and consuming the data, and the exchange formats. BRGM has chosen to provide for the possibility of storing all the raw test data, so that future users can assess the quality of the data and re-analyse the tests.

A demonstrator called OpenGeotech is currently being developed in-house at BRGM. A first public version will be available by the end of 2024.

ABSTRACT: The Hostynnyi Dvir two-storey building erected in Kyiv at the beginning of the 19th century is complicated in plan and consists of two U-shaped parts. Under the building the metro tunnels pass with trains running on a normal (non-vibration-isolated) track every 2 minutes. The nature of the foundation structures damage indicates that the main cause of its occurrence is an uneven deformation of the foundations base due to the additional soil compaction under dynamic effects. The damage analysis shows that in fact the building is divided into several blocks and has experienced the spatial rigidity reduction. According to the results of the vibrodynamic tests carried out with the use of the Internet of Things during the metro trains movement, the additional vertical dynamic loads on the building foundations up to 1%, on the soil near the building up to 7%, and on the building floor up to 5% from the object own weight were determined. Modelling of the stress-strain state of the "base – foundation – metro" system is performed using the Midas GTS NX software package. The constructed Digital Twin is a three-dimensional model reflecting the actual soils layering and including the subway tunnels structures, foundations and superstructure parts. The building superstructure parts are included in the model for obtaining a more accurate initial stress-strain state for the base taking into account the building spatial rigidity. The obtained calculated acceleration values coincide with the results of vibrodynamic studies at the IoT sensors installation points.

RÉSUMÉ: Le bâtiment à deux étages Hostynnyi Dvir érigé à Kiev au début du XIXe siècle est de plan compliqué et se compose de deux parties en forme de U. Les tunnels du métro passent sous le bâtiment avec des trains circulant sur une voie normale (non isolée des vibrations) toutes les 2 minutes. La nature des dommages aux structures de fondation indique que la principale cause de leur apparition est une déformation inégale de la base des fondations due au compactage supplémentaire du sol sous les effets dynamiques. L'analyse des dommages montre que le bâtiment est en fait divisé en plusieurs blocs et a subi une réduction de la rigidité spatiale. Selon les résultats des tests vibrodynamiques effectués sur la base de l'Internet des objets, les charges dynamiques verticales supplémentaires sur les fondations du bâtiment jusqu'à 1%, sur le sol à proximité du bâtiment jusqu'à 7% et sur le sol du bâtiment jusqu'à à 5% du poids propre de l'objet ont été déterminés lors du mouvement des rames de métro. La modélisation de l'état contrainte-déformation du système "socle – fondation – métro" est réalisée à l'aide du progiciel Midas GTS NX. Le Digital Twin construit est un modèle tridimensionnel reflétant la stratification réelle des sols et comprenant les structures, les fondations et les parties de superstructure des tunnels de métro. Les valeurs d'accélération de conception obtenues coïncident avec les résultats des études vibrodynamiques aux points d'installation des capteurs IoT.

Keywords: Dynamic loading; metro; compacted urban development; finite element method; experiment.

1 INTRODUCTION

Hostynnyi Dvir is the main and central element of 'The Buildings Complex on Kontraktova Ploshcha (Contract Square), the 10th – the end of the 19th centuries' Architecture and Urban Planning Monument of Local Importance, which comprises a monumental trading store on Kontraktova Ploshcha in the historical neighborhood of Podil. It had partially been constructed in 1809–1813 under the project of Luigi Rusca and was then rebuilt in 1828–1833 according to the project of Andrii Melenskyi. The Hostynnyi Dvir two-storey building (HDB) with a

basement has a complicated plan as it consists of two U-shaped parts forming a closed internal area with the axial dimensions 122.2 m x 65.5 m (Figure 1).

Figure 1. Hostynnyi Dvir, photo of 1930s.

High traffic volumes are observed on the motor vehicle and tram routes located nearby. The metro tunnels pass under the HDB, and the metro trains run on the normal (non-vibration-isolated) tracks every two minutes (Figure 2).

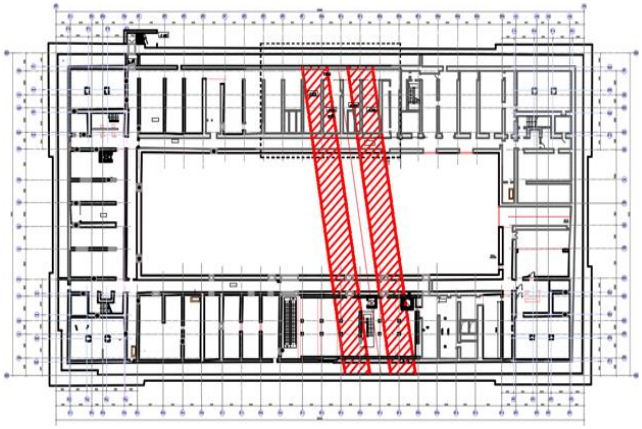

Figure 2. The layout of the Hostynnyi Dvir building. Two red stripes are the subway lines.

International concerns over cultural and natural heritage were reflected in the World Heritage Convention which was adopted by UNESCO in 1972 (World Heritage Convention, 2023). It aims at encouraging national governments to give greater protection to the sites of importance for nature conservation, to conduct research that allows gaining a deeper understanding of their cultural and natural heritage sites and the existing threats to them. The State Parties to this Convention are called on to integrate the protection of their cultural and natural heritage into regional planning programmes, to set up special services with an appropriate staff within their territories, to undertake scientific and technical conservation research, and to take measures giving their heritage a function in the day-to-day life of the community. The issues of dynamic effects on buildings and structures; transport vibration influence on the stress-strain state (SSS) of existing buildings, further deformations of their bases and foundations, their uneven settlements and other negative phenomena were considered in numerous works of such national and foreign researchers as Huston, 2011; Kaliukh et al., 2018; Lollino et al., 2006; Sedin et al., 2019.

2 METHODS FOR ASSESSING THE HDB BASE SSS CHANGES UNDER THE DYNAMIC EFFECTS

Assessment of the „base – structure“ system SSS change is generally made via comparing its specific technical parameters. The number and types of controlled parameters shall be determined according to the preliminary survey results, the regulatory and project documents requirements, and the conditions for maintaining the object operational characteristics throughout its lifecycle. The SSS technical parameters shall be identified pursuant to the results of the object technical conditions complex study including the following activities: visual inspection (defects, damage, assessment of compliance with the project etc.); instrumental studies of the materials strength; geodetic measurements of deformations (settlements, deflections, structures positions etc.); engineering geological and hydrogeological surveys; dynamic vibration tests of soils and structures; numerical 2llowance of the „base – foundation“ system SSS with an2llowancee for the parameters obtained from the investigations mentioned above. Reactions to changes in the structural components technical state are recorded by the monitoring system sensors, which allow receiving data on the object responses to the external and internal effects including the object and its individual components spatial displacements taking place in the form of deflections, settlements, rolls etc.; deformations in building structures; changes in dynamic characteristics of the building structures and building as a whole; and changes in the environment surrounding the object. The above information analysis and numerous examples of new construction activities under conditions of urban density in the city of Kyiv show an urgent need to elaborate a hybrid theoretical and methodological approach using the Internet of Things (IoT) as the logical continuation and development of the scientific and technical construction objects support for avoiding and preventing soil accidents in the future. The IoT sensors allow to carry out the tensometric measurements and the following physical quantities measurements: angles of buildings and structures inclination; levels of

crack opening (closure), object components shifts and expansion joints; vibrations; temperature; humidity; pressure etc. (Figure 3). The IoT basic elements in the sphere of geotechnics are as follows: procedures of sequential analysis when choosing the diagnostic criteria; means of technical diagnostics and methods for processing the obtained information; reference approximation models for the monitoring system testing by the in real time (online) comparison method; multilevel functions and means for monitoring research; diagnostic information concentration in the form of an appropriate database.

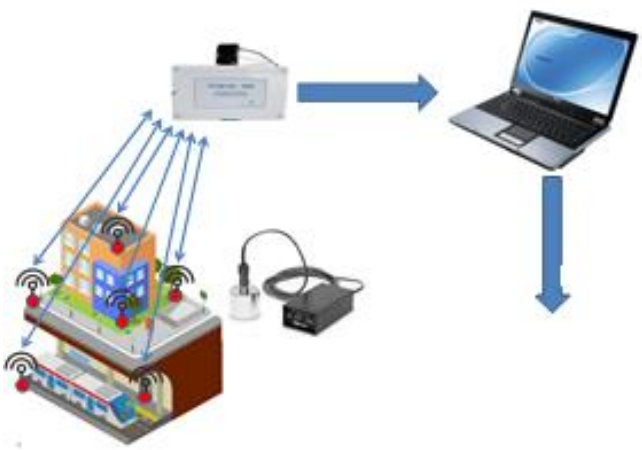

Figure 3. System for on-line monitoring of the object vibration characteristics using the IoT.

Numerical modelling of the HDB SSS under static and dynamic loads was carried out considering the results of checking the HDB mathematical model for its relevance to the real object. That allowed to take decisions on the possibility of using the data obtained after conducting computer experiments on the object mathematical model for setting up and clarifying the composition and placement of sensitive elements of the monitoring system determining the HDB load-bearing structures state. In this case, the relevance of the HDB computer model means that the HDB civil structures integral characteristics obtained from measurements during the field surveys and by means of modelling are almost identical; the discrepancy is within the acceptable range of permissible error.

3 EXPERIMENTAL STUDIES OF THE HDB USING THE IOT TECHNOLOGIES

The above-mentioned studies included the following elements: the visual inspection and instrumental studies of the structures materials strength; checking calculations to assess the "base – foundation – structure" system SSS for HDB; the vibrodynamic tests of soil, foundation and load-bearing structures under the effects of the metro trains, trams and motor vehicles traffic and construction equipment operation. The damage nature indicates that the building structures destruction is mainly caused by the uneven deformation of the HDB foundation bases due to the additional soil compaction under the dynamic effects. The damage analysis shows that in fact the building is divided into several blocks and has experienced the spatial stiffness reduction. According to the results of HDB vibrodynamic tests, the dominant frequencies of soil vibrations were determined as 15 Hz during the land transport movement and 55 Hz during the metro trains movement. The maximum vibration acceleration amplitudes determined with the values of 64 cm/s² in the horizontal direction and 42 cm/s² in the vertical direction under the simultaneous action of all possible dynamic effects were recorded for the soil near the building above the metro tunnels. During the metro trains movement, the HDB own weight caused additional vertical dynamic loads up to 1% on the building foundation, up to 7% on the soil near the building, and up to 5% on the building floor structures. The obtained calculation accelerograms serve as the initial conditions for the SSS modeling of HDB "base – construction – metro" system using the direct dynamic method.

4 SSS NUMERICAL MODELING FOR THE HDB BASE UNDER DYNAMIC EFFECTS USING THE DOUBLE TWINS METHOD

The existing methods do not allow to comprehensively solve the complicated task of forecasting the SSS changes in the "base – structure" system under the dynamic influences including the metro trains effects. The difficulty lies in the necessity of taking into account such important factors as urban density, which is often combined with a developed underground component, and complex engineering and geological conditions of the site with various soils layers. The modern software packages that implement the finite element method (FEM) allow taking into account all the above-mentioned features of real objects with sufficient accuracy. The Midas GTS NX is one of such software packages (Midas, 2018). To perform the numerical modeling, in this paper the Linear Time History is applied. In the GTS NX an implicit integration method for the direct time integration for the linear assignments is used. The GTS NX uses the HHT-α method proposed by Hilber, Hughes, and Taylor for the implicit direct integration. The proposed Digital Twins is a three-dimensional model presenting the actual soil layering, metro tunnel structure, and HDB foundations and

superstructure components. The superstructures are included in the model for obtaining a more accurate initial base SSS taking into account the building spatial rigidity. When solving FEM problems, the calculation area is considered as a collection of a finite number of elements. The main advantage of the SSS numerical calculations is that all components of stresses σ_{ij} (x, y, z), of deformations ε_{ij} (x, y, z) and of displacements u (x, y, z), v (x, y, z), and w (x, y, z) necessary for the SSS assessment and analysis for the entire soil massif are obtained at the output. As a result of the calculations, both the qualitative and quantitative pictures of the SSS parameters changes in the HDB foundations base under the dynamic impacts were obtained. The calculated values of the accelerations coincide with the results of vibrodynamic studies at the sensors installation points. Figure 4 present the assessment of the maximum zone of the dynamic impact during the movement of two trains.

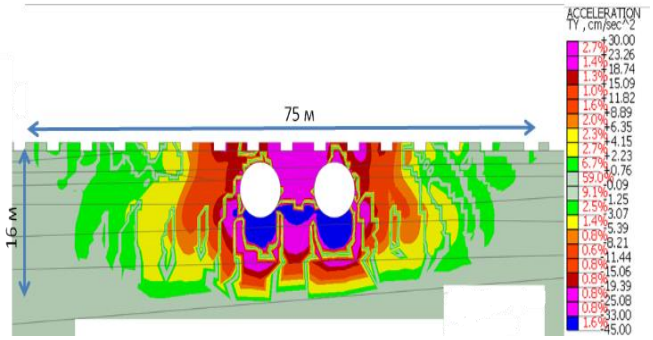

Figure 4. The maximum zone of the dynamic impact during two trains movement (acceleration). During the passage of metro trains, the maximum values of accelerations in the HDB foundation soil base reach 45 cm/s^2 (dark blue color) in the space between the tunnels and under the tunnels, more than 30 cm/s^2 is observed directly under the tunnels (pink and dark red colors), and approximately 20 cm/s^2 is recorded at a distance of 4 m from the nearest tunnel (pink color).

The influence zone of the metro is determined based on the analysis of changes in the parameters of the SSS system during static and dynamic calculations at characteristic points at a certain distance from the source of influence (metro tunnel). According to numerical calculations, it was found that vertical stresses at the base directly under the tunnel increase up to 35.8%. At a distance of 2 to 4 meters, the increase is in the range of [8.2; 11.3]%, at a distance of 8.5 meters, it is up to 2.5%, and at a distance of 13 meters, it is less than 1%. Horizontal stresses at the base directly under the tunnel increase up to 50.6%. At a distance of 2 to 4 meters, the increase is in the range of [8.1; 33.2]%, at a distance of 8.5 meters, it is up to 2.3%, and at a distance of 13 meters, it is less than 1%.

5 CONCLUSIONS

1. Based on the results of the SSS parameters analysis for the "base – foundation – building" system under static and dynamic influences, the qualitative and quantitative pictures of the HDB SSS parameters changes, as well as an idea of the actual vibrations distribution in the soil massif taking into account the real layering of soils, hydrological conditions, underground structures etc. were obtained.
2. The soil vibrations predominant frequencies of 15 Hz during the land transport movement and 55 Hz during the metro trains movement were experimentally determined. Considering the simultaneous action of all types of dynamic influence, the maximum values of vibration acceleration amplitudes of 64 cm/s^2 in the horizontal direction and 42 cm/s^2 in the vertical direction were recorded for the soil near the building above the metro lines.
3. In certain zones of the HDB soil base the excessive pore pressure occurs. The additional soil compaction is possible due to the vibrocompression.

Digital transformation in geotechnical engineering

Digitalisation en ingénierie géotechnique

A. Măgureanu*, L. Sata
SBR Soletanche Bachy Fundații SRL, Bucharest, Romania
**magureanu@sbr.ro*

ABSTRACT: Dealing with a huge amount of information, and being constrained by deadlines it is very important, nowadays, to add efficiency in managing design and execution processes. The first step was to create a transparent framework in all the company's departments, where everyone can access, share and review information, then to create and deliver automated and inter-connected workflows. Site visits simulated site organization or safety trainings are now made using virtual reality. To implement a digital model, it is necessary to know the tools, software suite that can create models, through which automated processes can be realized, interactive communication systems or for arranging and browsing information. Further, in the design department, many models of geotechnical structural solutions can be generated, studied, verified, adapted, and optimized in a very short time, due to automated generative design processes. All information is then stored in a cloud-based network and can be shared automatically through routine-based processes. Virtual reality helps also to understand site constraints, visualize design model applied on site, or to check built geotechnical structures on the site or in the office. Digital transformation in geotechnical engineering, is, in fact a complex and very exciting process for us, it is a strategic element of the company, which generates innovation processes and thus results in better services delivered to our partners.

RÉSUMÉ: Traitant une énorme quantité d'informations tout en étant contraint par les délais, il est très important, de nos jours, d'ajouter de l'efficacité dans la gestion des processus de conception et d'exécution. La première étape a été de créer un cadre transparent dans tous les départements de l'entreprise, où tout le monde peut accéder et ensuite créer et fournir des flux de travail automatisés et interconnectés. Les visites de chantier, les simulations de planification ou encore les formations à la sécurité au travail se font désormais grâce à la réalité virtuelle. Afin de mettre en œuvre un modèle numérique, il est nécessaire de connaître les instruments et la suite logicielle qui permettent de créer des modèles à travers desquels des processus automatisés et des systèmes de communication interactifs peuvent être réalisés. De plus, dans le bureau d'études, de nombreux modèles de solutions structurelles géotechniques peuvent être générés, étudiés, vérifiés, adaptés et optimisés en très peu de temps, grâce à des processus de conception générative automatisés. Toutes les informations sont ensuite conservées sur Cloud et peuvent être partagées à l'aide de différents processus automatisés. La réalité virtuelle permet également de comprendre les contraintes du site, de visualiser le modèle de structure appliqué sur le site, ou encore de vérifier les structures géotechniques réellement construites sur le site. La digitalisation en ingénierie géotechnique est, en fait, une méthode complexe, un élément stratégique de l'entreprise qui génère des pistes d'innovation et se traduit ainsi par de meilleurs services fournis à nos partenaires.

Keywords: Digitalisation; transformation; virtual reality; generative; automation.

1 INTRODUCTION

The latest impact on all aspects of society and business involves a fusion of technologies that blur the boundaries between the physical, digital, and biological spheres. It is a force for change, the reason why companies must combine technology solutions for continuous innovation, which leads to rethink the way they operate.

Digitalization means progress, after all, and it has become increasingly discussed since the beginning of the pandemic. In the context in which construction sites are spread all over the country, the mobility of a person to go through all the construction sites, to assimilate all the information and to physically see their progress became more difficult.

Therefore, the current needs to create a transparent framework, a place where each person in the company can access the desired information at a click away, to visit a construction site virtually or to collect technical information in real time, have led to the creation of a virtual environment, an interactive storage space, a suite of intuitive programs and the individual transposition into a special foundation site through virtual reality.

In other words, by embracing digital technology, construction companies can improve their way of work

by increasing efficiency, bring solid communication to another level and be much more sustainable.

Figure 1. Digital customization of a construction site.

2 THE NECESSARY STEPS FOR DIGITALISATION

To implement a digital model, it is necessary to know the tools, the suites of programs that can create models, through which automated processes can be realized, interactive communication systems or for arranging and browsing information.

The next step is to share within the network (cloud based) the information and processes that require the input of the users. This ensures a clear and transparent communication of the entire process.

By a simple notification, each user is informed and becomes aware of the appearance of an information, of the taking over of a certain task or of the status of a project or construction site.

The most important stage is the horizontal integration (within the company) – that is, a real-time interconnection between the company's employees and the intra- and inter-departmental cooperation. After establishing the internal routine and processes, vertical integration completes the process by involving business partners in the digital interconnection process (e.g., creating an automated flow of orders, notices, invoices, notifications, etc.).

Digital transformation is having a great impact on the construction industry, making its mark on the organizational concept and Soletanche Bachy subsidiaries.

3 DIGITAL TRANSFORMATION IN GEOTECHNICS

At the group level, within Soletanche Bachy, we believe that digitalisation contributes to improving productivity and profitability, reduction of "downtime", increasing the interest of our clients and colleagues (interactive environment), capitalizing on the information and experiences gathered from our projects.

While every piece of information is filtered specifically and is stored altogether, having feedback from previous built projects is very important, whether it is technical, financial, or operational.

As such many breakdowns, high material consumptions can be avoided while the greenhouse gases emissions are reduced.

Figure 2. Digital site organization layout.

3.1 Design digitalisation

Design processes require comprehensive documentation, use of correct instruments and software and a continuous iteration regarding different structural models.

Therefore, it is very important to have routines which will allow automatic search for similar site conditions experienced on previous construction sites, for which, different design solutions were chosen. Of course, those preliminary trials, investigations, and tests (on piles, or on different materials, for example) will help significantly in choosing the right solution perfectly suited for project's purpose.

Nevertheless, return of experience for different solutions in various site conditions can have a great impact for the first step of project development.

The integration of all digital tools makes the design process smoother and with high level of precision.

For example, within a commercial centre foundation piles project, there are many iterations which can be done, to find the perfect balance between pile diameter, pile lengths, pile distribution and reinforced concrete footings.

Our tools make possible the integration of ground conditions, from current or past projects, architectural and structural detailing (columns dimensions, geometry of the building), loads and design and conformation local regulations to offer in a matter of seconds the most convenient piles diameter, distribution and even reinforced concrete footings.

Basically, what we call generative design is a design process that uses algorithms and artificial intelligence (AI) to generate a large number of design solutions that meet a set of constraints.

The user can then choose between the proposed alternatives and detail the project further, considering a lot of restraints as local conditions, site dimensions, materials efficiency, available machinery, and cost optimization.

Putting all the information altogether to have a unified model constantly adapted to real site conditions and updated by all the people which are working together for a specific project is a critical condition for improving the way all the information is shared, the processes used and the way that things are managed.

3.2 Construction site digitalisation

One of the biggest game changers in site management digitalisation is augmented reality (AR) which is bringing a sustainable support in project management, quality assurance and cost control. The software used, allows the user to envision different site layouts by superimposing 3D models into real life environments.

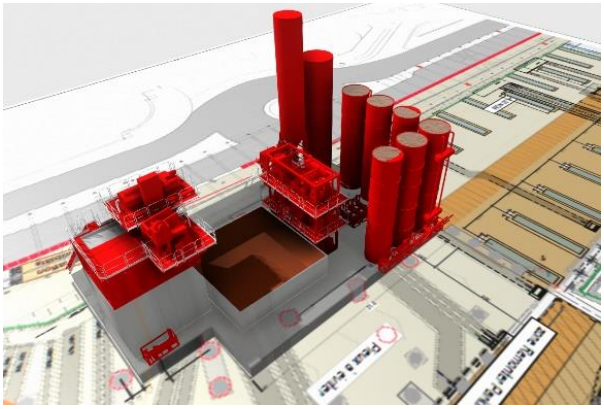

Figure 3. 3D projection of bentonite slurry plant.

This allows workers to see the planned layout of the project and to identify any potential problems early on. AR can also be used to provide workers with real-time instructions and feedback.

Augmented reality is used also to improve safety on construction sites, to highlight potential unsafe situations and to provide workers with instructions on how to avoid them. AR is also a great tool to improve collaboration between construction teams, engineers, architect and the final client.

Zetta-Lyze® is an interactive database platform, created by Soletanche Bachy, multi-application, multi-profile / profession, with multiple sources, easily accessible from anywhere, that offers real-time production information.

More than a working tool, it is a system for the automatic collection of design and production data of a project.

This data can be accessed, organized, and analysed, for an improved monitoring of the project in execution, simplifying our processes, and can be used for a response to a request for quotation, a discussion with a client.

Zetta-Lyze® allow engineers to prepare construction sites, store data, access all maps, display and analyse site data and edit reports.

Currently, there are over 1,150 connected construction sites and over 100 machines equipped throughout Europe, including Romania.

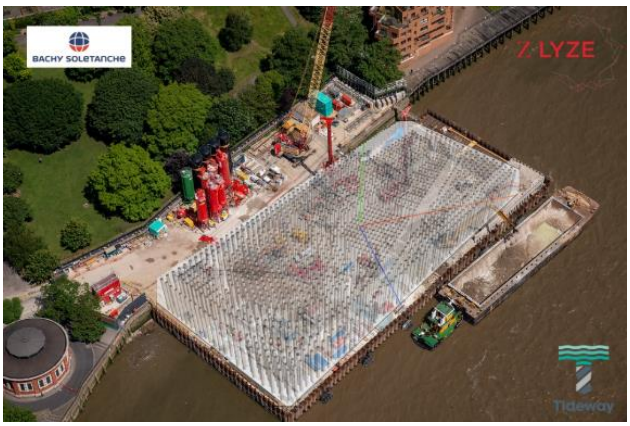

Figure 4. Site view on Z-Lyze.

3.3 Virtual reality

Research on the learning process shows that we acquire knowledge more effectively if we have the chance to test it in practice. Surviving a dangerous situation is therefore the best way to remember what should not be done and what should be done in the face of a real threat.

Virtual reality is used to enrich the introductory training in the field of health and safety, and after the completion of the theoretical part, the user enters our site through the VR kit.

The software allows the user to have a realistic experience on what to expect on a special foundation construction site.

This does not mean, however, that the user is automatically safe.

He can experience what it's like to fall into a trench or what can happen if he's within the working range of the machines. In this way, he is faced with potential threats, thanks to which in the real world there is a greater chance of remembering what can happen if he does not take the appropriate precautions.

Figure 5. Virtual reality safety training session – screenshot.

3.4 Integration of digital tools

Finally, at company level, we have decided that the best way to collaborate effectively is to reassemble all the tools we have created for our daily business.

There are a lot of processes, which when connected give a whole new meaning of the big picture.

From receiving the input for a design and build project, for example, all requirement data is cloud stored giving all workers access to initial data and alert everyone engaged in that project of any update or modification.

Because ground conditions data is essential for our engineering activity, all important information is uploaded in an internal ground database which extract and compare ground parameters from current conditions with the ones from previous built projects. In this manner, we are aware about possible difficulties which we may encounter on site.

Based on the ground report, digital tools can draw lithological profiles and propose deep foundation elements geometry.

After different restraints and criteria selection, design goes further with calculations integrated with finite element method (FEM) design software, offering results which automatically lead to a structural detailing of a special foundation element in an integrated drawing software.

At any moment, if any design input modifies, reiteration can be easily made and finally all the elements can change accordingly (geometry, material properties, capacities, structural detailing and drawings for example).

From that point on, project is being shared with other departments within the company and can be used on site for different purposes, including augmented reality and virtual reality.

Actual progress of working, productivity, materials usage, as-built updates, quality issues, optimization proposals, as well as cost control activity can be accessed and monitored by the team, ensuring a better response time for any action required.

4 CONCLUSIONS

Digital transformation is a complex and very exciting process for us, it is a strategic element of the company, which generates innovation processes and thus results in better services delivered to our partners.

Overall, digital transformation brings the wind of change for construction companies, which nowadays must keep up with the required fast pace and to be one step ahead of any challenges may appear.

ABSTRACT: In the last decades, Lisbon Municipality has implemented a database – GeoSIG to collect, analyse and produce specific outputs suitable for planning and management, using geological and geotechnical data obtained through several work field campaigns. This information allows the identification of the main constraints to occupation, such as a high thickness of coverage deposits or low depth of the water level. In addition, the same information can be used as an input to promote sustainability actions, such as better underground water management or a more responsible underground occupation. Besides the geological and geotechnical setting, Lisbon has also been doing a 3D underground structures and infrastructures representation, considering the impact that these objects can have on natural resources, specific the water flow. To achieve this, the geological and underground information was joined to promote the development and implementation of policies regarding the underground occupation, considering the impact mitigation and the possibility of exploring underground resources, allowing better decision-making.

RÉSUMÉ: Au cours des dernières décennies, la Municipalité de Lisbonne a mis en place une base de données - GeoSIG pour collecter, analyser et produire des résultats spécifiques adaptés à la planification et à la gestion, en utilisant des données géologiques et géotechniques obtenues au cours de plusieurs campagnes sur le terrain. Ces informations permettent d'identifier les principales contraintes à l'occupation, telles qu'une grande épaisseur des dépôts de couverture ou une faible profondeur du niveau de l'eau. De plus, ces mêmes informations peuvent être utilisées pour promouvoir des actions en faveur de la durabilité, telles qu'une meilleure gestion des eaux souterraines ou une occupation souterraine plus responsable. En plus du contexte géologique et géotechnique, Lisbonne a également réalisé une représentation en 3D des structures et infrastructures souterraines, en tenant compte de l'impact que ces objets peuvent avoir sur les ressources naturelles. Pour ce faire, les informations géologiques et souterraines ont été combinées pour favoriser le développement et la mise en œuvre de politiques relatives à l'occupation souterraine, en tenant compte de la réduction de l'impact et de la possibilité d'exploiter les ressources souterraines, ce qui permet de prendre de meilleures décisions.

Keywords: GeoSIG; geotechnical database; three-dimensional modelling; underground water; thematic cartography.

1 INTRODUCTION

Lisbon Municipality has a significant amount of geological and geotechnical characterization data obtained through numerous prospecting campaigns conducted within the city over the past decades.

These data constitute a valuable resource and, when properly organized, can generate highly applicable information in several areas of urban planning and management. Given the potential of this information, Lisbon Municipality (CML) has been working to optimize it so that it can be integrated into its Territorial Management Instruments (IGT), including the Lisbon Master Plan.

The continuous growth of available information resulting from geological-geotechnical studies, raises some issues, regarding data organization, standardization, validation, and integration into a three-dimensional model. This is aimed at transforming the data into dynamic tools for urban planning.

Two fundamental steps were identified: 1) the creation of a database that would gather, in a standardized and georeferenced manner, the information contained in the existing geological-geotechnical reports, resulting in the GeoSIG Platform (CML, 2016); and 2) the integration of this geological-geotechnical information with existing data related to

the underground occupation (basements and foundations).

Given the current occupation of the consolidated area of Lisbon, urban expansion will preferably occur through in the underground. This occupation will not be only through parking structures but also to railway and road infrastructures, part of the city's mobility system. The volume occupied by these structures and infrastructures is not yet available, and when such data exists, it is not properly organized and systematized, which in a certain way constrains the management of Lisbon subsurface.

To enhance subsurface management, Lisbon Municipality has initiated a project called the Three-Dimensional Underground Occupation Model - MODSUB 3D (CML, 2021).

The project aims to use the information available in construction projects stored in Lisbon archives, including the geometry and attributes of buried structures and foundation elements. Through a specialized data loading tool developed for this purpose, this information will be used to maintain an integrated database and a geographical layer within the GeoSIG application.

This information will serve as a base for the development of a three-dimensional subsurface model. When combined with the ongoing development of hydrogeological suitability mapping within the CML, it will enable a more effective assessment of the impact of subsurface occupation on the local hydrogeological flow.

Once integrated into the planning instruments, this information becomes a crucial support and decision-making tool in the context of urban management.

2 GEOTECHNICAL DATABASE – GEOSIG

Lisbon Municipality has been working in the development of a database supported by a management system with the aim of updating the processes of data input and updating. This effort also enables logical data storage, effective data management, optimization of editing and querying processes, and the provision of results for the necessary outputs. This action was developed under the framework of the LISBOA-01-0527-FEDER-000894 - Geotechnical Mapping in Urban Areas - Application to Lisbon, a project financed by the European Regional Development Fund (FEDER).

GeoSIG – Geologic, Geotechnical, and Hydrogeological Data Management for the Municipality of Lisbon is a web application designed for managing geological, geotechnical, and hydrogeological data within the Lisbon municipality. The primary goal is to integrate and apply this data in urban planning and simultaneously seeks to manage a sparse and often incomplete asset that was predominantly in paper format, with limited accessibility and processing capabilities.

This application was designed based on specific functional requirements allowing data management, several users interaction, access control and the definition of specific outputs to decision support purposes.

Currently, access to GeoSIG is limited to internal use by the Lisbon City Council due to copyright restrictions on existing data in geological and geotechnical reports. However, the spatial distribution of the information can be accessed in Lisboa Aberta platform of Lisbon Municipality (CML, 2018).

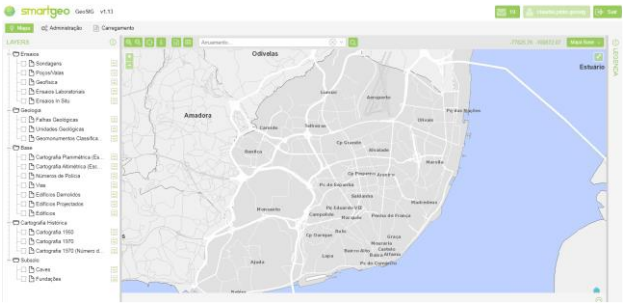

Figure 1. GeoSIG application main screen (Source: GeoSIG).

Until now, this platform integrates more than 13,000 boreholes, corresponding to 2,400 geological-geotechnical reports (Figure 2). The information from the geotechnical boreholes is added to the GeoSIG database by the municipality's technicians. This data comes from the geotechnical reports that are submitted by developers during licensing procedures, along with the excavation and peripheral containment projects.

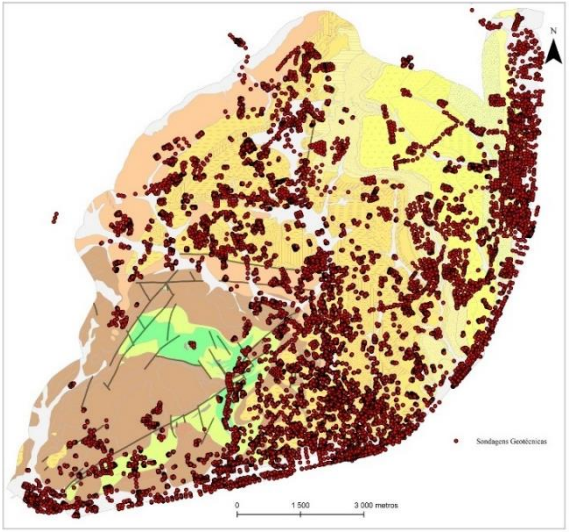

Figure 2. Distribution of geotechnical surveys available in the GeoSIG application (Source: GeoSIG).

Associated with each borehole are data related to the lithology, the water level, SPT test values, recovery rates, and other relevant information.

In addition, sample classifications submitted to laboratory analyses may be added, to record some physical properties of the samples, namely lithology, AASHTO, unified and RTR classes, as well as the granulometric index. It should be noted, however, that the vast majority of geological-geotechnical reports available do not include this type of information, so it will be incorporated into the platform at a later stage

The GeoSIG works in a georeferenced table format, where the depth value is associated with a parameters mentioned above. Currently this data are introduced into geosig by municipal technicians.

It should be noted that the GeoSIG database is intended to provide a macro-scale approach, which does not invalidate local studies. Thus, GeoSIG provides data for modeling more generic geotechnical characteristics, particularly lithology, lithostratigraphy, resistance (through SPT tests) and water levels. The information in the database is a fundamental tool for urban planning (Pinto et al., 2023) and can also be used to perform more specific studies (e.g., Oliveira et al., 2019)

3 THEMATIC MAPPING

To produce thematic mapping, it was necessary to implement a Geoscientific Information System which involve creating specific queries to the GeoSIG database to select the most relevant data for each purpose.

The thickness of coverage deposits and the water level are not limitations to urban development, but they can influence it due to problems related to land suitability and consequently construction costs. Therefore, modelling these factors can optimize projects and reduce costs, making it an essential tool in planning and management.

To achieve this, data obtained from geological-geotechnical boreholes were interpolated, specifically the depth of surficial fills and alluvial deposits, as well as the position of the water table. The operation was conducted using the IDW (inverse distance weight) interpolator.

The water table level was represented by points of different shades according to depth, and in the area, allowing the definition of depth classes. This knowledge facilitates the optimization of groundwater use and management.

From the analysis of Figure 3, it is clear that in the riverside area, the water table position is closer to the surface. Given that this area borders the Tagus River, this result was expected. In general, the water table is located between 3-6m, with exceptions in hilly areas where the water table is deeper. This is also related to the geological formation's permeability.

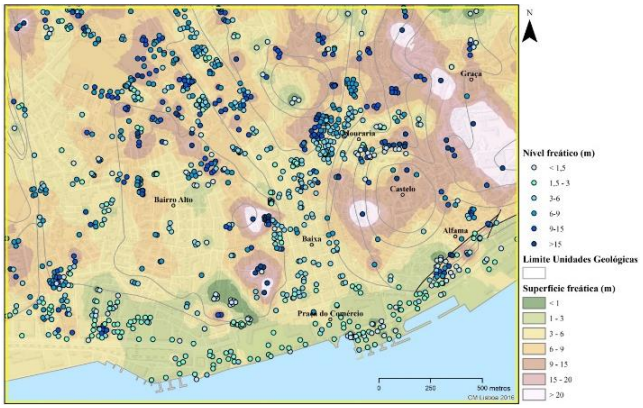

Figure 3. Factor map: Water level position (Source: GeoSIG).

4 MODSUB 3D

To support decision-making Lisbon Municipality has developed a tool that allows the input of the geometry and attributes of the structures and infrastructures existing in Lisbon subsurface – MODSUB 3D. These data will allow the development of three-dimensional models for the subsurface occupation in the city. This information combined with hydrogeological mapping, will enable the assessment of the impact of this occupation on the local hydrogeological flow. As part of the project implemented in pilot areas, data related to basements and foundations of 8,900 buildings were loaded.

The MODSUB 3D application is built upon a tool that allows the user to search for the building in question, make a spatial selection, and subsequently load the data obtained from the construction volume.

This tool allows the registration of the location, geometry, and alphanumeric attributes that define each of the information layers within the application, namely basements, tunnels, and foundations. It's important to note that basement and foundation objects must be associated with a building, while tunnel objects have geometries separate from the building stock.

The information loaded can be visualized through the GeoSIG application, as the geographic layers developed within the scope of MODSUB 3D have been integrated here (Figure 4).

Figure 4. Visualization of geographic information - GeoSIG application (Source: GeoSIG).

In addition to the thematic information presented here, the data included in MODSUB 3D also allows the generation of three-dimensional models. The example in Figure 5 demonstrates how it is possible to obtain a three-dimensional representation of an area (Parque das Nações), using information of the superficial and subsurface occupation.

Figure 5. Representation of the three-dimension model.

5 CONCLUSIONS

The GeoSIG application provides the bases to develop thematic maps and three-dimensional models for several purposes in a quick and efficient manner, making it an essential decision support tool. With this information, we identify the most critical areas of the city where it becomes mandatory to conduct geological-geotechnical and hydrogeological studies before construction works.

The developed working methodology can be easily generalized and replicated for other areas, as long as the basic information is available in a representative quantity for the territory and the data quality is adequate.

These tools can be used by several stakeholders, including designers, planning professionals, and others, to assess constraints and estimate costs related with with specific geotechnical projects. This, in turn, allows for project optimization and cost reduction from the early stages. Lastly, it's worth noting that the construction of underground infrastructure creates a physical barrier to the natural water flow. With these tools Lisbon services can perform a better management of this resources.

ACKNOWLEDGEMENTS

The authors are grateful for the financial support provided through the project LISBOA-01-0527-FEDER-000894 - Geotechnical Mapping in Urban Areas - Application to Lisbon, financed by the European Regional Development Fund (FEDER).

Challenges in assessing the hydrogeological impact of underground structures in urban renewal projects

Défis liés à l'évaluation de l'impact hydrogéologique des structures souterraines dans les projets de rénovation urbaine

R. Ramos*, F.T. Jeremias, L. Caldeira
Laboratório Nacional de Engenharia Civil, Lisbon, Portugal

ABSTRACT: Lisbon's urban renewal projects have led to an increase in the construction of underground structures such as basements and tunnels. As riverfront areas are prone to flooding, since 2010 the City Council has made it mandatory to carry out hydrogeological impact studies for urban developments involving underground works in alluvial areas. The Laboratório Nacional de Engenharia Civil (LNEC) has been carrying out these studies for twelve years, facing increasing model complexity due to the spread of underground structures. This paper provides some guidelines for conducting hydrogeological impact studies, highlighting the difficulties and challenges met in developing these studies and the strategies used to overcome them.

RÉSUMÉ: Les projets de rénovation urbaine de Lisbonne ont entraîné une augmentation de la construction de structures souterraines telles que les sous-sols et les tunnels. Les zones riveraines étant sujettes aux inondations, le conseil municipal a rendu obligatoire, depuis 2010, la réalisation d'études d'impact hydrogéologique pour les aménagements urbains impliquant des travaux souterrains dans les zones alluviales. Le Laboratório Nacional de Engenharia Civil (LNEC) réalise ces études depuis douze ans et doit faire face à une complexité croissante des modèles en raison de l'extension des structures souterraines. Ce document fournit quelques lignes directrices pour la réalisation d'études d'impact hydrogéologique, en soulignant les difficultés et les défis rencontrés lors de l'élaboration de ces études, ainsi que les stratégies utilisées pour les surmonter.

Keywords: Hydrogeological impact; urban area; underground constructions; groundwater; numerical modelling.

1 INTRODUCTION

Urban renewal projects in the city of Lisbon (Portugal) have led to an increase in the construction of impervious underground structures such as basements and tunnels. These structures affect groundwater, mostly in terms of water level, water quality, flow direction and flow rate, due to the barrier effect caused by their presence.

Coastal urban areas as Lisbon are prone to flooding. Consequently, since at least 2010, Lisbon City Council has required specific studies for projects involving underground works in alluvial zones. These studies include the characterisation of hydrogeological conditions and the assessment of hydrogeological impacts, with the aim of predicting whether the design works will increase the risk of flooding.

An impermeable underground structure that crosses the direction of flow can raise water levels upstream and lower them downstream, increasing the risk of flooding around the structure (Ricci *et al*., 2007).

LNEC has been carrying out hydrogeological impact studies in the Lisbon riverfront area for the last twelve years. Experience has shown that the development of this type of study is becoming increasingly complex, given the number of underground structures already built, under construction and planned.

Accordingly, based on LNEC's practice, some guidelines are given for carrying out hydrogeological impact studies, highlighting the difficulties and challenges identified during the development of these studies and the strategies to overcome them.

2 HYDROGEOLOGICAL IMPACT ASSESSMENT

In order to assess the hydrogeological impact of an underground structure, it is often necessary to simulate groundwater conditions by means of numerical modelling (Bonomi and Bellini, 2003; Ricci et al.,

2007; Yang et al., 2009; Paris et al., 2010; Pujades et al., 2012).

Since 2012, LNEC has carried out around twenty hydrogeological impact studies related to the construction of buildings (with one to seven underground levels) in the Lisbon riverfront area, mainly located in the lower part of the Alcântara valley.

The studies were performed using Aquaveo's Groundwater Modelling System (GMS), which includes the computer code for solving the groundwater flow equation (Modflow) developed by McDonald and Harbaugh (1988).

The methodology defined and applied by LNEC in these studies over the last twelve years comprises the following steps:

a) 3D simulation of the reference phase, representative of the situation before the construction of the underground structure, duly calibrated with the results of a hydrogeological monitoring campaign;
b) 3D simulation of the final construction phase, representative of the situation after construction of the underground structure (predictive model number 1);
c) Impact assessment based on a comparison of the results of the two previous simulations;
d) Evaluation of potential remedial measures to minimise the hydrogeological impact (predictive model number 2 also in 3D);
e) Validation of the prediction model(s) based on the results of the hydrogeological monitoring to be carried out after the construction of the underground structure.

Figure 1 shows an example of a hydrogeological impact assessment for the construction of a four-level basement near a hospital, with a gravity drainage and pumping systems installed at the bottom of the building. In this case, although the water level upstream of the underground structure was expected to rise by up to 1m, the impact was considered small as the water levels were expected to remain negative.

3 DIFFICULTIES AND CHALLENGES IDENTIFIED

During the development of the hydrogeological impact studies, several difficulties and challenges had to be overcome in order to obtain reliable results. The following sections introduce and describe them.

3.1 Data type

The geological/lithological model is the basis for the assembly of the hydrogeological model. Firstly, the geological solid model is developed based on borehole data, and then the numerical model is created and fitted to the previous model, as shown in Figure 2.

In order to develop a hydrogeological model that accurately represents the conditions at the future construction site, it is therefore essential to have a set of information on the characteristics of the ground and the aquifers that will be intersected by the structures.

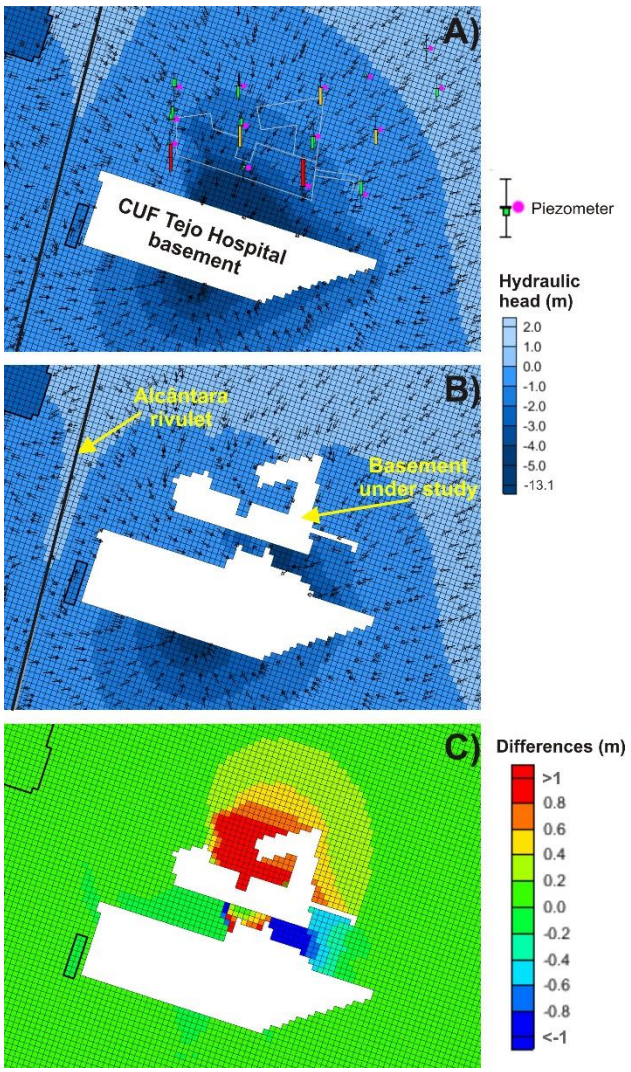

Figure 1. Example of hydrogeological impact assessment. A) Simulation of the reference phase (calibrated); B) Simulation of the final construction phase of the structure under study; C) Impact assessment.

As the design of underground works in alluvial areas generally involves the construction of diaphragm walls down to the bedrock, regardless of the number of basement levels to be constructed, both the alluvial deposits and the bedrock formations should be characterised

Therefore, prior to modelling, a site investigation and monitoring programme must be designed and carried out to provide the following data:

- Geological characteristics of the alluvial deposits (composition, thickness and spatial distribution) and the bedrock formations (nature, structure and stratigraphic sequence) based on borehole data and sampling. Boreholes should preferably be located outside and on all sides of the building area. The lithological information is also of paramount importance in the analysis of the solution obtained in the numerical groundwater flow model during the calibration process. It can often justify hydraulic potentials that may appear erroneous at first sight.
- Hydraulic conductivity of alluvial deposits and rock formations determined by water permeability tests in boreholes and/or pumping tests. It should be emphasised that in these studies the use of high-water pressures on the bedrock chambers does not add any value to the determination of hydraulic conductivity, since the works to be carried out do not impose any additional hydraulic loads;
- Water pressure distribution and flow direction in the aquifers crossed by the works, through monitoring campaigns carried out in at least three non-collinear piezometers installed in each aquifer;
- Evaluation of the influence of tides (in coastal areas) based on the interpretation of a continuous monitoring campaign of the water levels during at least one tidal cycle (one high and one low tide) under spring tide conditions. The behaviour of the records (water level variation curves) can also be used as a check on the consistency of the permeability test results.

By analysing the water levels measured in piezometers with more than one water pressure chamber installed in different formations, it is possible to understand whether there are water levels under pressure, *i.e.* confined aquifers. It is also possible to determine if water levels are affected by anthropogenic activities such as water extractions (permanent or temporary).

3.2 Reliable data

Site investigation programmes designed by non-geotechnical professionals usually fail to provide reliable hydrogeological data because piezometers are installed with a single water pressure chamber across multiple and different aquifer formations. This makes it impossible to determine the water levels and flow direction in each aquifer affected by the works. To avoid this situation, it is important to check the specifications already drawn up and propose the appropriate number of water pressure chambers depending on the number of aquifer formations to be intersected by the structures. If there is more than one aquifer formation, the water pressure chambers should be properly isolated so that they are independent.

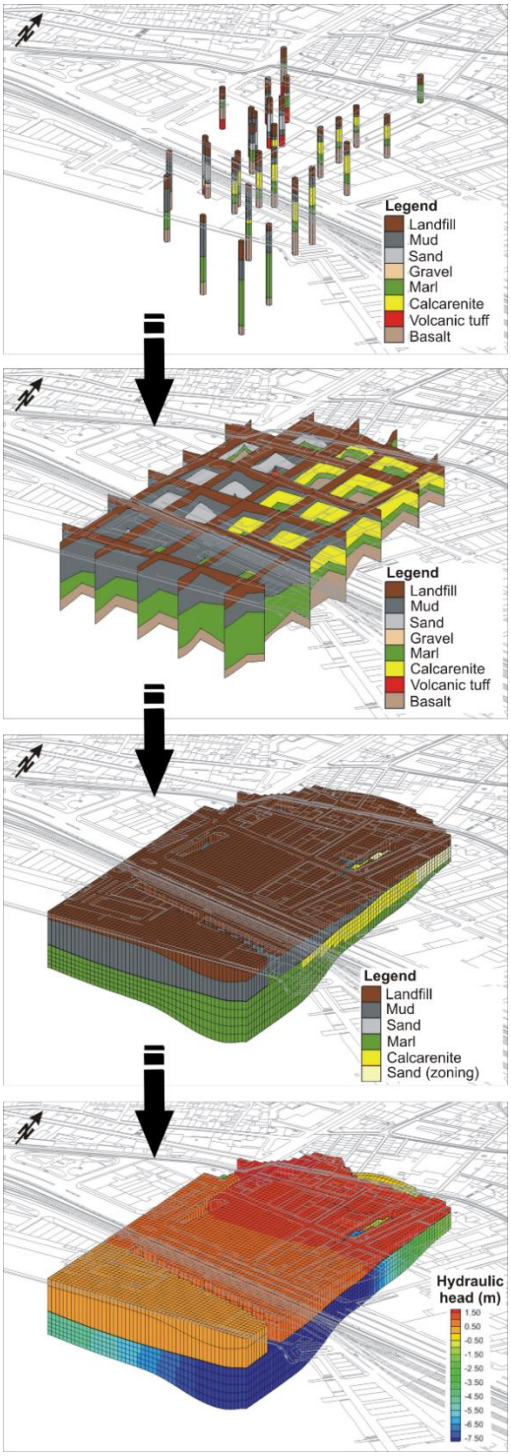

Figure 2. General stages in the creation of groundwater flow models.

Figure 3 shows the distribution of the borehole locations selected for the installation of piezometers where the construction of buildings with basements

was planned. After analysis of the existing information in the study area, it was determined that the data from previous site investigations works did not provided all the data needed to perform the study. Therefore, given the constraints identified in the study area, namely the density of buildings and the occurrence of infrastructures, a set of 7 borehole locations, shown in Figure 3, were defined for the installation of piezometers. Piezometers with double and triple water pressure chambers have been defined, depending on the number of aquifer formations that will be crossed by the building structure at each site.

During the drilling works, it is also necessary to check whether products that may affect the permeability of materials (such as bentonite) are used mainly in alluvial sands. The use of this type of product compromises the data obtained and prevents water permeability tests as well as the installation of piezometers.

As groundwater flows preferentially through permeable zones, it is important to determine the permeability of these layers associated with specific lithologies, such as sands and fractured rocks. These lithologies should therefore be selected for testing during or after drilling.

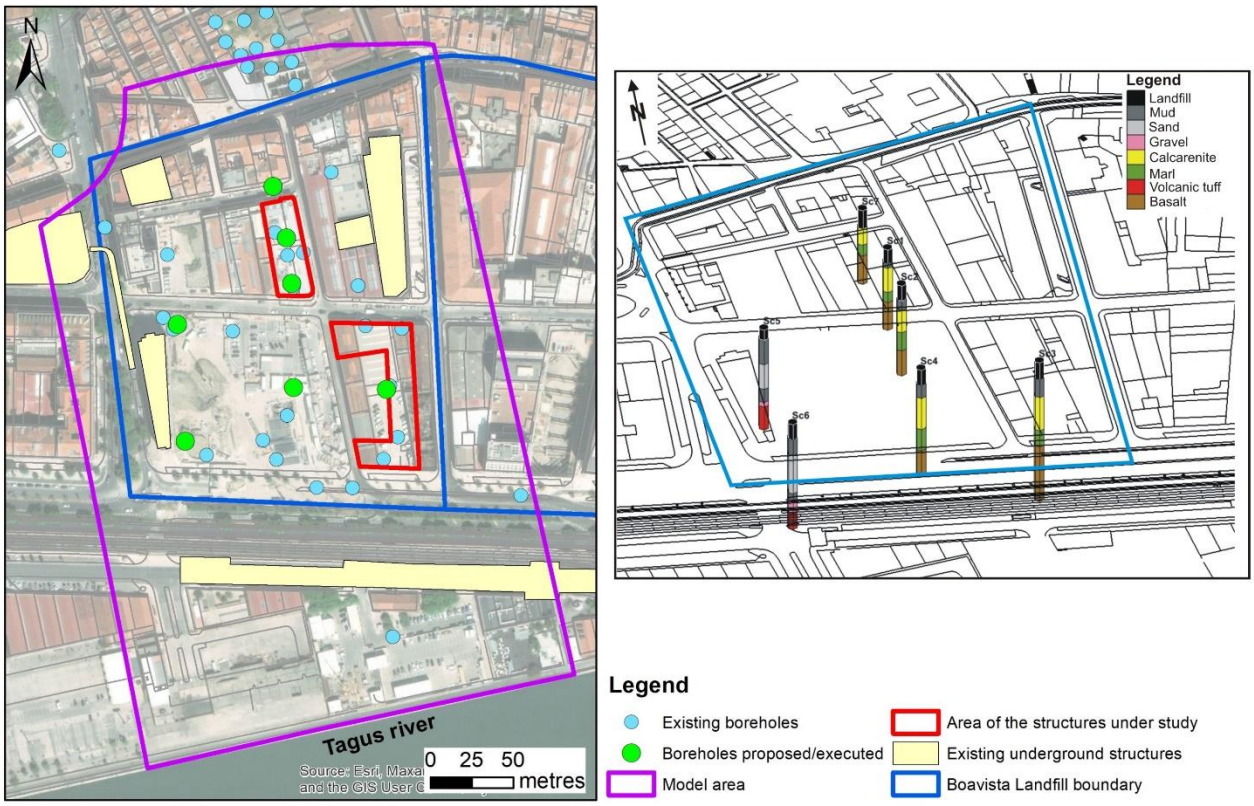

Figure 3. Distribution of the sites selected for the installation of piezometers in the Boavista landfill (Lisbon).

3.3 Model scale (dimensions)

However, such a study requires information on a very large area in order for the model to be representative of existing conditions and to take into account physical hydraulic boundaries and existing underground structures.

Hydrogeological impact studies are usually requested/contracted to consider only the construction area. However, such a study requires information on a wider area in order for the model to be representative of current conditions and to take into account physical geological and hydraulic boundaries and existing underground structures. Therefore, the geological and hydrogeological data should cover as much of the model area as possible.

3.4 Model complexity and calibration

The main challenge of the hydrogeological impact studies was undoubtedly the creation of highly complex numerical models and the respective calibration. The dimensions of the model to represent the physical geological and hydraulic boundaries the characteristics of the underground structures, as well as the interventions in the ground during the studies, all contributed in different ways to the complexity of the model.

The studies carried out in Lisbon's riverfront area focus on two important sites: the Alcântara valley and the Boavista landfill. Both areas are under constant development, with numerous building and tunnel projects in planning and construction phase.

An example of a model created for the Alcântara valley is shown in Figure 4. It is a very complex and extended model, covering an area of 1.3 km^2. This model includes several buildings with one to four basement levels, some of which have drainage and pumping systems installed at the bottom.

In areas affected by tides, the model should be run in a transient state, which increases the complexity of the modelling, especially during the calibration process.

In addition, in some cases water level behaviour can only be explained by water withdrawals whose location and characteristics are unknown.

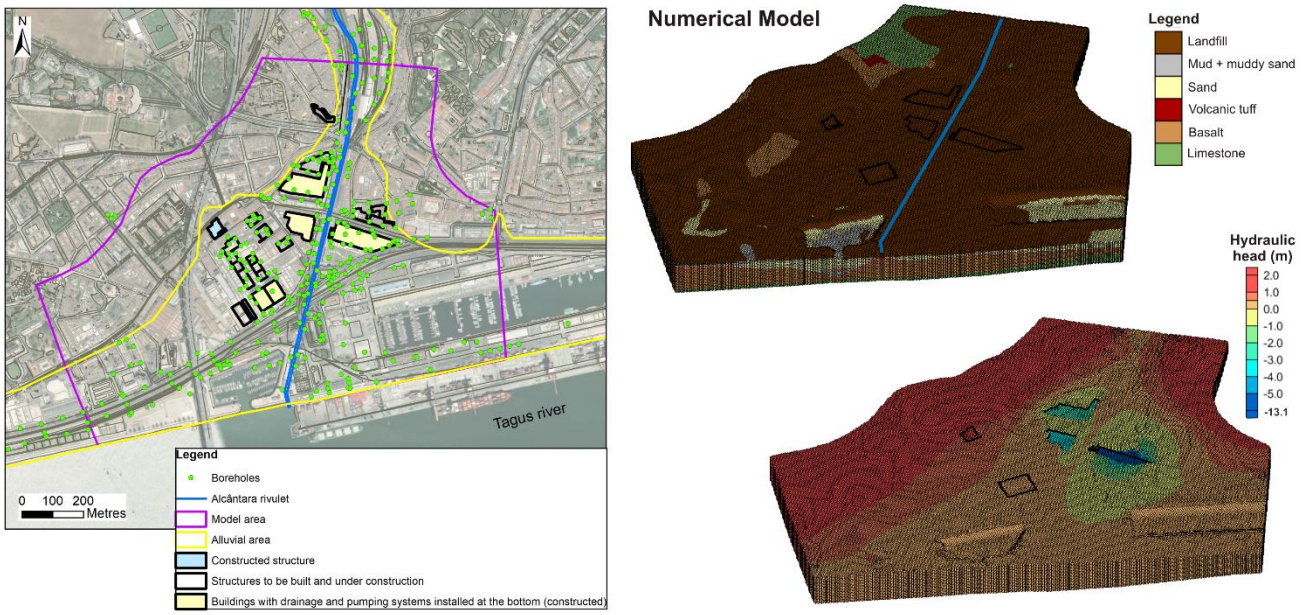

Figure 4. Dimensions, underground structures and characteristics of a numerical model developed for the Alcântara valley (Lisbon)

3.5 Study submission phase

According to the Lisbon City Council's administrative regulations, hydrogeological impact studies must be submitted at the earliest stage of the process, i.e. when the architectural project is being analysed.

This poses a problem because for the impact analysis it is necessary to include the geotechnical solutions in the model, namely the elevation of the bottom of the excavation and the base of the retaining walls, for which there is usually no concept or design at this stage.

As it is not possible to conduct the study without this information, part of the geotechnical concept and design must be developed before the architectural project is approved or alternatively, the worst-case scenario can be analysed, i.e. retaining walls that extend down to the bedrock. However, the best solution would be to require the study to be submitted with the geotechnical design.

3.6 Model validation

Numerical modelling is a representation of reality. It is then important to validate the results of the hydrogeological impact prediction models with field observations collected in piezometers during and after the construction of an underground structure. With this in mind, the data for the model must come from an area larger than the construction site, and the water levels must be monitored during the various phases of the work by means of piezometers installed outside the perimeter of the retaining walls.

3.7 Model reuse

Each study requires the creation of a groundwater flow model in sufficient detail to take into account the geological information of the site and the existing underground structures.

Since the studies and works are not carried out simultaneously and each new study provides data to update the knowledge of the geological and hydrogeological conditions, a new model must always be developed.

4 CONCLUSIONS

This paper provides a comprehensive overview of hydrogeological impact studies in the context of urban redevelopment projects involving the construction of

underground structures. These studies aim to support sustainable urban development by mitigating flood risks.

It also outlines a methodology for the studies, which involves numerical modelling to simulate groundwater conditions before and after construction. These simulations are used to assess the impact of the construction of underground structures on groundwater flow and to evaluate potential mitigation measures.

Based on LNEC's experience, several difficulties and challenges have been identified in the development of hydrogeological impact studies over the past twelve years, including obtaining reliable data, modelling at an appropriate scale, managing model complexity and validating model results.

Accurate groundwater modelling depends on comprehensive data on geological and hydrogeological characteristics obtained through site investigation and monitoring programmes. However, the main challenge is the development and calibration of complex numerical models that have to represent both the geological conditions and the underground structures. Finally, it should be emphasised that validation of the models with water levels measured in piezometers is a crucial task to ensure the accuracy of the predictions.

Norwegian Geotechnical Institute, Oslo, Norway

N.B. Hansen
Geovita AS, Oslo, Norway

**magnus.romoen@ngi.no*

ABSTRACT: In recent years, geotechnical engineers at NGI and Geovita AS have adopted new ways of creating and using parametric 3D/BIM models in their engineering design. The models are used through the life cycle of the project, from idea to construction to as-built documentation. This new way of working has successfully been adopted on several ongoing, major infrastructure projects in Norway. All models for underground structural design, such as retaining walls, soil improvement, rock support etc., are developed through parametric modelling. The models mature throughout the project and adding information in the models makes them fully functioning BIM-models which can be used directly by the contractors. The use of parametric design greatly improves communication and multi-disciplinary design, reduces risk of collision and errors, and can lead to significant time and cost savings in projects compared to a manual geotechnical design. This article shows the possibilities of parametric modelling in geotechnical engineering and will hopefully inspire more geotechnical engineers to open this digital toolbox.

RÉSUMÉ: Ces dernières années, les ingénieurs en géotechnique du NGI et de Geovita AS ont adopté de nouvelles approches pour créer et utiliser des modèles paramétriques 3D/BIM dans leur processus de design d'ingénierie. Ces modèles sont utilisés tout au long du cycle de vie des projets, de l'idée à la construction, jusqu'à la documentation finale. Cette nouvelle manière de travailler a été intégrée avec succès à plusieurs projets d'infrastructures majeurs en Norvège, pour lesquels tous les modèles de design des infrastructures souterraines, comme les murs de soutènement, l'amélioration des sols, le support rocheux, sont développés à l'aide de la modélisation paramétrique. Les modèles évoluent tout au long du projet, et l'ajout d'informations dans les modèles BIM les rend entièrement fonctionnels et permet leur utilisation directe par les entrepreneurs. L'utilisation de la conception paramétrique améliore considérablement la communication et la conception multidisciplinaire, réduit les risques de collisions et d'erreurs, et peut entraîner des économies de temps et de coûts significatives dans les projets, comparativement à une conception géotechnique manuelle. Cet article présente les possibilités de la modélisation paramétrique en géotechnique et vise à encourager davantage d'ingénieurs en géotechnique à ouvrir cette boîte à outils numérique.

Keywords: Parametric modelling; BIM; automation.

1 INTRODUCTION

Focusing on infrastructure projects and geotechnical engineering, the subsurface in urban areas is becoming more congested, increasing complexity for new developments. BIM (Building Information Modelling) is increasingly being used in subsurface engineering (Gondar et al., 2019; Satyanaga el al., 2023), also for specific applications such as soil nailing (Nappa et al., 2019). In general, underground construction is moving towards more digitized workflows (Huang et al., 2021).

Geotechnical engineers should be prepared for the drawing-free projects that are coming and adopt to a more model-based design workflow following the principles of BIM.

A few years ago, NGI and Geovita AS began improving our design workflows largely enabled using parametric 3D-modelling tools and the development of scripts to automate the 3D modelling tasks.

2 3D MODELLING WORKFLOWS

2.1 The past workflow

Both companies have been 3D-modelling for several years. This was often static 3D-modelling in AutoCAD, which often gave very large and hence slow models. Since there often is late changes in the projects, these models were established at the end of the design phase to avoid too much re-work in the projects. And even if these models were only produced once, production of these models was very time consuming.

Late modelling also resulted in the lack of possibility for interdisciplinary class detection, which again could result in undetected conflicts and reasons for higher costs. The modelling was also mainly done for the geotechnical-structures, and not for the soil layering except for the bed rock surface.

2.2 Present workflow

Basis for the change in workflow was to find more suitable software, which would enable more dynamic models. Both companies ended up with using Leapfrog Works (Seequent) for modelling geology/soil/soil layering and the combination of Rhino and Grasshopper (Robert McNeel & Associates) for modelling geo-structures.

These software gives the possibility to establish the geotechnical models early in the projects, and the models will then evolve with the projects. The level of the model is of course always communicated with a given LOD- or MMI-value. The establishment of these models has several advantages:

- They are improving the communication about uncertainties (more about this later).
- They are basis for the calculations of the geotechnical engineer, which saves time in the calculation process.
- The early establishing of these models ensures better interdisciplinary clash control.
- They will early give a picture of both cost and carbon footprint.
- They are basis for execution for the contractors, both as models and as geodata.

Since we are using dynamic modelling, the always present changes in the projects will only result in a minimum of extra work, will cut the cost dramatically and makes new, updated models extremely quick.

3 PARAMETRIC MODELLING

Parametric design is something that has been in use for quite some time within other fields such as e.g., architecture and construction industry, but is still relatively new in the geotechnical world.

In short, parametric design is a new way of defining work tasks and planning throughout the entire construction process. In the CAD software Rhino there is a built-in framework for visual programming called Grasshopper. This works in such a way that you create a work process by "visually" connecting different components (or parameters) with nodes.

As an example: the work process can be "set out piles along an axis" and the components in this case will be e.g., "create a reference point", "set diameter of piles", "set pile length", "set centre distance between piles", "set number of piles further along the axis" and "construct cylinder object". Connecting these components then creates a kind of network, or a script, which together performs the desired work process. Updating a single component, e.g., "moving the reference point for the cylinder", will automatically cause all piles along the axis to move to the new reference point. This is what is called parametric modelling – that a dynamic network of interconnected components enables a complex work routine that is updated seamlessly with each update of a single component. As a bonus, you can reuse the same work routine over and over on project after project. This saves a lot of time and requires increased quality of each modelling task and delivery.

3.1 Sheet pile wall with tie-back anchors

As an example, for use in the geotechnical design, we take a closer look at a construction pit. We are in an early planning phase and the only thing we have received from the project is a line of proposals for the placement of the basement wall. In addition, we have a terrain model and a rock model. With these input parameters and a pre-defined script that creates sheet pile walls, see Figure 1, we get a 3D model of the construction pit within a few seconds.

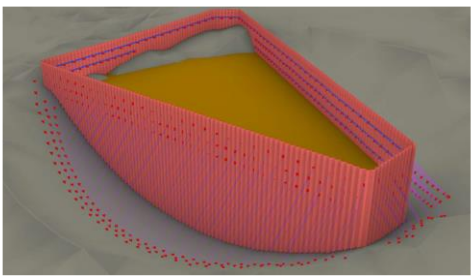

Figure 1. Sheet pile wall with tie-back anchors.

In addition to a script for generating sheet pile walls, we have developed scripts for different types of retaining structures (such as diaphragm walls, Berliner wand etc.), struts, tie-back-anchors, beams, lime-cement columns, jet grouting etc. All these scripts are

re-used, which gives a huge time-saving on new projects.

Back to the example above, if we now want to add tie-back-anchors in the model of our construction pit, we simply add it by serially connect the sheet piling script with a new script that generates anchor braces. The model with the anchors and the bed rock surface is given in the figure below. What is very important to point out here and which is essential for the models to be dynamic, is that these scripts must be connected. The reason for this is that if you move or change the original line, defining the basement, then both the sheet pile walls and the anchors are moved according to the new position.

3.2 Settlement analysis

The software is also used for performing an analytical settlement calculation over a larger area to assess the impact on the surroundings because of our planned construction pit.

The procedure involves creating a grid that covers the area you want to assess. A direction vector is then calculated and the distance from each cell in the grid to the construction pit. At the intersection between vector line and cell, three points are taken out (far, middle and nearest). In each of these three points, in each cell, the depth to rock and the depth is divided into segments with e.g. 0.5 m thickness. Soil parameters are calculated in the same way for each depth segment with Python code components in Grasshopper. Based on this, one can then perform a 1D settlement calculation (Janbu, 1970) in each individual point with a time component through approximation of the degree of consolidation from Terzaghi and Fröhlich (1936).

With this script it is possible to visualize the effect on the surrounding area because of the construction site. In Figure 2, one can see that the calculations indicate an influenced area up to 340 m from the construction pit.

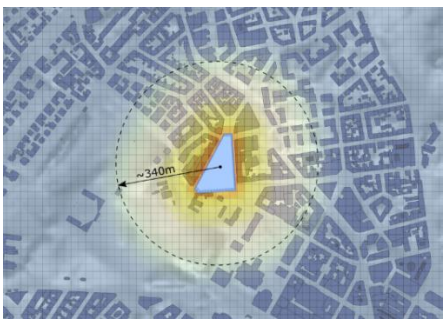

Figure 2. Calculation of influence area.

The effect of the construction work can also be calculated for points on each building object around the pit, see Figure 3. Resulting potential for damage to surrounding buildings can be visualized as damage classes.

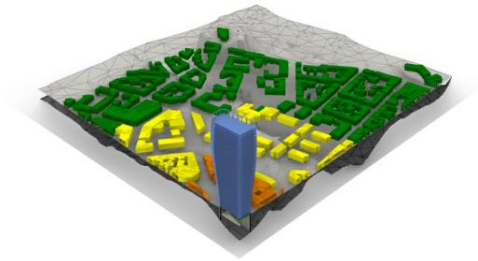

Figure 3. Visualization of potential damage on buildings.

3.3 Ground improvement with deep soil mixing

Parametric modelling is also used for establishing models for ground improvement with deep soil mixing.

There are several methods to improve the strength and stiffness of the ground, using vibration, impact, or by mixing a binder material into the soil. In this modelling example, we will focus on deep soil mixing, known in Norway as lime-cement-columns. With this method a binder, typically lime and cement, is mixed into the soil using air pressure and a rotational tool. These columns can be approx. 20 to 30 m long and commonly have a diameter of 600 to 800 mm. Columns are installed in various patterns such as grids, ribs, panels or single column, depending on the purpose and structural function of the ground improvement.

Large construction projects in soft-clay areas may have several tens of thousands of these columns installed to improve constructability and reduce ground risk. The modelling of the deep soil mixing with parametric modelling gives not only dynamic models, but the models are also basis for the execution by the contractor.

In our given example we connect another script, producing the lime-cement-columns to our construction pit, and we will then quickly get the result shown in Figure 4. Of course, we could now easily change parameters in the model.

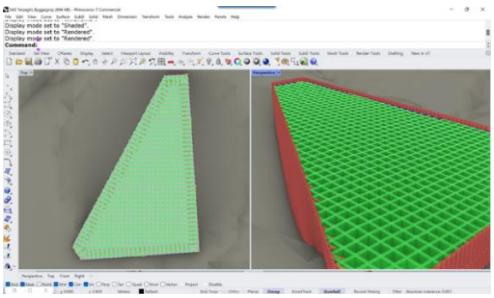

Figure 4. Excavation pit with lime-cement-columns.

3.4 Quantity take-off and sustainability

In all the scripts producing the models, we have also implemented a system for defining the properties of the objects which are summed up in geotechnical Psets, easily readable in the IFC-files we make in Rhino/Grasshopper. This is not only details about the structural element, but can also be details about tolerances, material properties, execution etc.

As the models develops through the project, this also means that we easily can see how the cost, emissions, etc. develops with changes in the models.

3.5 Visualization of uncertainty

Geotechnical engineering has a lot of uncertainties. The geotechnical engineer has often information about the soil conditions in points, but between these points the knowledge is uncertain.

One way to communicate to project stakeholders in the BIM model that geotechnical point information is interpolated and extrapolated to create continuous surfaces, such as the bedrock model, is to visualize on the surface mesh the closest distance from the mesh cell centre to the nearest borehole. Applying a colour map where green is “close” and “red” is further away yields a triangulated bedrock rendering as shown in Figure 5. This method does not quantify the uncertainty, e.g. a standard deviation, but is merely used as a simple visual communication tool in the BIM model.

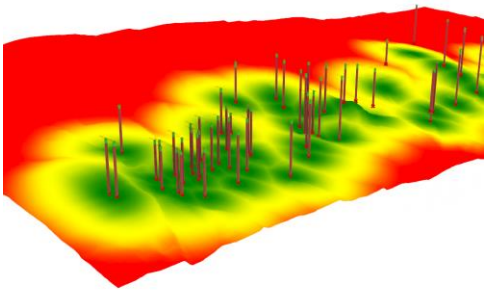

Figure 5. Visualization of pseudo-uncertainty based the distance of each mesh cell to the nearest borehole.

These models can further be part in a collaboration software which then easily can communicate the uncertainty to other participants in the project. Are your planned new building placed in the middle of a red area, then you have acquired a project with a high level of uncertainty, geotechnically speaking.

4 CONCLUSIONS

This paper describes how NGI and Geovita have adopted parametric 3D modelling to deliver examples of geotechnical analysis, BIM models and how to effectively communicate geotechnical uncertainty to projects stakeholders in the BIM model. The use of parametric design has greatly improved our engineering and project workflow, especially for larger infrastructure projects such as road and railway developments. The dynamic 3D models are updated continuously throughout the project and yields significant timesaving when the 3D geometry generation is automated using Grasshopper-scripts. Parametric modelling can be applied a wide range of geotechnical problems, including analysis of settlement and generating quantity take-offs for construction works. The authors highly recommend design and engineering firms within the geotechnical domain to adopt this way of working.

ACKNOWLEDGEMENTS

The authors are grateful to our clients for letting us develop the codes for the parametric design over several of our projects over the recent years.

ABSTRACT: We are currently immersed in the era of big data, where large volumes of data is generated and stored daily. However, the true challenge lies in transforming this data into meaningful and actionable information. To extract insights from these vast datasets, there is a growing dependence on machine learning techniques, which essentially build upon the foundation of traditional statistical methods. These techniques enable the creation of models that enhance our understanding of diverse subjects and facilitate informed decision-making. This study focuses on the establishment and exploration of a database derived from dynamic load tests on piles (DLT). In DLT on piles, impact hammers are employed, characterized by their potential energy or kinetic energy just before impact. Testing on high-capacity drilled deep foundations presents several challenges, including the need for sufficient energy to mobilize compressive static resistance of the pile. The investigation delves into understanding the correlation among various DLT test variables and uncovering potential relationships using supervised models, such as linear and non-linear regressions. The findings from this exploration have unveiled crucial insights, such as the influence of diameter on resistance and the existence of a non-linear relationship between resistance and the maximum energy transferred to the pile.

RÉSUMÉ: Nous sommes actuellement plongés dans l'ère du big data, où un volume immense de données est généré et stocké quotidiennement. Cependant, le véritable défi réside dans la transformation de ces données en informations significatives et exploitables. Pour extraire des insights de ces vastes ensembles de données, il existe une dépendance croissante aux techniques d'apprentissage automatique, qui s'appuient essentiellement sur les méthodes statistiques traditionnelles. Ces techniques permettent la création de modèles qui améliorent notre compréhension de sujets divers et facilitent la prise de décision éclairée. Cette étude se concentre sur l'établissement et l'exploration d'une base de données dérivée de essais de chargement dynamique de pieux (DLT). Dans le DLT sur les pieux, des marteaux d'impact sont utilisés, caractérisés par leur énergie potentielle ou leur énergie cinétique juste avant l'impact. Les essais sur des fondations profondes forées à haute capacité présentent plusieurs défis, notamment la nécessité d'une énergie suffisante pour mobiliser la résistance statique en compression du pieu. L'enquête vise à comprendre la corrélation entre diverses variables de test DLT et à découvrir des relations potentielles en utilisant des modèles supervisés, tels que des régressions linéaires et non linéaires. Les résultats de cette exploration ont révélé des informations cruciales, telles que l'influence du diamètre sur la résistance et l'existence d'une relation non linéaire entre la résistance et l'énergie maximale transférée au pieu.

Keywords: Dynamic load testing; exploratory data analysis; supervised models; pile foundation.

1 INTRODUCTION

Dynamic load testing systems use a mass to apply load to the head of the pile. This can be achieved either through a pile driving hammer, known as an impact driving system, or by dropping a mass, referred to as a drop mass system. Dynamic load testing can be conducted during the pile installation of precast concrete piles or steel piles (displacement piles) when driving with a hammer. Drop mass systems are employed to test cast-in-situ piles (bored piles, continuous flight auger, or other cast-in-situ piles) or testing associated with re-driving. These drop mass systems are characterized by their mass and maximum stroke (drop height), or the respective potential energy

(mass × acceleration × stroke) or kinetic energy immediately just before impact.

Testing high capacity drilled deep foundations poses several challenges, one of which is determining the required energy level to mobilize the compressive static resistance of the pile. Hussein et al. (1996) conducted a wave equation analytical study for the selection of a hammer for DLT of cast-in-place shafts. The studied shafts have ranges of diameters from 750mm to 1500mm and lengths from 10 to 30 diameters. Analysis results suggest as a general guideline that the hammer weight should be about 1.5% of the pile resistance.

According to EN ISO 22477-4:2018, the mass of the drop mass should be chosen to be greater than 2% of the design compressive static resistance of the pile (where the mass of the drop mass is expressed as a weight). In very hard soils, piles resting on hard bedrock, or where a pile is installed with a rock socket, drop mass weights of 1 % of the required design compressive static resistance can be sufficient to mobilize pile resistance.

Ideally, the applied energy or the stroke of the drop mass should be adjusted to achieve full mobilization of the pile skin friction and tip resistance. This study focuses on the establishment and exploration of a database derived from dynamic load tests on cast-in-place foundation piles of the Tagus River Lezíria Bridge River.

2 CASE STUDY

The Tagus River Lezíria Bridge comprises the north viaduct, the main bridge and the south viaduct with a total length of about 12 km. The viaducts are supported by piles with a diameter of 1500mm, and their lengths vary between 25 and 55 meters.

The construction methodology defined to install the piles is the following (Caputo, 2009):

i. Placement of a guide-steel tube with 6.00m of length.
ii. Driving a temporary casing with the use of vibrator down to the design depth.
iii. Internal cleaning of the casing up to the design depth with a hydraulic rig.
iv. Placement of the steel reinforcement cage.
v. Cleaning of the pile tip by “air-lift”.
vi. Pouring of the pile concrete simultaneously with the removal of the steel casing.

To validate the construction methodology and the pile design, a series of static and dynamic load tests were conducted (Santos, 2005).

Dynamic load tests were performed on 9 trial piles (6ϕ800mm and 3ϕ1500 mm) using specific equipment called SIPEX — Impact System for Trial Piles.

This system utilizes the free fall of two 100kN weights with a maximum drop height of 3m, capable of acting together or separately. The setup includes a guide tube and an attached steel cap block placed over the pile. The cap block ensures the centred and vertically applied impact and serves as protection against potential damage to the pile head (Figure 1). While this equipment is designed for testing ϕ1500 mm piles, it can also accommodate lower diameter piles using a reducer.

Multi-blow dynamic testing technique was employed, with applied energy varying between 40 and 600 kJ (or kNm) (Paraíso and Santos, 2020).

Figure 1. SIPEX: Drop mass system 100+100 kN.

The load tests were carried out in 3 locations along the route of the viaducts, and a supplementary ground investigation campaign was defined, consisting of boreholes accompanied by SPT tests and SCPT tests. There are alluvial deposits (soft silty clay, sands) overlying gravels, boulders and the Miocene bedrock (Figure 2).

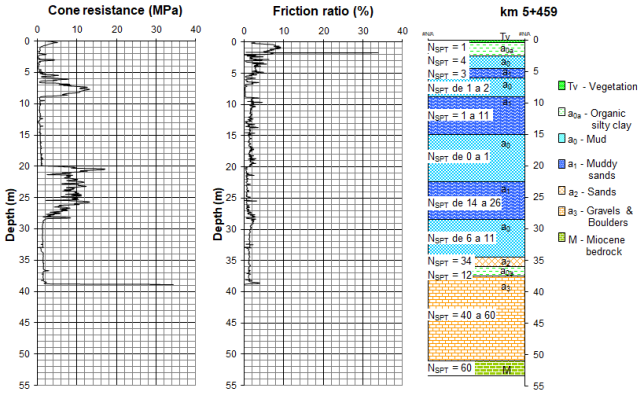

Figure 2. Typical Geological and Geotechnical Profile.

3 METHODOLOGY AND RESULTS

In the current investigation, we have at our disposal four variables derived from the DLT test: the diameter of the pile (D), the maximum potential energy of the hammer or rated energy (EP), the maximum energy transferred from the hammer to the pile (EMX), the mobilized resistance (R), and the ratio between the mobilized resistance and the service load $\left(\frac{R}{Qs}\right)$. To gain a deeper understanding of our data and the interplay among these variables, we initiated an exploratory data analysis (EDA). This type of analysis enables us to discern the strengths of relationships between variables and to further elucidate these connections. The data underwent processing utilizing the Python open-source language, leveraging prominent libraries including Pandas, Scipy, NumPy, Seaborn, and Matplotlib.

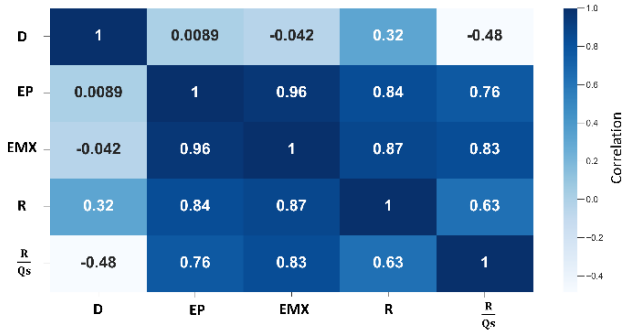

Figure 3. Correlation matrix for input variables.

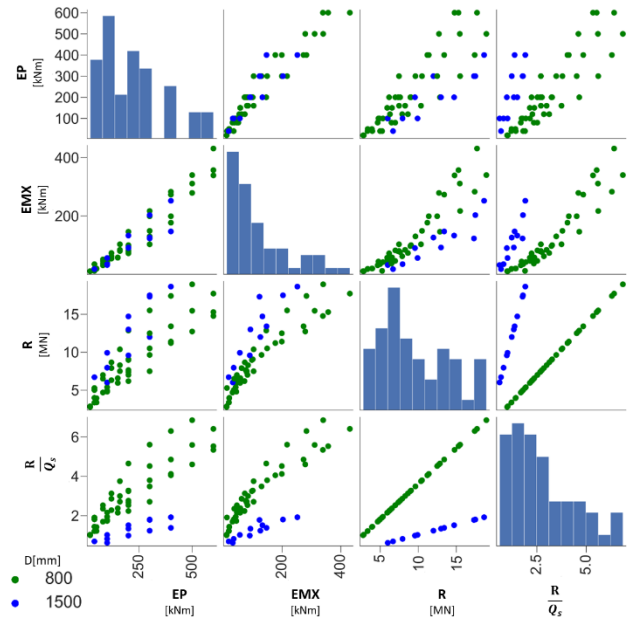

Figure 4. Scatterplot matrix depicting the relationships among the investigated variables. The green color represents the piles with 800 mm diameter and the blue the ones with 1500 mm.

Figure 3 showcases the correlation matrix for the aforementioned variables, while Figure 4 illustrates scatter plots for variable pairs. In this plot, piles with a diameter of 1500 mm are depicted in red, and those with an 800 mm diameter are represented in blue, complemented by variable histograms. A careful examination of these visualizations reveals that the diameter (D) demonstrates linear independence from rated energy (EP) but shows a weak correlation with the mobilized resistance (R). As anticipated, a larger diameter would correspondingly increase resistance. Additionally, it is apparent that there exists a non-linear relationship between mobilized resistance (R) and maximum energy transferred from the hammer to the pile (EMX), with a correlation coefficient of 0.87. The influence of pile diameter is also evident, separating the data into two groups, easily discernible by colour in the scatter plot.

Efficiency of the hammer is commonly assessed by calculating the ratio between the rated energy (EP) and the maximum energy transferred from the hammer to the pile (EMX). The maximum hammer height of drop is 3m leading to a 600 kNm rated energy, displayed in Figure 5 as EP, we can see that the survey was carried out for several heights (multi-blow testing technique), since the weight of the hammer was kept constant and equal to 200 kN. As depicted in Figure 5, it is evident that EMX is approximately 0.7 times EP, indicating a 30% energy loss.

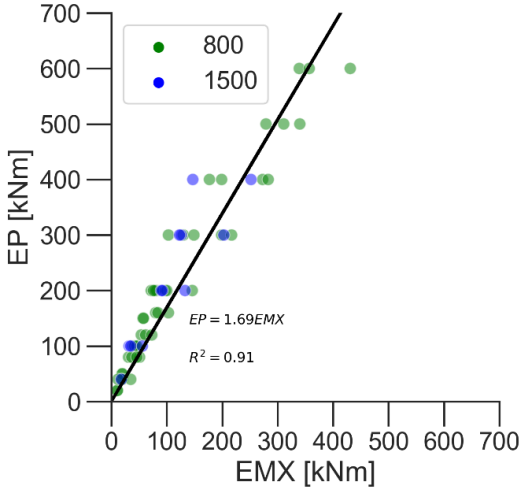

Figure 5. Relationship between the rated energy (EP) and the maximum energy transferred from the hammer to the pile (EMX), for both diameters 800mm (green) and 1500 mm (blue).

In this study, we determined the equivalent η coefficient to be 0.024m, as depicted in Figure 6 (η=EP/R). This value aligns with existing literature; for instance, Paraíso and Costa (2006) reported a value of 0.033m, while Paikowsky (2004) presented a value

of 0.025m. The dataset in our study displays lower dispersion, and the regression analysis yields a coefficient of determination (R^2) of 0.89, indicating a strong fit to the observed data.

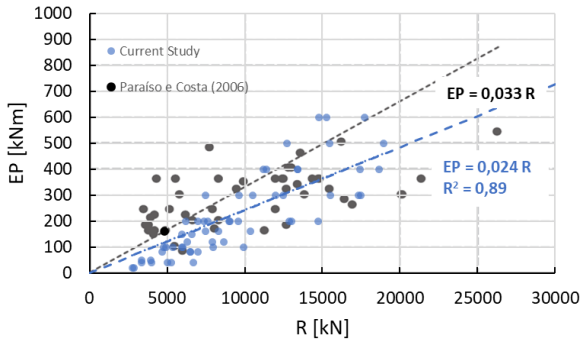

Figure 6. Comparison between the dataset of the current study (in blue) and the one presented in Paraíso e Costa (2006) (in black).

It is well-known that not all energy can be transferred from the hammer to the pile. If this were possible, the coefficient η would represent the displacement associated with the plastic deformation occurring at the lateral interface of the soil-pile and at the tip (Paraíso & Santos, 2020).

As indicated by EN ISO 22477-4:2018, Rausche et al. (2008) and Hussein et al. (1996), recommends that the weight of the hammer should be 1% - 2% of the desired resistance. Figure 7 elucidates this reasoning, where the ratio between the maximum energy transferred from the hammer to the pile (EMX) and the rated energy (EP) is plotted against the ratio between the hammer weight (W) and the resistance (R).

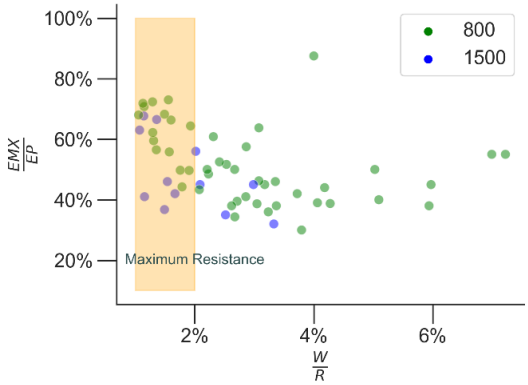

Figure 7. Relationship between the ratio of maximum energy transferred from the hammer to the pile (EMX) to rated energy (EP) and the ratio of hammer weight (W) to resistance (R).

It is evident that for the 800 mm diameter, the loss of energy is minimized when the weight/resistance ratio falls between 1% - 2% (shaded area in Figure 7), more precisely between 1% – 1.3%, in this study, for the blows which mobilized the maximum resistance. However, for the 1500 mm diameter, three points deviate from the trend, and within this interval, they still exhibit a lower energy ratio, approximately 40%. The efficiency of the hammer range from 30% to 87.5 %, with a mean of 50.9%.

If we look closer to the distribution of EMX for both diameters, depicted in Figure 8, we observe that both exhibit similar means. However, the 1500 mm diameter piles display higher dispersion due to the limited number of samples, which could justify this misalignment with the trend in Figure 7.

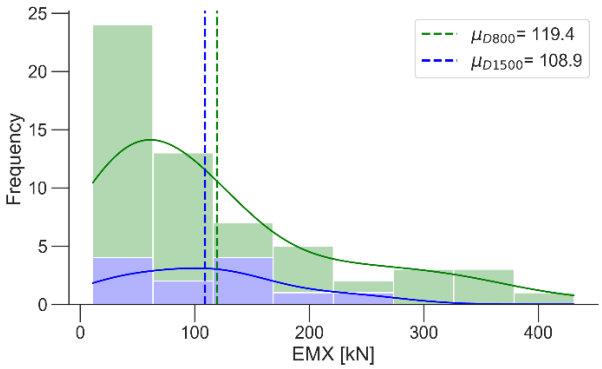

Figure 8. Distribution of the maximum energy transferred from the hammer to the pile (EMX) for both diameters. The green color represents the 800 mm diameter while the blue represents the 1500mm. The dashed lines are the mean of each distribution.

While the presented results are intriguing, the ultimate aim is to offer practical insights beneficial for designers. A key interest lies in determining the hammer parameters required to attain a specific resistance. To address this, we conducted a non-linear fitting between EMX and R, as depicted in Figure 9. Various functions underwent testing, and the one presented yielded the lowest Root Mean Square Error (RMSE).

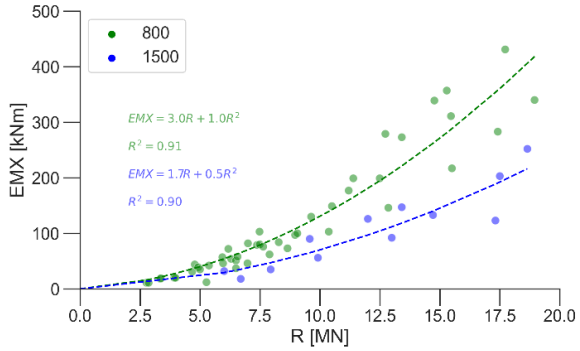

Figure 9. Non-linear relationship between the maximum energy transferred from the hammer to the pile (EMX) and the mobilized resistance (R). The green color represents piles with a 800 mm diameter while the blue represents those with a 1500mm diameter.

Notably, the equation for the 800 mm diameter is approximately double that of the equation for the 1500 mm diameter, revealing the influence of the diameter at the equation. It's essential to highlight that we constrained the regression to pass through the origin, underlining our expectation of zero energy applied for zero resistance. This graphical representation underscores that the requisite energy for achieving a given resistance is consistently lower for the larger diameter, thereby justifying an increased cost in pile designs with a corresponding reduction in associated equipment, or where the applied energy should be limited due to displacement issues.

4 CONCLUSIONS

In this comprehensive investigation, we examined variables derived from the Dynamic Load Test (DLT) such as the maximum potential energy of the hammer or rated energy (EP), the maximum energy transferred from the hammer to the pile (EMX), the mobilized resistance (R) and delved into their interrelationships. Practical implications to predict pile compressive resistance from dynamic load tests energy measurements are underscored and materialized by means of regressions equations. The results obtained not only align with current literature but also pave the way for valuable insights. Specifically, the formulated equations for predicting pile compressive resistance demonstrate excellent agreement with the dataset, boasting a coefficient of determination (R^2) around 0.9 (Figure 6 and Figure 9). This high level of correlation underscores the robustness and reliability of the equations in capturing the dynamics of the system.

As we strive for a more comprehensive understanding, future investigations should extend beyond the scope of this study. Exploring relationships with other variables tied to in situ characteristics, such as soil parameters, the lateral resistance, and tip resistance separately, holds the potential to enhance the accuracy and applicability of the derived equations. This broader inquiry would not only augment our confidence in employing these equations but also contribute to a more nuanced comprehension of the dynamic interactions at play during pile driving operations.

This study stands as a significant contribution to the field, providing practical tools for engineers and designers involved in pile-related projects.

A geotechnologist network

Un réseau de géotechnologues

S.D. Thomas*, K.G. Higgins
British Geotechnical Association, UK

**stephen.thomas@ogi.co.uk*

ABSTRACT: A Geotechnologist Network provides a platform and community to recognise and promote the valuable contribution to the Ground Engineering Industry delivered by skilled, knowledgeable and practical individuals that are critical to the delivery of a project. Whilst these individuals may not have the traditional education and qualifications as attained by chartered geotechnical engineers, their project contribution and responsibility, certainly equals and often exceeds those with more theoretical knowledge but lacking in practical experience. Network activity, including regular online webinars, serves to share the experiences of practitioners in the industry. These practical webinars are interlaced with other learning events, aimed to encourage practitioners to increase theoretical knowledge. This encourages progression to achieve qualifications, enabling individuals to aspire to advance within the industry. Webinars shared and delivered between practitioners, are growing exponentially, with this growth anticipated to continue in Europe and Worldwide.

RÉSUMÉ: Un réseau de géotechnologues fournit une plate-forme et une communauté pour reconnaître et promouvoir la précieuse contribution à l'industrie de l'ingénierie des sols fournie par des personnes compétentes, compétentes et pratiques qui sont essentielles à la réalisation d'un projet. Bien que ces personnes n'aient peut-être pas l'éducation et les qualifications traditionnelles acquises par les ingénieurs géotechniciens agréés, leur contribution au projet et leur responsabilité sont certainement égales et souvent supérieures à celles qui ont des connaissances plus théoriques mais qui manquent d'expérience pratique. L'activité de réseautage, y compris les webinaires en ligne réguliers, sert à partager les expériences des praticiens de l'industrie. Ces webinaires pratiques sont entrelacés avec d'autres événements d'apprentissage, visant à encourager les praticiens à accroître leurs connaissances théoriques. Cela encourage la progression vers l'obtention de qualifications, ce qui permet aux individus d'aspirer à progresser dans l'industrie. Les webinaires partagés et dispensés entre praticiens connaissent une croissance exponentielle, et cette croissance devrait se poursuivre en Europe et dans le monde entier.

Keywords: Geotechnologist; network; skilled; knowledgeable; practical.

1 INTRODUCTION

It has long been recognised that there are many talented skilled, knowledgeable and practical individuals (Figure 1), working in the Ground Engineering Industry; these individuals have a wealth of knowledge, that could be shared with others, but they rarely get the opportunity to speak at public society events. To promote the interaction between individuals with such attributes, the British Geotechnical Association (BGA) has initiated a Geotechnologist Network, as it is considered that the term Geotechnologist is appropriate to describe any skilled, knowledgeable and practical individual, with experience working in the Ground Engineering Industry. A geotechnologist is unlikely to be qualified in the professional sense, nor following a traditional route towards qualification. With a "Technologist" defined as an individual with a high level of skill and ability, who applies their scientific knowledge to the practical aims and purposes of human life, and "Geo"

Figure 1. A geotechnologist monitoring on site.

originating from the Greek word meaning "earth", it follows that a geotechnologist can be defined as:

An individual with a high level of skill and ability, who applies their scientific knowledge to achieve the practical aims and purposes of human life relating to the earth.

This definition could apply to individuals carrying out activities including, but not limited to, site investigation, laboratory and field testing, field monitoring, geospatial mapping, dewatering, piling, grouting, numerical modelling, drafters of drawings etc. The field is wide open, and we do not pretend to know all the possibilities.

The purpose of this Geotechnologist Network is to assemble skilled and practical individuals together as a knowledge-sharing community. Exactly how skilled and knowledgeable individual practitioners could assemble as a community of Geotechnologists was not known at the beginning of our journey.

Nevertheless, with the outcome to include and involve skilled and practical individuals within the Ground Engineering Industry, we chose to start our journey without knowing every step ahead of time, but reflecting on progress and then pivoting our guidance as feedback was received.

2 THE CONCEPT

The BGA is the United Kingdom Chapter of the International Society of Soil Mechanics and Geotechnical Engineering (ISSMGE). The ISSMGE is a Learned Society, with one of the objectives being:
"the promotion of international co-operation amongst engineers and scientists for the advancement and dissemination of knowledge in the field of geotechnics, and its engineering and environmental applications."

The object of the BGA, along with other national learned scientific societies, share the mission of:
"*the advancement of public education in the subject of soil & rock mechanics, and engineering geology, and their application"*
with these learned societies existing to promote:

(i) an academic discipline,
(ii) a profession, or
(iii) a group of related disciplines.

The authors recognised that whilst our Geotechnical Societies are very good at items (i) and (ii), by promoting those in the academic and professional world; through presenting lectures in grand theatres, with statues and names of famous engineers carved in stone around the walls, we have not recognised in the same way the individuals with skill and practical knowledge within item (iii) on whose shoulders much of the weight of the industry is supported.

With this accepted as an inherent weakness in our lack of recognition of skilled and practical individuals working within the Ground Engineering Industry, the BGA committed to initiating the development of a programme to incorporate those in the Ground Engineering Industry, who did not always enter our industry from the traditional qualification route, but nevertheless provide a hugely valuable contribution to the industry.

As published in Ground Engineering, in 2019 (EMAP, 2019a) Prof. Kelvin Higgins (author), as newly appointed Chair of the BGA, presented his wish to develop a technician community within the BGA. This followed a round table discussion, at which the need for advances to be made in the education of a Geotechnologist community through increased learning opportunities, and for continual professional development (EMAP, 2019b). A meeting was held with several employers to develop ideas. All were extremely supportive, but with the outbreak of the COVID-19 pandemic, the initiative stalled.

In 2022, BGA Executive member Dr Stephen Thomas (author) accepted the challenge set, and took the lead in developing this initiative in practice. Before the launch of this initiative in 2023, Dr Thomas undertook a year of research to provide guidance and focus on where this initiative could best deliver results.

This paper presents the key findings of the research, and whilst not a fully comprehensive research study, can nevertheless be used to advance this initiative and apply it to other societies in Europe and Worldwide.

3 THE JOURNEY

In the early days of the development of the initiative, the focus started with recognising those individuals who were, we thought initially to be at the periphery of the Ground Engineering Industry, but did not have an association of their own with which to belong.

The BGA Executive Committee considered initially the action of forming a sub-group within the BGA to which we could invite those who consider themselves not recognised to be openly acknowledged as valued individuals who provide a central and major contribution to the ground engineering community.

Our initial focus, we later learned, was centred too much on ourselves, i.e. the academics and professionals; inviting skilled and practical individuals to become one of us. However, after speaking to many of these skilled practitioners on a personal level, it became clear at an early stage, that without question, backgrounds were immensely varied, and much more multi-dimensional than the classical monoculture of School and University, Graduate-Engineer, and

ultimately a Professional, and that is just speaking about the authors. With this new focus in mind, based on our experience of working with skilled practitioners in the industry, enhanced by one year of speaking and learning from numerous practitioners explaining our vision to organise a society, we received an interesting clarity of response.

3.1 Opinion of professionals and academics

Whilst not a vast survey, there were some striking similarities in comments. The first was their perception of professional engineers, most of whom had studied and received higher degrees at university. It was as if we were Greek Gods, looking down at them from afar above the clouds. However, as authors, we are acutely aware that those working daily with geotechnology, are far more knowledgeable in essential practicalities to ensure solutions are implemented correctly in action.

3.2 Self-opinion of practitioners

Many practitioners consulted, described themselves as lacking in confidence with regard to their theoretical knowledge. They often referred to themselves as "*just me*", or "*it is only my view*", as well as having the opinion of their own knowledge compared to us in more fruitful and less confident language.

The lack of confidence in their own knowledge was despite the fact that many of the individuals conferred with, had extraordinary major project responsibility. For example, some held the responsibility for sinking shafts in loose saturated ground, whilst their workers were digging and launching a tunnel, describing their minute-by-minute decisions of ground strength, again in more fruitful language than in a standard textbook.

This practical experiential knowledge is gained from repeated observation, and in the authors' view, is no less valuable to a project. In fact, this is possibly more valuable than theoretical knowledge, because during construction processes, especially underground construction, the ground encountered is rarely as expected, and real-time decisions are often made from observations by skilled and practical individuals, rather than by those with more theoretical knowledge (Figure 2).

The individuals we spoke to were generally unaware of the much bigger picture with regard to the design and construction process, and particularly how this process depends to a high degree on their skill and knowledge. Our initiative is aimed at helping and guiding these individuals to understand where the meticulous work they accomplish contributes to the overall process. This dissemination of information has been achieved by providing speakers who have focussed on their role within a project (the importance of investigations, testing, monitoring etc.) or by interaction between the Geotechnologists themselves exchanging ideas.

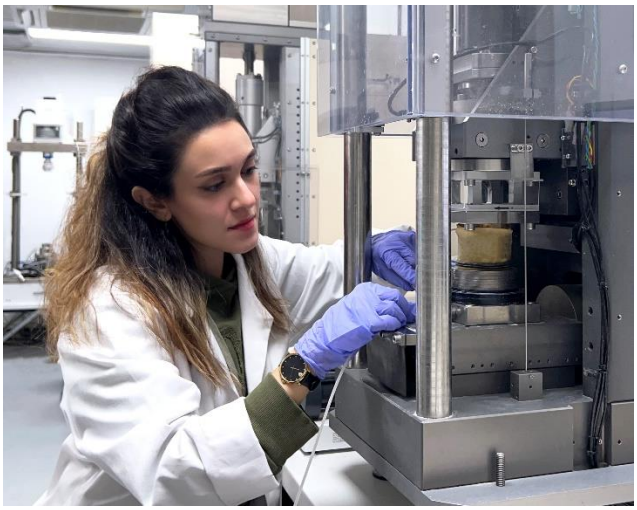

Figure 2. Geolabs laboratory technician.

As previously noted, the initial feedback from employers was very positive and they were willing to provide tangible support for this initiative. They were keen that their workforce became more engaged and understood the importance of their work.

4 REDEFINING A LEARNED SOCIETY

The essence of the authors' passion is that as a society we need to recognise all aspects of learning within our field, including academic, professional and practical.

Whilst the initial thoughts of the BGA were indeed to assemble a community of skilled practitioners, the initiative has now developed into one in which Geotechnologists are very much encouraged to lead and develop each other. As a consequence, the BGA plan is now to incorporate the Geotechnologist Network as a sub-group of the BGA, so having its own identity (similar to the highly successful Early Career Group), but at the same time being able to benefit from the established BGA administrative structure.

The fact is that many substantial developments and innovations arise from situations that are observed in practice. Here skilled and knowledgeable individuals, of the focus of this initiative, pull together to develop solutions in practice, that rarely require the modelling of second-order differential equations!

Learning resulting from developing solutions in practice, is known as experiential, or kinaesthetic learning, as opposed to theoretical learning.

We often treat these types of learning as either-or. Either we are academic, learned, theoretical thinkers, or we are practical, hands-on, technicians.

Whilst we all know that the most balanced and rounded knowledge is a blend of both theoretical and practical understanding, our learned societies do not necessarily recognise and reward the practical end of the knowledge spectrum.

In 1984, David Kolb (Kolb, 1984) published his groundbreaking Kolb Learning Cycle as depicted in Figure 3. This learning cycle is a pedagogical approach to human learning. He developed this model to teach his students at Stanford University. His goal was to help them learn better through self-directed study.

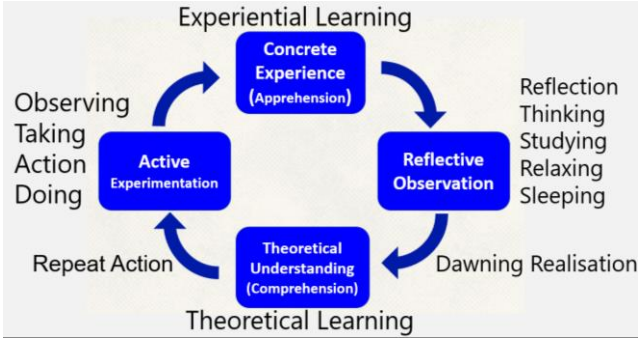

Figure 3. Kolb's four stages of learning (Kolb, 1984).

This theory of learning demonstrates how the practical knowledge gained by Geotechnologists can be very valuable to the Ground Engineering Industry.

Whilst a generalisation, those steeped in academic thinking can often focus around the bottom right area of the Kolb cycle i.e. reflecting & comprehending, with less focus on taking action in practice, so missing out on observation and apprehension.

Conversely, practical, skilled and knowledgeable individuals can spend their lives taking action, experiencing, observing and understanding behaviour through apprehension. This style of kinaesthetic learning, whilst gaining experience, can result in not fully comprehending the reasons behind the behaviour observed, and can miss out on a deeper understanding.

It is clear from this Kolb cycle, that when there is a full cycle of action and observation, with reflection and study, this results in both apprehension and comprehension, so leading to a deeper learning.

To this end, it is one of the aims of the Geotechnologist Network that individuals share their experiences, and then provide encouragement and guidance towards organisations that can provide tuition, learning and qualifications. This is being achieved initially by running webinars, delivered every two months, by the practical and skilled Geotechnologists themselves. Figure 4 presents the initial webinars presented and scheduled.

Date	Name & Organisation	Webinar Title
2023 Sep	Stephen Thomas, BGA	A Geotechnologist Network
2023 Nov	Christopher Wallace, Geolabs	Things that affect soil strength
2024 Jan	Christopher Swainston, Consultant	Environmental Sampling: What can go wrong
2024 Mar	Brian Sharkey, One Bore Tunnelling	Lab coats: white, Brown or Hi-Viz. Research & Innovation in the Workplace
2024 May	Jim Sheilds, RoGEP	Routes to becoming a Ground Engineering Professional
2024 July	Julian Lovell, Equipe Group	Diplomas in Field and Laboratory Geotechnical Activities

Figure 4. Webinars by the Geotechnologist Network.

The development of the webinars, delivered by the growing network of geotechnologists, has proved most successful on a number of counts.

(i) The network interest is growing exponentially.
(ii) A Geotechnologist sees their skills being shared.
(iii) A Geotechnologist sees their skills as recognised.
(iv) A Geotechnologist is directed towards learning.
(v) Theoreticians see more practical examples.

COMMENT

This initiative of a Geotechnologist Network is fully consistent with the aims of a learned society. It is not the intention of this network to provide a qualification or certification. However, this network can provide a catalyst for encouraging and guiding individuals towards organisations that provide further education to provide advancement to practitioners in our industry.

Much is to be gained by all working in our industry from the interaction with individuals with such practical skills, knowledge and experiences. The aim is that this initiative will promote these interactions and help develop and advance the pool of skills and knowledge within the entire geotechnical community.

ACKNOWLEDGEMENTS

We are most grateful to Andrew Ridley, David Toll, Peter Reading and others on the BGA committee, who provided advice and guidance throughout our collective journey.

A particular thanks also go to the numerous practitioners, each an early Geotechnologist, who have spoken to us in much-needed plain language of their industry experiences.
